The railway coal-cars as they enter the plant are dumped by means of a Robins-Scherzer rotary car dumper, and dropped into a track hopper with bottom shaker feeders, fitted by the Robins Belt Co. Belt conveyers (36-in.), with a total capacity of 250 tons per hour at a speed of 250 ft. per min., then convey the coal over a magnetic separator to remove any iron particles, and pass it through a two-roller crusher and hammer mill, where it is crushed to a size, say, all through a ¾-in. mesh, the capacity of this crushing plant being 150 tons of mine coal per hour. The crushed coal is then conveyed by another installation of three belt conveyers to overhead green-coal bunkers in the pulverizing-plant building, each belt having a travelling trip arrangement to enable the coal to be discharged at any point as required. This green-coal bunker has a storage capacity of 3 400 tons, that is, 3½ days' supply for maximum duty on all boilers, and the crushed coal is taken from here by means of three screw conveyers over automatic weighing scales, which record the daily coal consumption of the plant, and delivered to another set of screw conveyers for conveyance to the driers. It has been found by experience that variation in the moisture content is most objectionable, particularly as it prevents a regular and controllable flow of the pulverized coal in the burners. As already stated, the results at Oneida-street show that drastic drying down to 1 per cent is not absolutely necessary, but not over 2 per cent is certainly preferable. The actual drying installation at Milwaukee consists of three separate cylindrical driers each of a capacity of 10 tons per hour, reducing the moisture in the Illinois coal from 10 per cent to 2 per cent. These driers are of the improved double-shell type, consisting of a long, slightly inclined, rotating double cylinder through which the coal passes by gravity, whilst the hot gases from a small furnace are passed between the inner and outer shell in opposite directions, the amount of coal used being about 1 per cent of the total dried from 10 per cent down to 2 per cent. This double drier has the advantages over the older single-drier type of greater capacity, increased efficiency and, especially, freedom from internal fires.

From the driers the coal is discharged into screw

conveyers, which convey it to bucket elevators, these in turn passing it on to other screw conveyers to be transferred to the dried-coal bunkers over the pulverizing mills.

Since the date of the installation of the Milwaukee plant, the Lopulco equipment has been further improved by the invention of a much simpler form of drying plant, a small stationary gravity drier which has now rendered obsolete the more complicated and expensive revolving plant hitherto always used. In this new drier which is being installed at the Cahokia plant, St. Louis, and the Vitry station, Paris, the crushed coal flows by gravity from overhead bunkers through the vertical stationary driers underneath. Through these about 10 per cent of the hot exit gases, diluted with air from the boiler plant so that the temperature does not exceed 215° F., are caused to circulate by means of a fan. This is an important feature, since if the temperature much exceeds 215° F. a slight volatilization of the volatile matter of the coal begins to take place. But with a temperature of 215° F. in the drying gas current the general temperature of the mass of the coal of course does not reach this figure. With the ordinary rotary drier the coal is heated to at least 250° F., causing a loss of volatile matter. The coal is thus dried as it passes straight through to the pulverizers under the driers, the speed of the coal travel simply being governed by the speed of the pulverizers, the whole operation of drying being rendered perfectly simple.

The two standard pulverizing mills in America are the Raymond and the Fuller, which are built in standard sizes of 2–6 tons per hour when grinding to 95 per cent through 100 mesh and 80 per cent through 200 mesh, with average bituminous coal containing less than 1 per cent of moisture, although these extreme figures are not generally necessary, as already stated.

The plant actually at Milwaukee consists of 8 pulverizers (both Raymond and Fuller types) each with a capacity of 6 tons of coal per hour, and driven with a direct-connected 100-h.p. motor, pulverizing the coal so that about 65 per cent would pass through a 200-mesh screen and 90 per cent through a 100-mesh screen, each pulverizing mill being also equipped with a fan for separating the powdered coal from the contents as soon as it has been reduced to a sufficiently fine state.

It is found by experience that the easy working of the pulverizing plant depends largely on efficient drying, in the sense of uniform moisture content, and thus on the ability of the drier attendants to dry each different quality of coal, from small pieces to dust, after passing the crusher, so that the amount of moisture continues the same. This, however, they soon learn by experience. The fan incorporated with the pulverizers then discharges the pulverized coal into overhead cyclone separators, where it falls by gravity into a screw conveyer at the bottom of the separator. It is then conveyed to the pulverized-coal bunkers, from which it is transferred to powdered-coal bins in the boiler house by an air system of conveying. This consists essentially of a hopper, high-speed screw, and a delivery nozzle, air being supplied at 40 lb. pressure to force the coal through small pipes. Although otherwise satisfactory, these conveyers were thought to use too much power for ideal working, and have since been replaced by screw conveyers.

From the storage bins in the boiler house the pulverized coal is conveyed to the burners by special Lopulco coal feeders. These consist essentially of a heavy cast-iron casing, forming the bottom of the pulverized-coal storage bin and containing a cast-iron screw feed driven through gear wheels by means of a variable-speed motor underneath, or, in the case of a duplex feeder, by a Reeves variable-speed device, by which the supply of pulverized coal can be regulated instantly as required. This screw conveys the pulverized coal to the end of the feeder, where it meets a current of air (at a pressure of 12 in. of water) passing through the inner wall of an annular orifice, the amount of air supplied in this way, to act primarily as a conveyer of the coal, being 10 per cent of the total required for combustion. At this point also the mechanism includes four agitators or paddles revolving at high speed in gear with the screw, so as to mix the air thoroughly with the pulverized coal. The mixing is, in fact, so intimate that from this point the mixture of coal and air acts practically as a heavy gas.

The mechanism of the coal feeder also includes an automatic cut-out so that when the air blast is shut off from the burners the coal-feed motor is also stopped automatically, so as to prevent plugging up the burners and pipes with pulverized coal.

There are several types of Lopulco burner, but at Milwaukee the six burners supplied to each boiler, facing in a downward direction, are of the heavy triplex pattern, composed of three rectangular chambers surrounded on four sides by air ports. Through the centre of each inner chamber is a $3\frac{1}{2}$-in. fuel nozzle terminating $9\frac{3}{4}$ in. from the outlet, so as to give the mixture a chance to expand before emerging into the furnace, instantaneous combustion resulting on combination with a supply of secondary air.

As already stated, 10 per cent of the air for combustion is supplied through the burner as a carrier for the coal, so that the secondary air amounts to 90 per cent of the total. This secondary air passes into the installation at the back of the furnaces and then through channels in the hollow furnace walls which it keeps cool whilst itself being heated, and enters the combustion chamber chiefly through ports or openings in the furnace front, as well as through air ports in the burner itself. The air is heated in its passage to various temperatures, depending on the portion of the hollow firebrick which it has traversed, but averaging 300° F.–700° F., and the supply is regulated by damper mechanism in each of the secondary air ports.

The latest principle, not adopted at Lakeside, is to preheat also the air conveying the coal from the feeder to the burner, this primary air supply being passed either through the side walls or under the bottom of the furnace. This method is stated to be particularly valuable in the case of undried coal, sometimes used when the moisture content is not over 5 per cent.

This arrangement of hollow air-cooled furnace walls, in addition to increasing the efficiency of the combustion by supplying heated air, is claimed to eliminate entirely

all excessive wear and tear on the brickwork, as will be discussed later.

The furnaces are 22 ft. wide and 14 ft. long, whilst the combustion space is very large, being 25 ft. high under the boiler tubes and 22 ft. under the arch. The design of the furnace is on the multiple-zone system, a feature of the Lopulco installations, in which three zones of differing intensity of heat are maintained. Just under the arch or roof of the furnace is the hottest zone of maximum combustion, whilst below this is the intermediate zone. The lowest stratum is a cooling zone, in which the temperature is constantly below that of the fusing point of the ash, chiefly because of the design of the secondary air admission.

In order to prevent any possibility of "slagging," an essential feature of the Lopulco design is the water screen, which cools the ash deposit, whilst at the same time the heat extracted is returned to the boiler. Much of the practical success of the Lakeside and other installations undoubtedly seems to be due, as already stated, to the efficiency of this water screen. The trouble is not only that the fine ash would otherwise fuse with the heat and corrode or "flux" the brickwork, but, as previously indicated, a change in the running conditions or a slight alteration in the quality of the coal causes the corrosive, molten mass to become sticky and refuse to flow off the brickwork, i.e. to slag, which has been a very serious obstacle to the success of pulverized fuel, because of the difficulty of removing the pasty, red-hot mass.

It will, of course, be understood that in some cases, both of generating stations and of ordinary power plants, coals are available that give no trouble in this respect and would work quite well without a water screen, but as a rule it is quite impossible to confine the coal to qualities in which the ash has a definite fusing point.

The water screen consists essentially of a series of 4-in. steel pipes in the lower part of the furnace. These pipes are an integral part of the boiler itself, being under full steam pressure and having the boiler water circulating through them, so as to cool the ash. The general arrangement is that part of the tubes are connected at one end with a header or the water drum of the boiler, and at the other to water boxes at the bottom of the furnace. From this header, pipes pass through the furnace and into another header, from which the circulation is continued to the drum or to the front header of the boiler.

The principal dimensions of the water-screen installation at Milwaukee as applied to each boiler are as follows :—

Number of tubes in water screen ..	22
Diameter of tubes	4 inches
Pitch of tubes	14 inches
Average length of exposed part of tubes	13¾ feet
Total heating surface of exposed part of tubes	320 sq. ft.
Total heating surface of boiler and water screen	13 380 sq. ft.

It is claimed that this water screen has practically eliminated slagging, so that a very wide range of fuels can be burned with any reasonable variation in boiler capacity, and enables guarantees to be given of an evaporation of 13·8 lb. of water per square foot of boiler heating-surface—a very remarkable figure.

Finally, as regards ash disposal, the plant is fitted with steam ash-ejectors to handle the very small amount of fine ash produced, the ash being taken through pipes direct from the combustion chambers and soot pits and discharged direct into railway wagons.

The generating plant at Milwaukee is of course outside the scope of this paper, but it may be stated that the present installation consists of two General Electric 20 000-kW, three-phase, 13 200-volt, 60-period, 1 800-r.p.m. turbines, calculated at 250 lb. steam pressure at the stop valve with 200 degrees F. superheat and 1 in. (absolute) back pressure, the rated power factor being 0·8. The auxiliaries for each 20 000-kW turbine are one 35 000 sq. ft., 3-pass condenser, one 24-in., 18 000-gallons-per-minute circulating-water pump driven by a 170-h.p. motor, another identical pump driven by a 170-h.p. steam turbine, one condensate pump driven by a 50-h.p. motor, one turbo air pump driven by a 100-h.p. motor, and one steam-jet air pump. Both pumps are required during the summer months when the water is warm, but only one in winter, and, as usual, the load is distributed equally between electrically-driven and steam-driven auxiliaries.

Finally, it is stated that since starting up in December 1920 the plant has been in continuous operation without a single hour having been lost through stoppages, although the new staff were not experienced in the use of pulverized fuel.

The New Installation at Vitry.

In connection with the Lakeside installation it will be of interest at this stage to insert a brief account of the Lopulco installation that is now in course of erection at the Vitry (Paris) power station of the Union d'Électricité, which will be the first very large, modern, pulverized-fuel installation in Europe, as well as including the largest water-tube boilers outside the United States. The plant consists of four Delauney-Belleville-Ladd boilers of 16 678 sq. ft. heating surface, each including a superheater and having steel-tube economizers of 9 684 sq. ft. heating surface, the boiler pressure being 256 lb./sq. in. (18 kg/cm^2) and the temperature of superheat 662° F. (350° C.), whilst the feed water is to enter the economizers at 140° F.

There is also included for each separate boiler a combined unit of one pulverizer with a duty of 6 tons of coal per hour, a vertical gravity drier of a maximum duty of 8½ tons of coal from 10 per cent to 2 per cent of moisture, one fan exhauster and trunking to remove by air separation the pulverized fuel from the pulverizing mills, 5 duplex fuel feeders to supply a regulated amount of pulverized fuel to a unit of two burners, and 10 triplex burners. In addition, of course, there are the water screens, hollow air-cooled furnace walls and very large combustion chamber on the same general lines as at Lakeside.

The guaranteed duty per boiler per hour is 140 580 lb. of water from and at 212° F., with a long overload period of 4 hours when the evaporation will be 210 870 lb.

of water from and at 212° F. This corresponds to 12 800 lb. of coal per boiler per hour (normal) and 19 700 lb. (overload), the calorific value of the coal used being 12 600 B.Th.U.'s (higher or gross value), corresponding to an evaporation of 10·98 lb. of water from and at 212° F. per lb. of coal on normal load, and 10·70 lb. on heavy overload, the guaranteed boiler-plant efficiency being 84 per cent at normal load. This is also equivalent to a normal evaporation of 8·4 lb. of water (from and at 212° F.) evaporated per sq. ft. of heating surface, or 12·6 lb. maximum, a very high capacity.

Finally, the power consumed in the preparation of the fuel, including handling, crushing, drying, pulverizing, air-separating and delivering to the burners, is guaranteed not to exceed 19½ kWh per ton of coal burnt, equal to, say, 1·0 per cent of the steam production of the plant. This figure depends, of course, on the efficiency of the generators, but in general it may be stated that in practice it will be actually less than 1 per cent of the steam output.

A Detailed Consideration of the Performance of Pulverized Fuel in Competition with Mechanical Stoking under the most Modern Conditions.

Difficulties of comparison.—It is somewhat difficult to compare the results of a modern pulverized-fuel equipment, such as that at Lakeside, with present mechanical-stoker practice from the point of view of a consideration of the relative merits in general of the two systems of firing.

The chief reason is that the Lakeside station is run on thoroughly modern and scientific lines, both of control and costing, but most large power stations in the world with mechanical stokers are not operated on anything even approaching these efficient methods. Thus, in very few power stations—at any rate in Great Britain—is there any real idea of the efficiency of the steam generation from week to week, nor are there even kept any very adequate records of the wear and tear and maintenance costs of the various sections of the plant, e.g. the mechanical stokers, the coal-elevating and conveying plant or the ash-handling plant, whilst practically nothing is known about the variations in the steam or power used auxiliary to the production of the steam, which may easily correspond to 3–5 per cent of the coal bill of the whole station, and often much more. Thus in many power station plants there is not even a boiler-feed meter in use, and, in general, little attempt is made to utilize feed meters, steam meters, pyrometers, CO_2 recorders or other instruments of precision on the right lines. Consequently, many of the conclusions arrived at as to the average performance of mechanical stokers are somewhat of a conjecture and may be unduly optimistic.

(1) *Efficiency figures.*

(*a*) *The present figures for mechanical stoking.*—It is particularly difficult to decide upon an average boiler-plant efficiency figure for mechanical stoking under the most modern conditions, and to state what advantages—if any—pulverized fuel possesses in this respect. In the first place there is no proper boiler-testing code or even standard methods of calculating the results. The author has considered this matter at length in his book on "Boiler Plant Testing," and he will therefore merely state that in Great Britain the situation is aggravated because what is supposed to be our standard code, that of the Institution of Civil Engineers, is so impractical that it is doubtful if anyone has attempted to carry out a test strictly according to its recommendations. The American Mechanical Engineers' code and the Continental code, primarily of the German Association of Engineers, are certainly better, but the utmost confusion exists on all kinds of points, such as—to mention only a few—whether the heat value of the coal is to be taken on the higher or lower figure, and, if the latter, what this means precisely, whether the auxiliary power is to be deducted in calculating the efficiency, and, if so, exactly what items; and also, if any corrections are to be made for variation in the heating value of the fuel over or under a given figure. For these and other reasons some confusion often exists even as to how the Lakeside figures of 85–86 per cent are calculated, and it must be remembered that a difference of, say, 3 per cent in the efficiency is easily possible, depending on how the various codes are interpreted in carrying out the test.

Further confusion also exists in Great Britain with regard to the unscientific American method of using the term "boiler horse-power." In reading the results of American boiler tests it has to be remembered that the American "boiler horse-power" means an evaporation of 34½ lb. of water from and at 212° F. per square foot of heating surface of the boiler. This arbitrary figure was adopted in 1876 at the Centennial Exhibition at Philadelphia because at that time the average steam engine took 34½ lb. of steam per indicated horse-power. Consequently, a "boiler horse-power" means an evaporation of enough water per square foot of heating surface to give 1 h.p. in the average American steam engine of 1876, i.e. 34½ lb. A boiler under American standards is allowed 10 sq. ft. of heating surface per horse-power, so that a boiler at normal American rating evaporates 3·45 lb. of water from and at 212° F. per square foot of heating surface, and in Table 7, for example, the rating of 137 per cent corresponds to 4·6 lb. of water per square foot of heating surface.

Another difficulty is that most boiler tests are carried out under what are practically abnormal and freak test conditions bearing little or no relation to the real everyday running. An efficiency of 80 per cent, for example, as obtained on such a test, less than 50 tons of coal being burnt for a few hours—which performance the majority of power station engineers believe applies to their plant all the year round—has nothing to do with the real results (more like 70 per cent) obtained with the burning of many thousands of tons of coal per annum. The point is that as results of 85–86 per cent are stated to be obtained at Lakeside regularly from week to week with pulverized fuel, what are to be taken as the corresponding yearly figures (apart from "official" test figures) for mechanical stoking with the plant performance recorded and calculated as nearly as possible under identical high-grade conditions?

The present all-the-year-round boiler-plant perform-

ance throughout the world, whether by hand or mechanical firing, and including many of the largest power stations, is deplorable. The author has carried out a large number of boiler-plant tests under actual working conditions during the past 15 years. Having referred to the results of these tests so often on previous occasions, he will only state that the net result of 400 separate tests undertaken in 41 different industries with 1 513 boilers, mostly of the Lancashire type, and burning 3 250 000 tons of coal per annum, was 58 per cent net working efficiency, including boilers, superheaters and economizers, and deducting the auxiliary steam or power used, the individual figures varying from 32½ to 82½ per cent. We are, however, here more directly concerned with the figures for water-tube boiler plants. In the first place, the general assumption that water-tube boiler plants are necessarily giving much better efficiency figures than cylindrical boiler plants has very little foundation in fact, and is almost on a par with the idea that power station boiler-plants are, in general, running at an efficiency of 80 per cent and evaporating 9–10 lb. of water per lb. of coal. The author's opinion, based also on the personal inspection of about 2 000 boiler plants, with an approximate total coal consumption of 15 000 000 tons per annum, including very many power station and water-tube boiler plants, is that the average figures at present obtained in Great Britain with water-tube boilers, of an average evaporation of 20 000 lb. of water per hour, can be classified as shown in Table 2.

TABLE 2.

Figures suggested by the Author as Representative Water-tube Boiler Practice (Mechanically Fired).

	Most efficient plant (5 per cent)	Average plant (85 per cent)	Bad plant (10 per cent)
(1) Duration of test, hours	12	12	12
(2) No. of boilers working	4	4	4
(3) Grate area (total), sq. ft.	560·0	560·0	560·0
(4) Coal used	Average	Average	Average
(5) Amount of coal used, lb.	137 275	141 040	139 765
(6) Calorific value of coal, B.Th.U.'s	12 000	12 000	12 000
(7) Percentage of ash in coal	10·5	10·5	10·5
(8) Coal burned per boiler per hour	2 859·9	2 938·3	2 911·7
(9) Coal burned per sq. ft. of grate area per hour, lb.	20·4	20·9	20·8
(10) Water evaporated, lb.	1 081 200	989 352	898 656
(11) Water evaporated per boiler per hour, lb.	22 525	20 611	18 722
(12) Water evaporated per lb. coal, lb.	7·87	7·01	6·43
(13) Equivalent evaporation from and at 212° F. per lb. coal, lb.	9·11	8·12	7·46
(14) Equivalent evaporation from and at 212° F. per 1 000 000 B.Th.U.'s, lb.	759·2	676·6	621·6
(15) Temperature of feed water before economizers, ° F.	110	110	110
(16) Temperature of feed water after economizers, ° F.	225	195	No economizer
(17) Coal bill saved by economizers, per cent	10·4	7·4	Nil
(18) Draught in back flue of boilers, in.	0·30	0·35	0·75
(19) Draught in chimney base, in.	0·65	0·50	0·75
(20) Temperature of flue gases before economizers, ° F.	450	475	575
(21) Temperature of flue gases after economizers, ° F.	250	200	—
(22) Percentage of CO_2 in flue gases	12·5	6·0	5·0
(23) Steam pressure, average, gauge, lb./sq. in.	160	155	150
(24) Temperature of saturation of steam, ° F.	370·5	368·3	365·9
(25) Temperature of superheated steam, ° F.	650·0	530·0	450·0
(26) Steam or power used auxiliary to the production of steam, per cent	1·5	2·0	2·5
(27) Thermal efficiency of plant:—			
(*a*) Net working efficiency, per cent	81·9	69·2	61·0
(*b*) Heat to boilers only, per cent	65·8	60·3	59·0
(*c*) Heat to economizers only, per cent	7·6	4·9	—
(*d*) Heat to superheaters only, per cent	9·7	5·4	2·6

That is to say, only 5 per cent of water-tube boiler plants are running with mechanical stokers at an efficiency of 80 per cent and over, whilst a reasonable average figure for 85 per cent of the plants is about 70 per cent, and the author would say further that in his opinion these figures are, if anything, on the optimistic side. The real state of affairs with regard to boiler-plant efficiency is now beginning to be realized.

It has been stated, for example, by more than one authority in the United States that the efficiency of the average modern mechanical stoker-fired boiler-plant in America does not exceed 65 per cent on regular performance, although a few hours' test on one boiler might give results of 75 per cent, and the fuel-economy campaign in the United States during the war revealed some astonishing facts. Recent investigations in Germany also bear these facts out, and the author would estimate that of the world's consumption of coal of, say, 1 250 000 000 tons per annum, about 500 000 000 cent, and Mr. Smoot feels that mechanical-stoker makers are not being treated fairly in the matter. That is to say, they supply a high-grade appliance which the customer will not work properly, the chief trouble being the failure to adjust the supplies of air and fuel.

With regard to excess air, it is very difficult to obtain authentic figures on this point. The very latest types of mechanical stoker are said to operate at 35–37½ per cent excess, although the average figure is probably 50–70 per cent, and in the case of hand-firing 75–100 per cent.

Table 3.

Figures of a 6 Months' Run (August 1921–January 1922) at Colfax Station, Duquesne Light Co., Pittsburgh, Pa.

	August	September	October	November	December	January	Average

Table 4.

Figures of a Typical Month's Run (December 1921) at Colfax Station, Duquesne Light Co., Pittsburgh, Pa.

Average calorific value of coal = 13 283 B.Th.U.'s. Average feed-water temperature = 193° F. Average superheat = 132 degrees F.

Boiler No.	Water evaporated	Coal burned	Time run	Efficiency	Average amount of CO_2	Exit gas temperature
	lb.	lb.	hours	per cent	per cent	° F.
1	60 020 000	6 638 060	559	76·6	9·9	489
2	55 291 000	6 089 230	480	76·9	12·0	482
3	75 435 000	8 319 030	696	76·7	10·3	460
4	75 542 000	8 324 290	691	76·8	11·9	481
5	32 242 000	3 519 710	285	77·5	11·5	—
6	73 474 000	8 138 360	688	76·5	11·7	479
7	70 546 000	7 761 900	640	77·0	11·0	481
Total	442 550 000	48 790 580	4 038	76·8	11·2	478

tons are used for the one purpose of steam generation at less than 60 per cent efficiency, corresponding to an avoidable loss of 100 000 000 tons of coal per annum.

As far as mechanical stokers are concerned, this is, of course, by no means altogether the fault of the stokers themselves. In a recent paper by Mr. Charles H. Smoot before the 1923 Convention of the American mechanical-stoker manufacturers, it is pointed out that most mechanical-stoker installations of any size in the United States will give a boiler-plant efficiency up to 80 per cent on test conditions, but that in practice few plants are running all the year round with an efficiency of 70 per

Let us consider, however, the relatively few mechanically-fired power station plants that are being run on the latest methods of control and that keep records of the weekly figures. Careful and long-period tests carried out, for example, at Connors Creek power station in America showed 75 per cent efficiency, and the Delaware station figures are 79·7–81 per cent, whilst exceptionally detailed tests at the Colfax plant, Duquesne Light Co., Pittsburgh, Pa., were given by C. W. E. Clarke, who designed the station, in a paper read before the American Society of Mechanical Engineers in December 1921.

The results of 6 months' run from August 1921 to January 1922 are represented in Table 3, while Table 4 gives the details for a particular month (December 1921), showing a result of about $76\frac{1}{2}$ per cent efficiency, the station always being under easy load conditions.

It is stated that the most efficient mechanically-fired power station in America is the Calumet plant of the Chicago Edison Company, but the author has not been able to ascertain the separate steam generation figures.

One of the most up-to-date power stations in Great Britain, both as regards design and equipment, and particularly from the point of view of scientific methods of control and continuous testing, is undoubtedly that at Dalmarnock, belonging to the Glasgow Corporation, and the author is indebted to Mr. R. B. Mitchell, the General Manager and Chief Engineer, for kindly supplying the fullest information as to the running of the station, and for giving every facility to examine on the spot the methods used. The arrangements for continuous testing, and the most modern methods of scientific control, including the keeping of a complete boiler-house log with full daily records, are hardly surpassed by any other station in the world.

The Dalmarnock station is, in common with Lakeside, intended eventually for 200 000 kW on full load with maximum output. At present half this installation has been erected. The boiler plant consists of two boiler houses, each containing 8 Babcock and Wilcox marine-type steel-cased boilers, arranged in 2 rows of 4 boilers each. These boilers are of 6 948 sq. ft. heating surface with an integral superheater of 2 452 sq. ft. heating surface, and work at 225 lb. pressure and 700° F. steam temperature, the ordinary evaporation being 50 000 lb. of water per hour at 150° F., and a long-period overload of 62 500 lb. Each boiler is also fitted with a cast-iron Green's economizer of 400 tubes of 5 155 sq. ft. heating surface, 14 ft. in length and $3\frac{1}{16}$ in. in diameter, on the new ring-stay pattern, heating the water from 150° F. to about 275° F.

The mechanical stokers are of two kinds, 36 Babcock and Wilcox forced-draught chain-grate stokers, and 12 Underfeed travelling grates, the total grate area per boiler being 273 sq. ft., consisting of 3 separate stokers each approximately 14 ft. 0 in. × 6 ft. 6 in. Each row of 4 boilers supplies (3 boilers working and 1 boiler as stand-by) a steam turbine of 15 000 kW ordinary load, and 18 750 kW long-period overload, and 5 of these are installed for the 4 rows of boilers so as to have one turbine as a stand-by, although, of course, 16 boilers and 5 turbines can be worked if desired. It is impossible to describe in the space available the elaborate nature of the methods of scientific control adopted. Briefly, however, the station is operated from a central control room, which is in communication with the boiler house and the turbine house by means of a complete equipment of marine signalling-apparatus and marine loud-speaking telephones. Each boiler is regarded as a separate unit as regards testing instruments, and is equipped with three Avery 2-cwt. automatic coal-weighing machines, one for each stoker, CO_2 indicator, complete draught gauge and pyrometer equipment, and British Thomson-Houston steam meter for the output of the boiler, together with a Lea **V**-notch recorder connected to a turbo-alternator for each of the 4 boilers.

The coal is also sampled and analysed continuously, being of inferior quality, averaging 10 500 B.Th.U.'s in the laboratory attached to the station, and the figures of the performance are plotted every shift all the year round. The plant is also provided with an ingenious and most accurate arrangement of two very large, calibrated, steel test-tanks each having a capacity of 28 000 lb. of water, so that weighed-tank tests can be quickly carried out, and the performance of the turbines is controlled in an equally scientific manner.

The guaranteed overall efficiency of the plant, using the inferior 10 500-B.Th.U. coal, including the boilers, superheaters and economizers, is 80 per cent, although this is presumably for short official test-figures only, and not for continuous running, whilst there also seems to be the usual confusion as to the exact meaning of the figure.

As regards the actual running results from day to day all the year round, the figures given in Table 5

TABLE 5.

Actual Operating Boiler House Statistics (One Day), taken at Dalmarnock Power Station; Friday, 21st September, 1923.

Total coal consumed, lb.	1 112 160
Calorific value as fired, B.Th.U.'s	9 905
Total ashes removed, lb.	141 689
Ashes, per cent of total coal	12·74
Total condensate, lb.	6 866 758
Total make-up water, lb.	384 011

Temperature of flue gases leaving economizers, ° F.	372
Temperature of water entering economizers, ° F.	161
Temperature of water leaving economizers, ° F.	286
Water evaporated per lb. coal, lb... ..	6·51
Coal per kWh generated, lb.	1·82
Water per kWh generated, lb.	11·88
Make-up water, per cent	5·60
Boiler-house efficiency, per cent	78·4

and supplied by Mr. R. B. Mitchell are typical for a recent date in September 1923.

Some further interesting information supplied by Mr. Mitchell was published in *Engineering*, 1st September, 1922. These figures embody the detailed results of 84 consecutive 8-hour shifts (4 weeks' run) with an aggregate output of 9 784 000 kWh, varying from 30 000 to 230 000 kWh per shift. During this month the average heating value of the coal was 10 500 B.Th.U.'s and the temperature of the feed water was 141° F., the steam pressure being 275 lb. (gauge) with a temperature of 700° F.

The results show that at a load of only 50 000 kW

for an 8-hour shift, the coal consumption was 2·116 lb. per kWh, and as the load increased to the maximum output this figure was reduced to 1·816 lb. per kWh. The performance of the station is approaching the maximum, and with everything under the best conditions an ideal evaporation of 6·722 lb. of water per lb. of 10 500-B.Th.U. coal, corresponding to a boiler plant efficiency of 80·92 per cent, together with 11·535 lb. of steam per kWh, will be attained.

It may be noted that when the station is doing no useful work the total constant losses due to banking up, condensation, radiation, etc., only correspond to an average of about 20 000 lb. of coal per 8 hours, being 5 123 lb. in the boiler plant and 14 877 lb. in the generating plant.

Mr. Mitchell, further, has very kindly supplied the author with the returns for the last financial year, 1922–3, in which the average boiler-plant efficiency for 52 consecutive weeks at the Dalmarnock station is 76·6 per cent. The figures are as follows:—

Total units generated	171 827 337
Average load, kW	19 600
Maximum load, kW	58 500
Load factor, per cent	33·4
Total coal consumed, tons	142 942
Coal per unit generated, lb.	1·86
Coal per unit delivered, lb.	1·95
Station efficiency (units generated), per cent	17·5
Boiler-house efficiency (52 readings), per cent..	76·6

As representative also of the figures obtained on special short tests, we have those given in Table 6, carried out on two boilers in March 1923, being in one case with induced draught and in the other with balanced draught, the figures being expressed for the two boilers as one compound unit.

We may therefore take as representative of the best conditions of mechanical stoking with poor quality coal the figures obtained at Dalmarnock, which indicate —as the result of the most elaborate tests—an all-the-year-round efficiency of 76·5 per cent on a poor load factor of about 34 per cent. Also, on theoretically the ideal load factor, the limiting efficiency is about 81 per cent. It is obviously very difficult to decide upon absolutely fair average figures, but the author feels that the efficiency of Dalmarnock could be taken as, say, 78 per cent with a 60 per cent load factor, emphasizing again, of course, that this applies to continuous week-in and week-out running all the year round, and not to official tests.

This comparison between Lakeside and Dalmarnock is, in fact, probably as good as can be obtained for the rival systems of firing. Both stations are designed for 200 000 kW, Dalmarnock now having approximately 75 000 kW easy working and 93 750 kW long overload, whilst Lakeside is running on 40 000 kW (50 000 kW overload). The present extensions to the latter will be completed in a few months, when the figures will be 80 000 kW and 100 000 kW respectively. The turbines at Lakeside are somewhat bigger, i.e. 20 000 kW as compared with 15 000 kW, but the boilers are nearly twice the size, in this respect truly representative of American practice as compared with British. The coal used in both cases is of inferior quality, that at Lakeside being 11 500 B.Th.U.'s and that at Dalmarnock 10 500 B.Th.U.'s, but unfortunately the load factors are very different, viz. 60 per cent at Lakeside and 34 per cent at Dalmarnock, because of bad trade in the Glasgow area. However, it will not be easy in practice to obtain a better general comparison.

Another point also of the greatest importance is that during the past five or six years, largely due in fact to the keen competition of pulverized fuel, considerable improvements have been made in the general principles of mechanical stoking, which was thought to have reached practical perfection. In the first place, there has been an enormous increase in furnace volume, and British power station practice in general has fallen hopelessly behind that in America in this respect. One of the chief causes of the inefficiency of the mechanically-fired boiler plants in Great Britain is that the tubes of the boiler are far too near the furnace, so that the flames touch the boiler long before the combustion is completed, and the reactions are at once damped down with the escape of unburnt fuel. The mere fact, therefore, of doubling or trebling the volume of the combustion chamber would result in greatly improved results with mechanical stoking. A feature of pulverized-fuel firing is, of course, the enormous combustion volume, at least 1 cubic foot of space for each 3 lb. of coal burned per hour.

Secondly, there has been the perfecting of the stoker itself; for example, the "compartmenting" of the air supply in the travelling grate stoker so as to adjust independently the amount of air passing at every stage in the length. Again, a very important new factor is that of air heating, which is now just being realized, and which is under consideration at Dalmarnock for the future boiler-houses Nos. 3 and 4. As yet there are only three or four plants of any considerable size equipped with air heaters in Great Britain and France, and in the United States not a single plant other than an odd boiler as an experiment. Further, so far as the author is aware, no mechanically-fired plant has yet adopted hollow air-cooled furnace walls (except in a very small section of the brickwork) and used the heated air for secondary combustion. It is interesting to note also that ordinary air-heating in addition is being considered for pulverized fuel at the Colfax station.

The author is quite prepared to admit that if Dalmarnock, for example, could be altered on these lines, a considerable improvement on 78 per cent efficiency (regular performance) at 60 per cent load factor would result, and that air-heating alone might bring the figure up to over 80 per cent. Also, he is aware that figures approaching 85 per cent are now being guaranteed in Great Britain with mechanical stokers. For example, the efficiency of one plant in London, with mechanical stokers, air heaters, superheaters and economizers, has been guaranteed to be 85 per cent on the higher value of the coal, after deducting the auxiliary steam or power, which is not to exceed the equivalent of $1\frac{1}{4}$ per cent of the evaporation of the plant. An article by the author in the *Electrician* on this plant and the uncertainty as to what these figures meant led

to correspondence in the columns of that journal during March, April and May, 1923. It is possible that such figures may be attained on a short test of a few hours, but when it is remembered that they imply continuously about 37¾ per cent excess air, 12 per cent CO_2, and a temperature of the final-exit flue gases in the chimney base of about 235° F., it is fairly obvious that they will not be the weekly figures all the year round.

Bearing in mind, therefore, the difficulties of the whole question and the natural differences of opinion on a matter so complicated, the author considers that a fair figure for the net yearly working efficiency of a mechanical-stoker plant under the most modern conditions, with superheaters, economizers, air heaters, large furnace volume, hollow furnace walls or any other equipment, combined with the most scientific supervision obtainable, and with average working conditions, particularly quality of fuel and load factor, is 81–82 per cent, including the higher value of coal and deducting all auxiliary power, which corresponds to about 40 per cent excess air.

(*b*) *The Lakeside figures*.—As regards the figures obtained with pulverized fuel at Lakeside, the net results are 85–86 per cent actual working efficiency, month in and month out, on the comparatively low-grade Illinois coal of about 11 500 B.Th.U.'s per lb. (high calorific value). These figures are based in the first place on a most elaborate series of special tests carried out under actual running conditions, probably unsurpassed in the world for care and accuracy and for the time and trouble taken. Secondly, they are the results of continual weekly records taken as part of the routine of the station control, and, so far as the author is aware, the Lakeside station is the only one in the world that publishes regularly, monthly and quarterly, the full details of the boiler-plant performance.

In May and June 1923, for example, the weekly figures averaged 86–87 per cent, and on one special test carried out under abnormal conditions on one boiler 89·1 per cent was reached, the highest recorded figure for a coal-fired plant. From these facts, therefore, it is clear that the Lakeside station contains the most efficient steam-generation plant in the world.

The modern Lopulco guarantee alone for pulverized fuel is 84–86 per cent, or 82–84 per cent without economizers under test conditions, a remarkable figure when it is remembered that such guarantees must always be on the conservative side. The exact figure depends of course on the particular circumstances, such as the quality of the coal, the nature of the equipment, the size of the boilers, and the fluctuation in the evaporation. As already stated, the guarantee at Vitry, for example, is 84 per cent.

At the new Cahokia station of the Union Electric Co., on the southern bank of the Mississippi, for supplying St. Louis, the capacity of which will eventually be 300 000 kW—the present section under construction being 8 boilers of 17 800 sq. ft. heating surface and an evaporation of 170 000 lb. from and at 212° F. for each boiler, corresponding to 10·40 lb. of water per sq. ft. of heating surface and 14·00 lb. for peak loads—the guarantee is 85 per cent. In the Cleveland contract, where four boilers—the biggest in the world—are being installed, having 30 600 sq. ft. heating surface and evaporating over 300 000 lb. of water from and at 212° F. per hour, the guaranteed efficiency is 85·4 per cent without economizers. The most interesting figures, however, in this respect are perhaps those for the new Trenton Channel station of the Detroit Edison Co. This installation is to consist of 6 boilers of 29 000 sq. ft. heating surface (say 290 000 lb. evaporation per hour, normal), and the guarantees are as follows:—

Evaporation, lb. water from and at 212° F. per sq. ft. heating surface	Efficiency
lb.	per cent
3·5	87·5
6·9	88·0
10·3	86·5
13·8	83·0

Thus with the enormous figure of 13·8 lb. of water per sq. ft. of heating surface, that is 400 000 lb. of water per boiler per hour, without economizers, the guarantee is 83 per cent and for normal working 86½–88 per cent. It is expected that both at Cahokia and Lakeside the average efficiency will be 88¼ per cent on normal output when the plants are completed.

Finally, with regard to the installation of pulverized coal now being erected at Colfax, the efficiency guarantee is 89 per cent, using air heaters. It is expected to obtain a performance of less than 16 000 B.Th.U.'s per kWh on test, and under 17 500 B.Th.U.'s on long periods. With the present mechanical stoking the best figures are 18 713 B.Th.U.'s for 90-day periods, but normally 19 000 B.Th.U.'s. At Dalmarnock the figure is approximately 19 900 B.Th.U.'s.

Typical of the extensive series of tests carried out at Lakeside are the condensed figures given in Table 7 for 15 trials of 17·6–42·3 hours' duration.

The detailed figures of 5 tests on one boiler, at different ratings, as set out in Table 8, give a good idea both of the performance of pulverized fuel under modern conditions, and of the elaborate care and attention to detail with which these tests at Lakeside have been carried out.

As seen from the figures, these elaborate tests were carried out at greatly different duties, varying from evaporations of 53 390 to 92 202 lb. per hour, the normal rating being 90 000 lb., and the coal consumption varying from 5 960 to 11 350 lb. per boiler per hour. The detailed efficiency and heat balance-sheet figures show an efficiency of 84·6 per cent for the whole plant at the high rating of 92 200 lb. of steam per hour, corresponding to about 85–86 per cent for normal rating and varying from 84·6 to 89·1 per cent. In general, therefore, it may be stated that the Milwaukee boiler plant is running at the extraordinarily high efficiency of about 85 to 86 per cent, and the previous general ideas of 82½–85 per cent efficiency with pulverized fuel on test figures have been far exceeded. Scheffler and Barnhurst, for example, in their 1919 paper stated that a pulverized-fuel plant ought to work all the year

round at 75 per cent efficiency, corresponding to an average saving of 12–15 per cent in the coal bill as compared with mechanical stoking.

It will be noted that the economizers reduce the flue-gas temperature from about 430°–496° F. leaving the boiler (a very low figure, showing the efficiency of working) to about 168°–251° F., whilst the feed water is raised from 124°–127° F. to 168°–195° F.

As regards draught, the figure varies from 0·525 to 2·38 inches of water leaving the economizer, but at normal running it is about 1¾–2 inches, whilst the water evaporated per lb. of coal varies from 8·12 to 8·92 lb., being about 8¼ lb. for normal working.

The actual amount of air used in excess of the theoretical was determined with particular care, and, as will be seen, this varied from 10·7 to 25·2 per cent, depending on the evaporation of the boilers. The figures in this respect can be stated to be approximately 25 per cent excess air for 5 per cent overload, about 22 per cent on normal load and 12½ per cent on only 60 per cent of full load, although it is extremely difficult to determine the figures accurately. In general, therefore, the old contention that pulverized coal is working with only 20 per cent excess air can be accepted as correct.

The analysis of the flue gases is given for the fourth pass of the boiler, the result being 14½–16 per cent CO_2, a very high figure, equal to about 16 to 17 per cent at the actual point of combustion, whilst the amount of CO present is nil, which is also found to be characteristic of pulverized-fuel firing because of the intimate mixture of air and fuel and also the high temperature. The air leakage in the plant, which it is almost impossible to prevent with any method of firing, is indicated by the fact that the CO_2 is down to 10½–13 per cent on leaving the economizer. The amount of this air leakage is not generally realized by power station engineers.

(*c*) *Comparison of pulverized-fuel stoking and mechanical stoking.*—The net result, therefore, allowing conservative figures, is that under the most modern conditions pulverized fuel is working at 86 per cent efficiency and mechanical stoking at 81½ per cent, the saving in the coal bill due to the former method being thus 5½ per cent. This, however, though strictly correct, is certainly rather unfair to pulverized fuel from a practical point of view.

There seems to be no question in the first place that it is very much easier to obtain the highest efficiency with pulverized fuel. To run a mechanically-fired boiler plant all the year round at 81½ per cent efficiency, including the comparatively heavy stand-by and banking-up losses, requires almost superhuman attention, both in equipment and control, and only one or two stations in the world are attaining such a figure. It is admitted, of course, that the attention at Lakeside is far above the ordinary, but the main point seems to be that, with what may be termed extremely good attention, pulverized fuel would probably give, say, 82½ per cent efficiency, the mechanical stoker-plant figure being taken as 75 per cent, equivalent to a difference of 9 per cent in the coal bill. Of course, if pulverized fuel were adopted in the average existing station, the saving would be something like 15–20 per cent.

The chief reasons why pulverized fuel gives a decidedly higher efficiency than mechanical stoking seem to be the reduced excess of air (because of the much more

TABLE 7.

intimate mixture of the fuel and air); the very high temperature of the combustion, combined with more intense radiation; the continual presence of a finely divided cloud of incandescent ash and burning fuel in the combustion chamber; and the perfectly even diffusion and distribution of the heat to every part of the boiler tubes.

The reduced excess air, 20–22 per cent, as compared with, say, 35–37½ per cent, means in the first place a very high CO_2 content, viz. 16–17 per cent, at the actual combustion. As is well known, it is not possible to work mechanical stokers with over 14–15 per cent CO_2, even with the most unusual attention, and of course the average figure is much less than 10 per cent, especially on chain-grate stokers, so that pulverized fuel has a considerable advantage in this respect. Reduced excess of air also means a continual high temperature of combustion, averaging over 2 000° F. with pulverized fuel, the figure at the River Rouge plant, for example, being 2 100° F., mixed blast-furnace gas and pulverized fuel being burnt, and, as already stated, one of the practical problems has been to get the brickwork to withstand the conditions. The very large combustion chamber means a slowing down and great expansion of the air-fuel mixture, so that, in addition to the intimate mixing, the combustion has ample time to complete itself, incidentally without friction loss against the brickwork.

Another factor which probably plays an important part is that the whole volume of the combustion chamber is continually filled with a cloud of highly incandescent ash, which would appear to act on the principle of the incandescent mantle in greatly increasing the radiation effect, over and above that of the furnace walls. As is well known, the secret of working a boiler plant efficiently by any method of firing is to have the maximum radiant heat and, consequently, the highest furnace temperature. Finally, the combustion is in direct and intimate contact with the boiler tubes, without any arches or baffles.

(2) *Unburnt material in the ash.*—There is no question that one of the practical advantages of pulverized fuel is the much more thorough combustion in the ash. The final results of the detailed tests at Lakeside, including many samples of ash taken from different stages of the plant, was 0·40–0·74 per cent unburnt carbon, and the general figure is considerably less than 1 per cent of the weight of the coal.

It is very difficult to get authentic figures for the loss caused by the amount of unburnt and partially burnt fuel in the ash and clinker with mechanical stoking. The amount of fuel in the riddlings from mechanical stokers in many power stations is very large, and quite often the net loss is easily 4–5 per cent of the coal bill, largely owing to carelessness in not re-burning the riddlings.

In one case in the author's own experience a power station was selling ashes to a large factory a short distance away for a few pence per ton for road-making purposes, and the factory was actually using the material in their cylindrical boilers for steam generation.

Some types of stoker are, of course, much worse than others, the ordinary chain grate being apt to be very bad. Various American authorities, e.g. W. C. Wilcox of the American Chemical Society, give the average figure of unburnt fuel in the ash and clinker with "overfeed" stokers as about 25 per cent, corresponding to 4½ per cent of the coal bill, whilst for chain-grate stokers the figure is 35 per cent unburnt carbon and about 6 per cent of the coal bill. The figures for hand-firing on small boilers are said to be even worse, viz. over 35 per cent unburnt carbon and about 6½ per cent loss in the coal bill. Further authentic data on this point are certainly required, and in this connection a paper read in September last by W. S. Patterson before the Yorkshire Section of the Society of Chemical Industry * is of interest. Detailed results of investigations carried out on the composition of the ash and clinker from 15 different mechanical-stoker plants are given, and the amount of carbon in the ash was found to vary from 5·2 per cent to 40·48 per cent, corresponding to 0·75–19·10 per cent of the original carbon in the coal. It should be noted, however, that out of the 15 plants 9 had over 15 per cent of unburnt carbon in the ash, and 12 plants had over 2 per cent of the original carbon of the coal in the ash, whilst 10 plants had over 3 per cent and 6 plants over 5 per cent.

It may also be pointed out that special plant has been developed extensively in Germany for the magnetic separation of ash and clinker from unburnt fuel, and one firm is stated to have supplied over 100 plants treating about 8 000 tons of ashes per day. The result of this very extensive experience is that the average unburnt fuel in ash and clinker exceeds 30 per cent and is in some cases actually over 50 per cent. What the figure is on the most modern type of mechanically-fired plant is not clear, but at any rate we may take a figure of 2 per cent loss on the coal bill as being the best stoker practice.

That is to say, with pulverized coal there is a saving due to less combustible in the ash of about 1·25 per cent in the coal bill in the case of the best stoker practice, and probably about 3–4 per cent with the ordinary present practice in, say, over 90 per cent of power stations.

(3) *Flexibility as regards the qualities of fuel that can be burnt.*—The great advantages claimed in the past for pulverized fuel in this respect have been more than substantiated by the experience at a number of installations in addition to that at Lakeside, and, in fact, almost a revolution has been effected in steam generation on this account alone.

Mechanical stokers are largely dependent—within very fine limits—on coal of good quality in order to obtain the most efficient results, that is to say, not only as regards the heating value, but other qualities as well, such as variation in the melting point and the amount of the ash, and the coking properties, i.e. the proportion of resinous matter in the coal. It is, of course, common knowledge that if a mechanically-fired plant is running at 75 per cent efficiency with coal of, say, 12 000 B.Th.U.'s per lb., any very great variation in the quality, such as a reduction to 9 000 B.Th.U.'s, would simply throw the whole plant entirely

* See *Chemistry and Industry*, 1923, vol. 42, p. 904.

out of gear, reduce the efficiency to, say, 65 per cent and cut down the evaporation by half, whilst the installation would very soon be congested with clinker. In other words, with mechanical stoking we are compelled to consider the performance of a boiler plant not so much from the point of view of the heat given to the furnace, but of the weight of a given coal possessing a number of distinctive qualities—quite another proposition.

With pulverized fuel the matter is altogether so different as to alter the whole method of regarding a boiler. Thus, if all qualities of coal are used, there is practically no difference in the efficiency or the steam output of the boiler. A drop to 9 000 B.Th.U.'s from 12 000 B.Th.U.'s merely requires some extra pulverized coal to be added to the combustion chamber, and the performance carries on as before. That is to say, with pulverized fuel all that is necessary is to apply to the boiler a definite amount of heat, and the weight and quality of the coal or other fuels are minor matters to be altered accordingly only so far as is necessary to keep the heat supply constant. Thus one of the chief reasons why the Detroit Edison Co. have finally decided to install pulverized fuel, after the most elaborate investigations into its possibilities, on a 300 000-kW installation is the advantage of being able to burn fuel of greatly varying quality with comparatively little reduction in the highest efficiency figures. Another reason is that with a given boiler one-third more capacity is available at any time. Pulverized fuel was also adopted for the Cahokia station, St. Louis, largely on this account, and, as further illustrating the advantages in this respect, mention may be made of the United Railways installation at Providence, Rhode Island, U.S.A., of 3 Bigelow-Hornsby boilers each of 174 000 lb. evaporation from and at 212° F., arranged to burn either good-grade bituminous coal or purely refuse anthracite coal, not hitherto burnt at all. The plant is specially adopted for this dual capacity, so that the bituminous coal guarantee is lower than usual, viz. 81·5 per cent efficiency on a normal evaporation of 10·5 lb. per sq. ft. of heating surface per hour, and 79 per cent on a 2-hour peak load of 13·8 lb. of water per sq. ft. of heating surface. The Rhode Island anthracite coal is extraordinarily difficult to burn, being of a graphitic character which burns well for a short time and then goes out, due to the ash preventing the inner portions from burning; as a consequence it is a waste product in spite of its high heating value. A similar anthracite fuel is found in the Alps, Belgium and Rumania, and important developments may result in this direction.

(4) *Combined working with liquid and gaseous fuels.*—The fact that pulverized fuel will give more efficient results either by itself or mixed separately with any gaseous or liquid fuel, or with both together, is in practice also a very important advantage. Thus it has made possible for the first time, at the River Rouge plant of the Ford Motor Co. at Detroit, a solution of the difficult problem of burning huge volumes of blast-furnace gas, erratic in delivery, along with coal so as to maintain a reasonably steady output of steam.

It is the present custom in many steel-works to burn the blast-furnace gas under a range of boilers, and solid coal in an adjoining range of boilers, whilst coal is also often burnt under the gas-fired boilers as well.

The results are almost always deplorable from the point of view of economical working. Thus in one large steel-works boiler plant tested by the author, an enormous amount of coal, over 60 000 tons per annum, was being burnt at about 50 per cent efficiency, using both water-tube and cylindrical boilers, in an endeavour to cope with a variable steam demand from rolling-engines and a widely fluctuating blast-furnace gas supply. Pulverized fuel used under such conditions would save something like 40 per cent of the coal bill, an almost incredible figure, which is also on the assumption that the efficiency of the blast-furnace gas-firing was not increased.

The River Rouge plant is, of course, the classic example of the advantages of pulverized fuel with respect to the burning of mixed fuels. The normal working conditions on this plant, with the present installation of 4 boilers (3 working), are 70 per cent blast-furnace gas and 30 per cent pulverized fuel, each boiler having 26 470 sq. ft. heating surface (2 650 American horse-power rating), running easily at an evaporation of 200 000 lb. of water from and at 212° F. each per hour (250 per cent American rating), at 235 lb. pressure and 600 deg. F. superheat. The usual fuel consumption per 24 hours under these conditions is 67 000 000 cubic feet of blast-furnace gas at a pressure of 1½ in. of water, a temperature of 300° F., and having a heating value of 100 B.Th.U.'s per cubic foot (at normal temperature and pressure) together with about 275 tons of pulverized coal, 94 per cent through 100 mesh and 78 per cent through 200 mesh, being therefore finer than usual. Any proportion of blast-furnace gas and pulverized coal can, however, be burnt as required, and alterations can almost simultaneously be made in the relative amounts of the two fuels, the gas being introduced horizontally into the bottom part of the furnace through grids. Thus, not only is pulverized coal alone often used, but, as required, varying quantities of coal tar from the by-product plant and coke-oven gas, whilst during the recent American coal strike oil fuel and coke breeze were also utilized.

(5) *Overload and flexibility in steam output.*—The flexibility of pulverized fuel from the point of view of overload and steam output on the plant is found to be, at the Lakeside and other plants, much greater than was imagined. Thus a boiler can, in a comparatively short time, be put on to full load from a "banked" condition, i.e. under pressure but with no combustion at all, thus differing, of course, from banking up with mechanical stoking.

As an example of the remarkable possibilities in this respect, one of the boilers at the River Rouge plant, because two other boilers were shut down for a short time on account of some boiler feed-pump trouble, rapidly increased the evaporation until, at the end of 30 minutes, the figure was 350 000 lb. from and at 212° F., the normal figure being about 200 000 lb. Mr. Bowden, the Chief Engineer of the Poplar Borough Council Electricity Works, who has recently visited a number of pulverized-fuel power stations in the United

States, told the author that he saw one of the River Rouge boilers started up after standing for several hours, and in 15 minutes the evaporation was 230 000 lb. per hour. This flexibility of pulverized fuel as regards steam output seems to be the chief reason why such enormous boiler units are now being adopted in America. As already stated, boilers of over 30 000 sq. ft. heating surface, much more than twice the size of anything in Great Britain, are now under construction, and there is every possibility in the immediate future of boilers having a normal evaporation of 400 000 lb. being erected so as to enable one boiler and one 35 000-kW turbine to be worked as an entirely self-contained and independent unit. So far as the author is aware, there is no boiler having a normal evaporation of over 150 000 lb. per hour working with mechanical stokers, and the above enormous units are only made possible by pulverized fuel. With a combustion chamber of ample volume and sufficient area in the fuel feed-pipe there appears to be hardly any limit to the output possible.

(6) *Reduced stand-by and banking losses.*—The great flexibility in the evaporation means also a very considerable reduction—and, in fact, an almost entire elimination—of the stand-by and banking losses. Several of the largest plants in the United States have adopted pulverized fuel largely because of this factor.

If a boiler plant is subject to very considerable fluctuations in the steam demand and has long periods of banking up, then pulverized fuel is said to possess an advantage over mechanical stoking corresponding to a saving of as much as 2–5 per cent in the coal bill.

(7) *Ease of scientific control.*—The extraordinary ease with which pulverized fuel may be conveyed through pipes, being handled and controlled almost as readily as gas, means that an extremely accurate control of the working of a boiler plant is possible, especially since practically the whole of the air used is similarly under control and passed through pipes. The most remarkable developments in this direction have recently been made in America, partly at Lakeside but particularly at the River Rouge plant at Detroit.

In the latter installation each of the four very large boilers is fitted with a separate 3-panel control switchboard, one for each boiler, in a control room remote from the boiler house. These switchboards are each provided in the first place with recording pyrometers, one giving a chart of the temperature of combustion within the tubes of the boiler, at the exit gas discharge from the boiler, and in the chimney base, together with the steam temperatures, and with draught gauges for a number of different parts of the boiler plant. The battery of instruments on each board also includes steam and air meters, CO_2 recorder, steam pressure-gauge and superheat gauge, and special apparatus giving a continuous record of the rate of flow of the feed water, pulverized coal and blast-furnace gas. The board is further equipped with a series of switches controlling the pulverized fuel, air, and blast-furnace gas supply. In practice an operator stands in front of the board and, by merely manipulating switches, controls almost the entire working of the boiler, keeping it at the highest efficiency at different rates of evaporation, as required. There is also one attendant in front of each boiler, but he has practically nothing to do except in case of emergency, and the boiler house contains more men cleaning and polishing than looking after the boilers.

Such ultra-scientific methods are only possible with pulverized fuel because of the ease of control, and it is understood that, with the four new boilers now being erected, there will be one instrument board only and one operator to control the working of a plant capable of evaporating over 800 000 lb. of water from and at 212° F. per hour, a normal long-period overload being 225 000 lb. of water per boiler per hour. In an emergency, over 1 000 000 lb. of water per hour can be handled on the plant for long periods.

The normal winter load on this present plant is 13 000 000 lb. of steam per day, i.e. about 8·5 lb. of water from and at 212° F. per sq. ft. of heating surface per hour, but 14·5 lb. can be taken as an overload. All the make-up is pure distilled water, of which on the average 1 380 tons per day is used, the evaporator room being 350 ft. long by 60 ft. wide, containing a double row of 9 evaporators connected in parallel, the heating being obtained by steam coils. As a consequence, since scale is eliminated and as the pulverized-fuel plant is absolutely reliable, these boilers are normally run for six months continuously and have often been in operation for nine months, whilst there will be no maintenance cost for three years. The present plant, as already stated, consists of 4 boilers of 26 500 sq. ft. heating surface, each unit being entirely independent with its own superheater and steel chimney, boiler-feed circuit, control panel, etc. The boilers are of the Ladd type having five drums, viz. four steam and water drums and one top steam-collecting drum. The boiler house containing the 4 boilers is 350 ft. long by 225 ft. wide, the roof being 120 ft. from the ground. The four steel chimneys are each 327 ft. high above the ash-level floor and 11 ft. internal diameter. The boiler house is divided into four main floor-levels, in addition to intermediate gangways. The top floor is the conveyer floor, to which the pulverized coal is brought from the adjacent pulverizer house by means of spiral conveyers and delivered to the pulverized-coal bunkers underneath, these bunkers having a capacity of 1 100 tons or about 4 days' supply. At a distance of 65 ft. below this level is the boiler-operating floor, whilst the next stage is the steam-pipe gallery floor, and finally the ash-level or ground floor. In each case the complete unit of the boiler, superheater setting, and steel chimney, weighing about 1 000 tons, is hung bodily on the structural steelwork of the building. The total height of the boilers from the ash-pit floor to the top of the superheater steam piping is 82 ft. 9 in. and the floor space of each boiler is 29 ft. by 31 ft.

The combustion chamber is approximately 23 ft. by 24 ft., and 55 ft. high, corresponding to a combustion volume of 5 cubic feet per rated American horse-power, whilst the pulverized plant has a capacity of 750 tons of coal per 24 hours, the pulverizer building being 200 ft. long, 60 ft. wide and 109 ft. high. It is estimated that the total cost of the River Rouge power plant and its subsidiary generating, transforming and dis-

tributing station is very nearly $10 000 000, and the present extensions, including the duplicating of the boiler plant, will cost another $6 000 000. The Ford works employ about 40 000 people and turn out normally 5 000 cars and 500 tractors per day. One of the problems is to handle the private cars of the employees, which are parked in acres of ground, and the works include 300 miles of railway, which is to be electrified by the Ford staff. It is, therefore, rather a striking commentary that the Ford Co. should have adopted pulverized fuel, and also be at present doubling the plant. For reasons of this kind, therefore, it is very difficult to give a really fair comparison as regard net efficiency, since the control with pulverized fuel is infinitely easier than mechanical stoking, a substantial advantage not possible to express in figures.

(8) *Labour costs.*—The net result of long experience at the Lakeside station is that the total labour and staff costs are about $0·465 per American ton (2 000 lb.), corresponding to 25d. per English ton (2 240 lb.) on the basis of American wages and conditions. The average rate of wages in Milwaukee (1922) was $0·620 (2s. 7d.) per hour, so that in Great Britain, where the wages are less than half, the total labour cost would be about 1s. 2d. per ton, whilst the corresponding figure in Great Britain for mechanical stoking is at least 20 per cent higher.

The detailed labour figures at Lakeside for a typical month (April 1922) for the complete boiler installation, divided into (A) boiler house, and (B) pulverizer house, are given in Table 9.

The total staff in the boiler house is 63 men at a total wage of $4 260·44, equivalent to, say, £852 per month, corresponding to a total cost of 27·63 cents per American ton (2 000 lb.), or 15d. per English ton (2 240 lb.) on the basis of American wages.

The total staff for the complete boiler house, boilers and pulverizing plant together, is 86 men at a total wage of $7 140·50, equivalent to, say, £1 428·1 per month, corresponding to a total cost of $0·465 per American ton or 25d. per English ton on the basis of American wages.

As already stated, the average wage in Milwaukee in 1922 was $0·620 (2s. 7d.) per hour. This is, however, more than double the wage in Great Britain, so that the British wage cost per ton is about 1s. 2d.

The exact labour costs of another large modern pulverized-coal installation of 3 000 h.p. described in a recent report by H. Kreisinger will also be of interest in this connection. The figures given are for 12 months' running, including all stoppages, during which 43 703 (American) tons of coal were burnt in the pulverized condition. As already stated, the total labour costs were $23 680·52 per annum, corresponding to $0·542 per ton, and for a given month of continuous running the labour figures for unloading, crushing, pulverizing, drying, boiler washing, and ash handling, for the burning of 3 150 tons, are given in Table 10.

TABLE 10.

Labour Costs for One Month's Continuous Running with Pulverized Fuel.

	Hours	Rate	Cost per month
		cents	$
Unloading cars to track hopper pulverizer	622	40	248·80

Repair man, acting foreman of washer and cleaner ..	208	60	124·80
Ash handler	208	40	83·20
Total			$1 385·60 (= $0·439 per ton)

In the first place these figures confirm in a striking manner those given previously by various American advocates of pulverized fuel, for example by Mr. N. C. Harrison, already mentioned. Again, Scheffler and Barnhurst stated that, as a typical example with a plant of 100 tons per 24 hours and wages at $0·400 per hour, it would take 34 labour-hours to prepare the fuel and deliver it to the conveyers, at a cost of $0·140 per ton. At Lakeside, a plant of 650 tons per 24 hours with labour at $0·620 per hour in 1918, the figure was 18·80 cents (9·50d.).

It is particularly difficult also to give fair average general figures for labour costs, because these decrease at a rapid rate as the size of the plant increases, and the rate of wages varies considerably. Thus it is stated that at $0·400 per hour, for a plant of 1 000 tons per 24 hours, the labour costs in preparing the fuel would only be 115 labour-hours or $0·04 (2d.) per ton. With an extremely large plant of 5 000 tons

per 24 hours this would be further cut down to \$0·025 (1·25d.) per hour.

The same difficulties apply, of course, to mechanical stoking. The actual detailed figure at Dalmarnock for 14 months, with a total of 78 men employed, was approximately 19·0d. per ton at 34 per cent load factor. Under better conditions of output this figure would, of course, be somewhat improved, but based on these comparative figures and the opinion of many American engineers it can be stated that, at any rate for a large plant of, say, 40 000 kW, and with scientific supervision, pulverized fuel is lower in labour costs to the extent of something like 20 per cent.

(9) *Amount of power consumed in the preparation of the fuel.*—The net result of many months' records at Lakeside covering the preparation and consumption of nearly 500 000 tons of pulverized fuel since the station opened, is that the total auxiliary power used for handling, crushing, drying and pulverizing the fuel, including that used for lighting and other incidentals, is equivalent to 2·13 per cent of the steam production of the plant, the preparation of the pulverized fuel accounting for only 1·75 per cent, which figure has now, however, in the case of the Lopulco system, generally been reduced by the new vertical drying, using merely the waste-heat gases. The net figure is about 1 per cent of the steam production of the plant, equivalent to about 19½ kW. per ton of coal. As previously pointed out, these are also the actual guarantee figures for Vitry.

The figures at Lakeside are well illustrated in Table 11, which gives the exact cost of light and power in the pulverizing building, with the output of dried and pulverized coal, together with the cost of pulverizing per ton, for four separate months (February to May, inclusive) in 1922.

Taking a typical month, that of May 1922, the exact amount of power used in the station, as recorded by a battery of meters, is shown in Table 12, the total number of units generated being 20 299 000.

It will be seen, therefore, that the total auxiliary power for all sources on the entire Lakeside station, including, of course, the turbine plant, amounts to 3·97 per cent of the power generated. Of this amount, however, only 1·75 per cent is used for the actual preparation of the pulverized fuel, and 0·38 per cent for boiler-house auxiliaries, such as handling the fine ash, lighting, etc., i.e. 2·13 per cent for steam generation.

It should also be mentioned that the pulverizing plant can in practice be run almost entirely at night when the load on the station is light, thus storing up fuel for the heavy day loads, so that with a little care in management the real net cost of the power used is extremely small, as of course the light-load losses of the stations are in any case continuous, and the value of the actual power used is practically nil. However, for the purpose of argument we can take the power at its full value, that is as if deducted from the day load available for sale.

With regard to drying, as previously stated, the rotary driers at Lakeside take the equivalent of about 1 per cent of the steam generated, but these are already obsolete. The new vertical driers, using 10 per cent of the waste chimney-gases, require merely 3 kW per ton of coal for the fans to maintain the drying current of mixed hot gases and air through the drier.

Some interesting facts have been brought to light as the result of the extensive experience obtained concerning the drying of coal and the amount of moisture that can be left in. It is now known, for example, that the difficulties of drying are chiefly caused by the extraneous or added moisture and not so much by the natural moisture. For example, if a coal at the pit face contains in its natural state 3–4 per cent of moisture it is not necessary to dry it down to 2 per cent of moisture, as in the case of a pulverizer coal-fired boiler plant near the pit-head. If, however, the coal contained, say, 1 per cent of moisture and 3 per cent of moisture was added due to exposure to the weather, then this coal would not work efficiently in the process and it would be necessary to dry it down to 2 per cent. Most coal, of course, contains 6–10 per cent of moisture, but a large part of this is extraneous moisture.

It can be taken as authentic that the auxiliary power consumption of a large, modern, pulverized-fuel installation for all practical purposes is a maximum of 19½ kW per ton, equal to, say, 1 per cent of the steam production of the plant, divided, in the case of the Lopulco system, as follows:—

Pulverizing mills	.. .. ..	12·0 kW
Conveyers	.. ..	1·0 ,,
Vertical driers	.. .. ..	2·7 ,,
Fans	.. ..	3·0 ,,
Pulverized-coal feeds	.. ..	0·8 ,,
Total	.. .. ..	19·5 kW

TABLE 11.

Cost of Power used in the Pulverizing Building at Lakeside, Milwaukee. (American ton = 2 000 lb.).

Month	Lighting	Power	Total units	Coal used	Units per ton	Cost per ton at 0·6 cent per kWh
	kWh	kWh	kWh	tons	kWh	cents
February	13 220	314 470	327 690	14 118	23·2	11·60
March	14 324	366 376	380 700	15 996	23·7	11·85
April	13 192	377 667	391 579	15 311	25·5	12·75
May	8 114	370 684	378 798	15 708	24·0	12·00

As regards mechanical stoking, it is, as usual, difficult to obtain authentic figures. The different methods by which auxiliary steam or power may be taken by a mechanically-fired water-tube boiler plant are given in Table 13, together with what may be considered to be average figures for the equivalent steam production.

Several of the items, viz. 5, 6 and 8, are common to both systems of firing, and of course many plants are not equipped with items 7, 8 and 9, and, as previously stated, the latest type of mechanical stoker requires less than 1 per cent for items 3 and 4 together. stations to this question of auxiliary power. In many industrial plants the figures are most unsatisfactory, often over 10 per cent of the steam generated being lost in the firehole.

In general, therefore, pulverized fuel certainly results in no more auxiliary power being used than in mechanical stoking, and many of the previous ideas held on this question were quite erroneous.

(10) *Maintenance costs.*—With regard to maintenance costs, wear and tear and breakdowns in the preparation plant, damage to the firebrick linings and settings, and damage to the boiler, the experience at Lakeside, after nearly 3 years' running, is that the ideas of many engineers as to the excessive cost of these items for a modern plant have not the slightest foundation in fact. Thus the total cost of repairs to the pulverizers has been less than 1¼d. per ton, and it is claimed that the maintenance costs, particularly of the brickwork, are less than with mechanical stoking.

Station total	799 050	7 534	806 584	—	100·00	3·97

As far as Dalmarnock (a typical, modern mechanical-stoker station) is concerned, the amount of auxiliary power for coal and ash handling, mechanical stoker, mechanism, mechanical draught, etc., was 1·68 per cent of the steam production of the plant, that is to say 0·45 less than that used at Milwaukee, or about 0·55 more than in the case of pulverized fuel with the modern vertical drier. Probably the average figure for British power station practice is 2–3 per cent of the steam production, inclusive of all the auxiliaries, although in many cases the figure is well over 3 per cent, and nothing like sufficient importance is attached in power

The actual figures at Lakeside as regards the pulverizing plant are as follows, taking the results of 15 months' continuous running, viz. March 1921 to May 1922 inclusive, during which period 183 046 American tons

(of 2 000 lb.) [equal to 163 430 English tons (of 2 240 lb.)] of coal were pulverized. The repairs, of which the most detailed record was kept, included the following number of balls replaced in the pulverizers:—

Mill No. 1	12 balls
Mill No. 2	17 ,,
Mill No. 3	13 ,,
Mill No. 4	12 ,,
Mill No. 5	16 ,,
Mill No. 6	6 ,,
Mill No. 7	9 ,,
Mill No. 8	4 ,,
Total	89 balls

The price of these balls is \$16·25 each, so that the total cost is \$1 446·25, say about 0·40d. per ton of coal for pulverizer ball replacement.

TABLE 13.

Mechanical Stoking.

Source of auxiliary steam or power used	Average steam or power consumption, expressed as percentage evaporation of the plant
(1) Coal conveyers	0·50
(2) Ash conveyers	0·25
(3) Mechanical stoker mechanism ..	0·50
(4) Mechanical draught	1·50
(5) Boiler feed pump	1·00
(6) Water - softening plant and accessories	0·50
(7) Economizer scrapers (with cast-iron tubes)	0·10
(8) Electrolytic corrosion treatment	0·50
(9) Soot cleaners, and other minor uses	0·01
Total	4·86 per cent

There were also replaced during the period October 1921 to May 1922 inclusive (8 months) two rings, one in No. 1 mill and one in No. 2 mill, at \$420 each, equal to a total of \$840, and during this period 115 630 American tons (of 2 000 lb.), equivalent to 103 240 English tons (of 2 240 lb.), were pulverized, the cost per ton for new rings therefore being 0·39d. Finally, from March 1921 to May 1922 inclusive (15 months), when, as already stated, 183 046 American tons (of 2 000 lb.), equivalent to 163 430 English tons (of 2 240 lb.), were pulverized, two new sets of drive gears were required, one for No. 1 mill and one for No. 4 mill, costing \$651 per set, a total of \$1 302, corresponding to about 0·38d. per ton of coal. The total cost, therefore, of repairs to the pulverizing plant for over 12 months' running is about 1·17d. per ton.

As showing the steady running of the pulverizers, Table 14 gives the output figure for 7 months.

With regard to the brickwork, it is strongly claimed by Mr. Anderson, as a result of a detailed experience of over two years at Lakeside, that the wear and tear on the modern type of brickwork is now less with pulverized fuel than with mechanical stoking, chiefly because of the water screens and the hollow air-cooled furnace walls.

This conclusive experience at Lakeside confirms the previous experience on other plants that under proper conditions—which there is no difficulty in attaining—pulverized fuel actually costs less in maintenance charges than mechanical stoking.

Scheffler and Barnhurst maintained in their paper of 1919 that pulverized coal is less liable than mechanical stoking to cause breakdowns and excessive wear and tear, because nearly all the mechanism is outside the furnace, whilst the Allegheny Steel Co., for example, have run boilers on Lopulco pulverized fuel for four years with only trifling repairs. Also the Lima locomotive works in Ohio ran 3½ years and the Oneida-street plant a similar period before the settings were rebuilt. There is no sign of damage to the boilers, and this is purely an exaggeration so far as modern installations are concerned.

TABLE 14.

Output of Pulverizing Mills for the Months November 1921 to May 1922 inclusive.

	Tons	Hours run	Tons per hour
November 1921..	13 564·55	3 213·25	4·22
December 1921..	11 576·90	2 499·92	4·63

March 1922 ..	15 995·66	2 239·50	7·14
April 1922 ..	15 311·19	2 419·25	6·33
May 1922 ..	15 706·50	2 481·25	6·33
Total ..	101 183·55	17 645·92	5·73 (av.)

The results at Milwaukee therefore show that the opinions often held, especially in Great Britain, that pulverized fuel causes excessive wear and tear and depreciation, together with continual repairs and costly breakdowns, are entirely erroneous. On the contrary, pulverizing mills have ground millions of tons of coal at only a trifling expense for repairs, and the costs of setting and brickwork are, as already stated, now claimed to be less than with mechanical stoking, always providing, of course, that both methods of control and the equipment are on modern lines.

Mr. Anderson gives it as his opinion that pulverized fuel has the advantage from the wear-and-tear point of view in that no ironwork—except the actual burners—is near the heat, and it is a striking commentary that the Lopulco guarantees are now stated to cover three years' life for the brickwork, a period for which no mechanical-stoker firm could give a guarantee with ordinary solid furnace walls.

There is no question also that a careful consideration of

the most modern American pulverized-fuel installation shows a smaller percentage of stand-by plant than in the case of mechanical stoking. Thus at the River Rouge plant of four boilers, three are working regularly and often four, and at the Trenton Channel station one boiler will be a stand-by, out of six. On very large boilers it is impossible to work mechanical stokers continuously as can be done with pulverized fuel, and a breakdown of a large stoker (which occasionally happens) is apt to be a very serious matter. To-day, of course, the tendency is practically to eliminate boiler breakdowns by the use of only pure distilled water for the make-up as well as for the main supply. At the Ford plant, as already stated, the boilers are run for 6–9 months without a stop. This is easily possible with distilled water and pulverized coal, but not with distilled water and mechanical stoking, because the latter is now more liable to breakdown, the best mechanical-stoker figures being 90 days, at Colfax.

fuel to the extent of over 3 000 000 tons per annum for steam generation, some of the largest and most efficiently managed power plants in America being concerned.

It is, of course, agreed that reasonable precautions must be taken. Thus all bins, conveyers, storage hoppers, driers and pulverizers are required to be dust-tight, and no wood must be used in the buildings, which have to be kept absolutely clean and free from coal dust.

This, however, is easily accomplished by means of vacuum cleaners, and various modifications in the design of the buildings have been introduced; for example, all the spars and girders are arranged so that dust cannot lodge on them and fall down in a shower.

Again, in a modern installation the pulverized fuel is only mixed with any considerable quantity of air immediately at the burner. Pulverized fuel itself in bulk is not particularly dangerous, but only when mixed with sufficient air in the form of a cloud.

TABLE 15.

Figures given by Scheffler and Barnhurst for the Cost of Preparation of Pulverized Fuel, per ton.

	100-ton-per-24-hour plant	1 000-ton-per-24-hour plant
	$	$
Power: 17 kWh per ton net, at 0·75 cent per kWh	0·1275	0·1275
Labour: 40 cents per hour	0·1400	0·0400
Coal for drying, at $5 per ton delivered	0·0600	0·0600
Repairs	0·0700	0·0700
Total cost of pulverizing	0·3975	0·2975
Interest at 6 per cent	0·1050	0·0390
Depreciation	0·1200	0·0400
Taxes and insurance	0·0350	0·0130
Total net cost per American ton (2 000 lb.)	$0·6575	$0·3895

As usual, it is very difficult to get corresponding detailed cost figures for mechanical stoking, but the maintenance is obviously greater than with pulverized fuel, even under the most modern conditions. In both systems the number of crushers and coal conveyers will be about equal, together with the fans and trunking, and the repairs to the brickwork and settings are less for pulverized fuel. The repairs to the average mechanical stoker mechanism are apt to be very heavy under ordinary conditions, and in the case of cylindrical boilers sometimes simply ruinous, but the author has not sufficient authentic data to suggest an average figure for high-class stoker performance.

(11) *Danger of explosions and fires.*—It is generally agreed in America that this, whilst naturally more pronounced than in the case of mechanical stoking, is not now a serious matter. There has been no explosion in any modern plant, and no serious fires, and the possibility of danger will not prevent, as already seen, the adoption within the next few months of pulverized

It is interesting also to note that the horizontal revolving drier has been responsible for most of the fires that have occurred, especially the completely obsolete pattern in which hot gases from the auxiliary furnace passed through the coal itself. Thus the coal often became ignited and the flames passed back to the pulverizer. The later types of rotary drier, as used at Lakeside, are of the double-shell variety in which the flames and hot gases pass between an inner and outer shell and never come into contact with the coal passing inside the drier. This type resulted in a big reduction in fires, and the new vertical drier already described will practically eliminate these altogether since there is no longer any need for an external furnace.

(12) *Ash troubles.*—With regard to the question of fine ash being blown all over the inside of the boiler plant installation, in the first place the distribution of the ash at Lakeside is found to be such that 25–50 per cent of the ash falls to the bottom of the combustion

chamber, 25–35 per cent is caught in the chimney base, and 12–25 per cent is blown out of the top of the chimney. The idea that 50 per cent or over is discharged from the chimney is not correct, unless the plant is forced much above the normal evaporation.

Of course, in comparison with the early types of plant the use of a very large combustion volume combined with the zone system of design has meant the rapid slowing down of the pulverized-fuel current, so that a large proportion of the ash separates before the boiler tubes are reached and is thus deposited in the bottom of the furnace.

On the average about 17½ per cent of the ash seems to be discharged from the chimney top, but it is in the form of an excessively finely divided, flocculent powder. As already stated, about 65 per cent of the coal is pulverized sufficiently to pass through a 200-mesh screen, so that the resulting ash must be much smaller. There seems to be no question that the combustion of the coal is so rapid that the particles have not time to soften and stick together, so that, if the coal contains 10 per cent of ash, the diameter of the ash particles will be approximately 1/4 000 inch.

It is stated that modern pulverized-fuel installations in America give no trouble at all in this respect and that the 12–25 per cent of the ash is never seen again, even in the most crowded centres. It must also be remembered that quite a considerable amount of ash and partially burnt fuel already goes up the chimney where mechanical stoking is used. This is, in fact, an intolerable nuisance in some cases because of the short steel chimneys now so largely used and also because of the large size of the particles. In the author's opinion there ought to be included in a proper boiler-test code some method of determining this solid material in the chimney gases. In a recent careful test in the United States it was discovered that with mechanical stoking no less than the equivalent of 3 per cent of the coal fired was discharged from the chimney top. This is quite as much as with pulverized fuel, except that the latter has the advantage of being in the form of an impalpable powder.

It is, of course, possible that some day all chimneys will be required to prevent the emission of both black smoke and solid particles, so as to purify the air, but, generally speaking, pulverized fuel should not present any more difficulties in this respect than other methods of firing.

The trouble of slagging, as already pointed out, has been completely eliminated by the water screen, as shown also by the low cost of maintenance of the brickwork.

(13) *Capital costs.*—The author is unfortunately not in a position to give authentic figures for the comparative costs of mechanical stoking and pulverized fuel in Great Britain, in any case always a difficult matter to deal with in a general way, because of differences in the local conditions and the size of the plants. Taking, however, the erection of a new power station, as far as the author can ascertain the cost of a pulverized-fuel equipment (including coal-handling plant, coal crusher, conveyer to crushed coal bunkers, crushed

coal bunker, conveyer to drier, driers, conveyer to dried coal bunker, pulverizers, conveyers to pulverized-coal bins, coal feeders, burners, furnace equipment, and small steam ash-ejector), as compared with the same duty for a mechanical stoker equipment (coal-handling plant, very large overhead bunkers, trunking to stokers, mechanical stoker equipment and accessories, furnace equipment, and large ash conveyers), depends very largely on the size of the installation.

Very roughly, pulverized fuel costs more than mechanical stoking for comparatively small plants of, say, less than 6 000 kW, at 10 000 kW the difference is very slight, and over this there is no difference, whilst in the very largest plants pulverized coal is cheaper. Generally, however, there is not much difference as regards capital cost.

Most certainly the idea that pulverized fuel requires extensive stand-by plant is entirely wrong, and pulverizers, driers, burners, etc., do not break down or need any more reserve plant than mechanical stoking, each boiler now having a drier and pulverizer just as it has a mechanical-stoker equipment.

It may also be pointed out that in the case of the latest type of Lopulco installation such as at Vitry, the combined vertical gravity driers and pulverizers are placed on the boiler-house floor, and occupy very little more space than mechanical stokers and accessories, being quite different, from the point of view of buildings and foundations, from the old-fashioned central pulverizing plant and long rotary drier.

General Operating Figures.

The additional figures given below, being the total operating costs of pulverized fuel and mechanical stoking, will also be of interest after studying the Lakeside performance.

Scheffler and Barnhurst in their 1919 paper presented figures for the cost of preparation of pulverized fuel (see Table 15). These agree remarkably well with those at Lakeside, taking the different labour, coal and power costs into account.

The recent report by Henry Kreisinger, already mentioned in connection with labour costs, on the full details of the performance for 12 months' continuous running of a pulverized-fuel-fired boiler plant of 3 000 h.p., burning 43 750 tons of coal per annum is valuable, as giving the long period results on another large modern plant.

(1) Coal used, high grade Eastern (America) coal, bituminous screenings:—

Fixed carbon, per cent	48·3
Volatile matter	33·4
Ash	13·0
Moisture (as received)	5·2
B.Th.U.'s (as received)	11 771
B.Th.U.'s (dry basis)	12 414
(2) Coal burnt	43 703 tons (Am.)
(3) Water evaporated	854 158 170 lb.
(4) Water evaporated from and at 212° F. per lb. coal	9·75 lb.

(5) Total operating costs:—

(a) Coal	$224 709·39
(b) Repairs	7 216·00
(c) Supplies	7 271·88
(d) Water	13 330·30
(e) Labour	23 680·52
	$276 207·99
(6) Operating costs per 100 lb. steam	$0·324
(7) Total capital charges at 20 per cent	$52 799·66
(8) Total inclusive cost of operation	$329 007·65
(9) Net cost per 1 000 lb. steam	$0·385

In a given month the cost of labour, power, unloading, drying, pulverizing and conveying, exclusive of overhead charges, was $0·470 per ton.

Scheffler and Barnhurst give the following as average figures for the costs of operation of mechanical stokers in the United States, taking a large plant of 1 000 tons (American) of coal per 24 hours.

	$
Power for stoker, 2 per cent of the total boiler horse-power developed	180·00
Power for mechanical draught, 2 per cent of the boiler horse-power developed	180·00
Coal-handling: 100 kW at 0·75d. per kW	18·00
Labour for coal-handling: 2 men per shift (3 shifts) at 40 cents per hour	19·20
Repairs for stokers at 30 cents per boiler horse-power per annum	17·50
Repairs for coal-handling equipment	10·00
	$424·70

Total cost of operating, per ton: $0·425

Finally, the exact cost of Dalmarnock for an average 12 months' running and also for two typical months is given in Table 16, the average load factor on the station being 34 per cent, as already stated.

Conclusion.

The position with regard to pulverized-fuel firing for steam generation in comparison with mechanical stoking may therefore be summed up as follows:—

(1) *Efficiency.*—Under the best conditions pulverized fuel gives 86 per cent efficiency, and mechanical stoking 81½ per cent, representing 5½ per cent saving in the yearly coal bill. Pulverized fuel is, however, much easier to work in obtaining these figures, and under ordinary conditions the saving is 9–10 per cent, and in most existing stations would be 15–20 per cent.

(2) *Unburnt fuel in the ash.*—With pulverized fuel the figure is 0·40–0·74 per cent of unburnt carbon, while with mechanical stoking it is 2·0 per cent under good conditions, and is often 5·0 per cent.

(3) *Flexibility in fuel burnt.*—Pulverized fuel is more flexible in this respect than mechanical stoking and gives less drop in efficiency as the coal varies.

(4) *Combined working with liquid and gaseous fuels.*—Pulverized fuel will work with liquid and gaseous fuels in a manner not possible with mechanical stoking.

(5) *Overload and flexibility in steam output.*—Pulverized fuel is much more flexible in this respect, will get up steam much quicker and will take a heavier overload.

(6) *Stand-by and banking losses.*—These are almost entirely eliminated with pulverized coal, and, in the case of a plant with fairly long periods of comparatively limited steam demand this corresponds to 2–5 per cent saving in the coal bill.

(7) *Ease of scientific control.*—Pulverized fuel lends itself to the latest methods of scientific control from a distant switchboard, in a manner almost impossible with mechanical stoking.

(8) *Labour costs.*—The labour costs with pulverized coal are approximately 20 per cent less than with mechanical stoking, but much depends on individual conditions.

(9) *Auxiliary power consumption.*—The total power consumption in the preparation of the fuel is about 19½ kW per ton, or 1 per cent of the steam production, whilst the very best stoker practice is also about 1 per cent of the steam production; but average figures are 2–3 per cent.

(10) *Maintenance costs.*—It is difficult to obtain these figures for mechanical stoking and, in a lesser degree, for pulverized fuel also. Generally, however, pulverized fuel is superior, and the pulverizing plant itself costs less than 1¼d. per ton, whilst the wear and tear on the brickwork is less than in the case of mechanical stoking.

(11) *Danger of explosions and fires.*—This danger is now much reduced because of simple vertical driers and modern design of burners, but it is still greater than in the case of mechanical stoking.

(12) *Ash troubles.*—With the most modern plant about 17½ per cent of the very fine ash is discharged from the chimney top, and this is stated to give no trouble, although opinions differ. Slagging has been eliminated, whilst mechanical stoking has to contend with the conveying of ash and clinker.

(13) *Capital costs.*—It is difficult to give general figures, but the situation seems to be that for smaller plants mechanical stoking is cheaper, that there is little difference for medium-sized plants over 10 000 kW, whilst for very large plants pulverized coal is cheaper.

It is, therefore, not altogether an easy problem to decide whether for a new plant pulverized fuel should be used in preference to mechanical stoking, and especially for replacing existing mechanical stokers. The efficiency is by no means the only factor, as shown in the paper, and in comparing the two systems of firing we have particularly to take into account the flexibility of steam output, the quality of the fuel, the convenience for individual conditions, and the running costs. Further, the correct design of details, for example the exact position of the firebrick walls, is very important, even when all the modern ideas described are embodied.

Although the principle of pulverization is applicable to a very wide range of fuels, with practically no difference in efficiency, it is interesting to note that the ideal coal for pulverizing has 30–40 per cent volatile matter, low sulphur content, and less than 10 per cent of ash, and has also a high melting point, i.e. it is a highly volatile fuel with low non-fusible ash content. As the volatile content is reduced, the coal is relatively somewhat less easy to ignite and the effect on the brickwork is more severe. There is, however, no real difficulty except in the case of anthracite with less than 5 per cent of volatile matter, and it is claimed that this can be burned if the grinding is finer than usual, the combustion chamber being reduced in volume so as to get the maximum help from the incandescent brickwork. In addition, high ash content generally increases the cost of pulverizing and preparation per unit of steam output, and factors of this description show how complicated is the comparison. It is a significant fact, however, that pulverized fuel has developed to such a remarkable extent in so short a time, although one has to remember the enormous amount of preliminary work that has been necessary to perfect the details that have finally resulted in the present success. It is stated that one company has spent over £300 000 during the past seven years in this field, which again illustrates the great experience American engineers have had with pulverized fuel and the uselessness of experimenting afresh in British power stations with the fundamental principles of this method.

Another significant fact is that many of the newest, most up-to-date and largest power stations in America have adopted pulverized fuel. Thus the Ford Company spent two years in a most exhaustive investigation of the performance of almost every type of mechanical stoker as compared with pulverized fuel, and for their conditions chose the latter. The engineers responsible for the Cahokia station at St. Louis also went to extreme lengths in a similar investigation, and decided on pulverizing for the inferior Illinois coal, and the Detroit Edison Co., well known to be one of the most efficient in the world in the field of power, are only going to adopt pulverized coal after a similar lengthy consideration. Finally we have the facts that the Lakeside station, after three years' experience, is doubling its plant, like the Ford Company; that the Union d'Électricité, after sending their engineers to America, are installing pulverized fuel at Vitry after equipping the largest station in Europe (Gennevilliers) with mechanical stoking; and that such stations as Cleveland and Colfax are now adopting the same principle, although the latter is one of the most efficient stoker plants in the world.

These facts require serious consideration, although it must be remembered that many of the largest American stations, such as Hell Gate, Calumet, Connors Creek, Hudson Avenue and Crawford Avenue, have not adopted pulverized fuel, whilst a limited number of stations are said to be obtaining, as regards the net yearly performance, results nearly equal to those where pulverized fuel is used, and the decision to adopt or reject pulverized fuel has in a number of cases been a very close one.

Pulverized-fuel firing has, however, another very important aspect which is certainly not yet realized. The power stations of Great Britain are burning raw coal to the extent of something like 7 million tons per annum, and are consuming in the process about 21 million gallons of motor spirit, 3½ million barrels of oil (of which at least 50 per cent is Diesel oil), and 63 000 tons of sulphate of ammonia, which latter ought to be employed as artificial manure. These figures

represent the valuable products that could be obtained by the low-temperature carbonization of the coal, a process which the author believes we shall be compelled to adopt in the future so as to eliminate black smoke and render ourselves independent of the world for motor spirit, oil, and fixed nitrogen. The residual low-temperature fuel, with, say, 3–12 per cent volatile matter (the figure depending on the process used) would then be available for steam generation, and is decidedly more efficient than coal, as it burns smokelessly with a high emission of radiant heat.

Pulverized-fuel firing is of the greatest importance because it lends itself particularly well to the burning of this low-temperature fuel, and would enable us to use economically a number of low-temperature processes in which the maximum oil yield is obtained, but where the residual fuel is already semi-pulverized and not suitable for household purposes without briquetting.

It is significant that the Ford Company are now actively investigating the Caracristi and Piron low-temperature process, which consists in carbonizing roughly-pulverized coal on a travelling iron-plate conveyer swimming on a huge bath of molten lead at 1200° F. The object is to recover the valuable low-temperature products, particularly motor fuel, in which of course the Ford Company are particularly interested, and then to burn the residual low-temperature fuel, containing 10–12 per cent of volatile matter in the pulverized condition, under the boilers at River Rouge now using pulverized raw coal.

Finally, also, the principle of pulverized fuel is being actively investigated for the burning of lignites and Esthonian shales; for the carbonization of coal, in which the process is almost instantaneous, even for low-temperature methods; for the total gasification of coal in conjunction with steam (producer gas); and in the manufacture of briquettes without the use of pitch or other binder.

Discussion before The Institution, 13 December, 1923.

Sir James Kemnal: The firm with which I am associated has followed the development of this method of firing with great attention, and, while the use of pulverized coal fills a want in many cases, we do not recognize it as of universal advantage or capable of being used in every instance, as the author appears to think is the case. The Lopulco system, in the main, differs only from other systems of conglomerating various mechanical appliances in that it embodies the water screen, which is, from the boiler constructor's point of view, a somewhat crude arrangement. I do not know from practice what advantage the water screen possesses. We are told that it prevents the ash from forming the glass-like substance which was common when pulverized coal was first used; but, using the unit system, we have found that if we make the furnace 20 to 30 ft. high the ashes are quite innocuous and can readily be removed, so that it does not seem to be an advantage confined entirely to the Lopulco system. The fact that the nature of the ash varies with the nature of the coal is not mentioned. American coals, as a rule, are much more friable than any coals with which we have to deal in Europe, and that has been shown by the fact that whereas in England we cannot use a mechanical stoker more than about 9 ft. wide, in America mechanical stokers to a width of 24 ft. are used. The idea of pulverized fuel is based upon an imitation of the advantages obtained from burning liquid fuel, and the theoretical amount of air required can be ascertained very closely. The disadvantage of pulverized fuel lies, however, in the amount of apparatus required. The author contends that a greater variety of fuel can be utilized than is the case with mechanical stokers. That is not my experience. The quality of fuel that can be utilized in the powdered form is much more limited than in the case of mechanical firing. In fact, it has been found that there is practically no kind of fuel that cannot be burnt in the latest design of Babcock and Wilcox stoker. In Russia both peat and Russian anthracite have been burnt on it, and in England we burnt any small coal, even coal and coke dust. The author makes a great point of the higher efficiency obtained, but a central-station engineer does not care very much whether he is getting 80 per cent efficiency or 85 per cent, so long as his total costs per unit generated are less. The cost of the installation, of which no mention is made in the paper, is a very vital matter. I take it that the cost is very high, probably five or six times as much as that of mechanical stokers of the best kind. I agree with the author that the cast-iron economizer has been an excellent servant, but the pressures that are common nowadays render it less suitable. Although the author may not be aware of it, there are too many cases of cast-iron economizers being replaced by steel economizers for his assertion to be taken as representing altogether the facts of the present day. With regard to the increase in boiler capacity achieved by the use of pulverized fuel, I can affirm that there are many instances in which the same results are obtained with mechanical firing. The amount of evaporation per unit of heating surface is not necessarily a criterion. A heating surface can be so worked as to evaporate 24 lb. per sq. ft. We have done it experimentally, and no doubt it can be done for a peak load, but that is not the point that the designer or engineer of a central station has to consider. On page 386 the author says: "In very few power stations—at any rate in Great Britain—is there any real idea of the efficiency of the steam generation from week to week." The statistics published by the Electricity Commissioners show, however, quite a different result and make it clear that, so far as the generation of electricity is concerned, accurate records are kept which will act as a valuable guide. In addition, of course, there are a great many private installations in which the cost of power is carefully established. The author states also that British power station practice is far behind that in America, but this is by no means my experience. Pulverized fuel is no doubt very good, but it is not everybody's good luck to make it successful, nor everybody's business to use it.

Mr. G. W. Partridge: Pulverized fuel has certainly come to stay. At the same time, when the author refers to the high efficiencies he gets, I do not think that he has taken into consideration all the improvements now being made in the present mechanical stokers. I agree with Sir James Kemnal that one of the chief concerns of the power station engineer is not so much the efficiency of his boiler house as the final and total cost of evaporation, which should include cost of labour, repairs and maintenance, and interest on capital. With regard to the capital cost, the author simply states in the summary of the paper that capital costs were difficult to obtain. It would be instructive to learn what these costs are in the case of pulverized-fuel installations compared with the present mechanical-stoker plant. I am not altogether certain that a comparison between the American tests and those made in this country is very convincing. The fuel used in America is not by any means similar to that at the disposal of the average power station engineer in this country. I notice that the average calorific value of the American coal mentioned in the tests was over 12 000 B.Th.U.'s. The engineers in the London area have hundreds of different classes of fuel at their disposal of various calorific values, etc., and at various prices. It is of great importance to have a stoker that will burn at a reasonable efficiency any class of fuel without any preparation such as drying and grinding beforehand, and I can quite conceive a power station burning a low-class fuel at a moderate efficiency with a lower cost of evaporation than that of a station as described by the author with the high efficiency which he claims, but with a very much higher initial capital cost. Some years ago we were thinking of installing a powdered-fuel plant in London, but every engineer whom we consulted told us that one of the main disadvantages was that dust was ejected from the stack. The author, however, says that the ash thrown out is not seen again. The particular power station of which he speaks is situated at the side of a lake, so the ash probably falls into the lake when the wind is in the prevailing direction. The London area is a very different proposition, particularly when one has to consider the stringent rules and regulations of the County Council and district surveyors. At the same time I think that there is a great deal to be said for the use of powdered fuel in the future, more particularly as regards Kent coal, which is mined only a short distance from London and has a high volatile and calorific value.

Mr. B. Pochobradsky: Boiler-firing is a difficult subject, and in endeavouring to compare systems we must examine very carefully the results already obtained. The paper compares the pulverized-fuel firing at the Lakeside power station with the mechanical stoker at Dalmarnock station. It is stated that the boiler efficiency over an extended period at Lakeside is 85 to 86 per cent and at Dalmarnock 76 to 77 per cent, and it is claimed that this difference in the efficiencies is due to the methods of firing. This claim appears to be erroneous, as can be seen from the figures in the paper. Let us compare the test taken on the 21st March, 1923, at Dalmarnock (Table 6) with Lakeside test No. 3 (Table 8). These two tests show practically the same CO_2 content and therefore one difficulty of comparison is removed. That is my reason for choosing these two tests. It should be noted that the coal used for the Dalmarnock test contained 14·8 per cent of moisture as against 3·59 per cent at Lakeside. The difference in moisture has nothing to do with the system of firing, but incidentally it influences the boiler efficiency. The loss in efficiency due to moisture at Dalmarnock is 1·5 per cent and at Lakeside 0·4 per cent. Had the same coal been used at Dalmarnock as at Lakeside, the boiler efficiency at the former station would have been 1·1 per cent higher, solely on account of the smaller moisture content. A further and more important factor is the temperature of the flue gases at the economizer outlet. At Dalmarnock this is 414° F. as against 205° F. at Lakeside. I propose again to use the author's figures to translate these temperature figures into efficiency figures. Table 7 contains under No. 3 the same test as Table 8. In Table 7 we find that the efficiency of the boiler with superheater is 82·5 per cent, which corresponds to a flue-gas temperature of 482° F. (leaving boiler), and the efficiency of the boiler, superheater and economizer is 87 per cent, which corresponds to a flue-gas temperature leaving the economizer of 205° F. In other words, to a difference in flue-gas temperature of 277 degrees F. corresponds a difference of 4·5 per cent in efficiency. Applying that to the two tests we are comparing, we find that the difference in leaving temperature between Dalmarnock and Lakeside is 210 degrees F., which means a difference in efficiency of about 3·4 per cent. Taking the steam duties of the two tests into account, we find that the Lakeside boiler has 66 per cent larger heat-transmitting surface in the boiler and 29 per cent larger heat-transmitting surface in the economizer for each pound of steam generated. It is beyond doubt that this enormous difference in the heat-transmitting surfaces of the two boilers is the principal cause of the leaving temperature at Lakeside being so much lower (naturally the boiler cost is increased) than at Dalmarnock, and, what amounts to the same, the principal cause of the efficiency of the boiler at Lakeside being higher. It is obvious that the extraction of heat from the flue gases, particularly near the exit, has nothing to do with the system of firing, and therefore the increase in efficiency experienced at Lakeside cannot be credited to the central pulverizing plant. The efficiency at Lakeside in the test under discussion was found to be 87 per cent and at Dalmarnock 83·56 per cent. If we correct the Dalmarnock test so as to bring it to the same basis of moisture in coal and the same ratio of heat-transmitting surfaces (or what amounts really to the same thing, the same leaving temperature, both of which factors are independent of the system of firing), we find the efficiency at Dalmarnock to be $83 \cdot 56 + 1 \cdot 1 + 3 \cdot 4 = 88 \cdot 06$ per cent, as compared with the Lakeside efficiency of 87 per cent. It is these two efficiency figures which are directly comparable if we desire to compare the performance of mechanical-stoker firing and pulverized-fuel firing, as we have eliminated factors which have nothing to do with the system of firing itself. These figures are test figures. We should consider as being more important, not the

test performance but a performance over an extended period. The boiler efficiency at Lakeside over an extended period is stated to be 85 to 86 per cent (or an average of 85·5 per cent with 60 per cent load factor) and 76 to 78 per cent (or an average of 77 per cent at Dalmarnock with 34 per cent load factor), or, on the author's assumption, 78 per cent if Dalmarnock had the same load factor (60 per cent) as obtained at Lakeside. These Dalmarnock figures for an extended period, compared with the test figure of 83·56 per cent (with the actual heat-transmitting surfaces and coal used at Dalmarnock and uncorrected), show that the boiler efficiency at Dalmarnock for an extended period is 5·56 per cent lower than the efficiency obtained on test. It is obvious that had the same wetness of coal and same ratio of heat-transmitting surfaces been available at Dalmarnock as at Lakeside, this loss of 5·56 per cent would still have taken place, as compared with 1 per cent at Lakeside. The difference, viz. 4·56 per cent, is due to firing systems, and it is here that pulverized fuel has a decided advantage. Having found that the test efficiency, reduced to the same coal moisture and leaving temperature as obtain at Lakeside, is 88·06 per cent at Dalmarnock and 87 per cent at Lakeside, we come to the conclusion that for identical boilers, but with mechanical stokers as installed and operated at Dalmarnock on the one hand and pulverized-fuel firing as at Lakeside on the other hand, the efficiencies over an extended period are: With mechanical stokers $88 \cdot 06 - 5 \cdot 56 = 82 \cdot 5$ per cent, and with pulverized-fuel firing 85·5 per cent. These figures, however, do not give us the final comparison. It is not merely a question of heat efficiency that determines the respective advantages or disadvantages, but the final criterion is the overall economy. It is necessary to take into account the consumption of auxiliary power, labour, first cost of plant and buildings, maintenance and repairs. It is highly probable that the first cost of plant and buildings for the central pulverizing plant at Lakeside is substantially higher than that of mechanical stokers at Dalmarnock, but as no figures are given in the paper I do not feel justified in making a comparison. I shall also disregard the cost of maintenance and repairs for the same reason, and compare only the auxiliary power and wages. In Table 12 the power required in the pulverizing building at Lakeside is given as 1·78 per cent of the total power generated, and the electrical energy required for boiler-house auxiliaries is given as 0·34 per cent (this latter figure obviously not including feed pumps and fans, which are steam-driven). It includes the power necessary in connection with pulverized-fuel firing and probably for handling ash. The total of this auxiliary power represents 2·12 per cent. The corresponding power at Dalmarnock is that required for the mechanical stoker which, according to Table 6, is 25 kWh for 28·7 tons of coal, or 0·88 kWh per ton of coal. This means, assuming with the author that 19½ kWh is equivalent to 1 per cent of the total steam production or of total power production, less than 0·05 per cent of total steam or total power production. To this figure we ought to add a fraction of 1 per cent on account of ash-handling, which seems to have been included in the figures for Lakeside. We will assume, in the absence of correct comparable figures in the paper, that to the figure of 2·12 per cent as the consumption of auxiliary power at Lakeside, corresponds 0·25 per cent of power consumption at Dalmarnock. Further, from the paper it appears that the wages, by using a central pulverizing plant, are increased by about 5d. per ton of coal, which means, assuming coal at 20s. per ton, 2·08 per cent of the total steam or power production. The coal-handling in both stations, assuming equivalent circumstances, will show no appreciable difference, as in one case the coal has to be transported to the pulverizing station and in the other case to the boiler house. The boiler-house wages appear in both cases to be very similar, so that the overall economic efficiency, considering the difference in auxiliary power and wages, becomes for the mechanical-stoker plant $82 \cdot 5 - 0 \cdot 25 = 82 \cdot 25$ per cent, and for the central pulverizing plant $85 \cdot 5 - 2 \cdot 12 - 2 \cdot 08 = 81 \cdot 3$ per cent. The author mentions that certain improvements are obtainable with the central pulverizing plant, which, if they are realized, would make the overall economic efficiency equal to that obtainable with the mechanical stoker, disregarding the higher cost of plant and buildings at Lakeside. These figures indicate no superiority of the central pulverized-fuel plant over the mechanical stoker. The author's claim that it is very much better and that the difference in boiler efficiency indicates the degree of that superiority, is a fallacy. I agree that pulverized fuel is better as regards flexibility and that it reduces the stand-by and banking losses, but when we compare systems of firing and means used to effect such firing, we must strive to eliminate from our comparison factors which have nothing to do with the firing. On the other hand, we must include all factors which have any influence on the overall economy or on the total cost of the generated power. The main reason for the central pulverizing plant at Lakeside showing no advantage over the mechanical stoker at Dalmarnock is in the large amount of auxiliary power and in the excessive wages. Had the paper given also the first cost, I believe that the central pulverizing plant would have been shown at a disadvantage. In comparing the systems of firing, and particularly in speaking about pulverized fuel, we must remember that there are two systems of pulverized-fuel firing, the central pulverizing plant and the unit system. The unit system will, on an average plant, show a first cost about equal to that of mechanical stokers and naturally substantially smaller than that of central pulverizing plant. On large plants the unit system will be cheaper than the mechanical stoker and cheaper also than central pulverizing plant. The power consumption on the unit system will be lower than for the central pulverizing plant, viz. about 25 kWh per ton of coal, including pulverizing and delivery of coal and all air required for combustion into the furnace. This represents about 1·3 per cent of steam generated, as compared with 2·12 per cent required for the central pulverizing plant. The wages in the case of the unit pulverizing system will be substantially equal to those necessary in the case of

the mechanical stoker, so that the unit system is likely to prove superior to the central pulverizing plant and the mechanical stoker by about 3 per cent in the overall economy. To illustrate the difference in cost of pulverizing plants, I would take the figure given in the paper, viz. £11 562, as the cost of pulverizing plant to deal with 50 tons a day. A unit pulverizer for the same duty would cost about £800. The efficiency of firing, whether unit pulverizer or central pulverizing plant is used, will be exactly the same, as the performance of a unit pulverizer is in every respect equal to that of a central pulverizing plant. While even the unit pulverizer will not in every instance be found superior to the mechanical stoker in overall economy, undoubtedly it will prove to be so in a great many cases. One special case requires prompt attention, and that is the utilization of waste coal which can be burned very efficiently in pulverized form. Here the unit pulverizer will render particularly valuable service. It goes without saying that if the so-called waste coal is utilized its price will rise. On the other hand, the production of coal generally will be cheapened because the collieries will have in the waste coal a new source of revenue. In the end the average price of coal will undoubtedly be reduced, and thus the pulverizer will contribute towards the cheapening of power production generally.

Mr. D. Wilson: The statistics given in connection with pulverized fuel are very clearly set out, but I feel that it is a pity that the author has rather obscured the issue by admitting irrelevant matter. He states that he has carried out 400 boiler tests, but those of us who have studied these tests will ask what possible bearing they can have on the issue raised. The results of these tests, if accepted, only go to prove that the operations were poor, and not necessarily that the design was bad. There is an underlying suggestion in the paper that we are lagging far behind America in this question of powdered fuel. The American lead is the Milwaukee lead, and, considering the size of the two countries, the rest of America seems more slow than England to follow this lead. We are told that up to the middle of 1923 only 9 Lopulco systems were installed, but it would have been instructive if the author had extended his inquiries and given some comparative figures. He would then have found that the total heating surface of stoker-fired boilers would have greatly exceeded his figures for powdered coal. What is his case? Briefly, it is that at Lakeside the average day-to-day efficiency is 85 per cent, and that the comparable figure for stoker firing is 81·5 per cent. The author is well aware that a difference in degree of supervision in a power station may mean a great difference in the percentage of efficiency. In fact, he himself confirms this when he says that the attention at Lakeside is far above the ordinary. He goes on to say that with extremely good attention pulverized fuel would probably give 82·5 per cent efficiency, whereas the mechanical-stoker plant figure would be 75 per cent. This latter figure must, I think, be a misprint. I can give the author instances of day-to-day efficiencies of 80 per cent with the mechanical stoker, and this on an ordinary plant, and not a modern one at that. The author admits that there has been a great advance in mechanical-stoker firing during the past few years, and I believe it is admitted in America that on test there is not much advantage, if any, in powdered-fuel firing. Thus we come to the last claim made for powdered fuel, namely, flexibility. Here, however, I am not so sure that station engineers would be in agreement. Modern stokers will give a high degree of flexibility. The Birmingham Corporation alone burn about 1 000 tons of coal per day, using coal of about 8 000 to 9 000 B.Th.U.'s, and obtain full load with this fuel. On the same plant they can obtain full overload duty when burning coke fuel with only 5 per cent volatile. We have yet to learn that powdered fuel will cover such a range as this. The author refers to Milwaukee fuel, giving a figure of 11 500 to 12 000 B.Th.U.'s as a low-grade fuel, but it would not be called low-grade in this country. A figure of 9 000 or even 7 000 B.Th.U.'s would come within that description, and we burn such coal on stokers. The author's figures, therefore, are unlikely to be accepted as representing boiler practice in this country. The author states that the efficiency with pulverized fuel is 85 or 86 per cent, but the Lopulco guarantee is confined to 84 per cent on test. If they are so certain that they can obtain 85 per cent day-to-day efficiency, why do they not guarantee something higher for test efficiency? A guarantee given in this country under penalty for the test efficiency of a stoker plant is 86 per cent. I think that the author's quotation with regard to carbon ash is inaccurate and liable to mislead. In a well-operated station the carbon in ash does not exceed 10 per cent, which, in the case of such coal as is used in America, would mean a loss of under 1 per cent, and indeed there should be no difficulty in keeping the loss down to 0·5 per cent. I agree that powdered-fuel firing must receive very serious consideration, but there are many doubtful factors to be eliminated before the suggestions made in the paper can be accepted. We know that Americans are much more ready to accept a new invention than we are in this country, but British station engineers are as capable of progressive endeavour as are Americans.

Dr. R. Lessing: I should like, as a chemist, to address myself to one particular point, namely, the question of the amount of ash in coal. It seems to me that this factor is very important in considering this problem. The disposal of ash from pulverized-fuel plants is a very serious problem. Even if only 12 per cent of the ash escaped through the chimney, it would mean that our vanishing smoke-problem was being replaced by a dust problem. I feel that the question of ash in coal—that is to say, the inorganic constituents of coal which we find in combustion in the form of ash—has not received the amount of attention from power engineers that it deserves. From the work which I and others have been doing during the past six years, we know to-day that in average coal about 60 to 70 per cent of the fuel contains not more than 1½ to 2 per cent of ash. The remainder of the coal would be rather higher in ash content, i.e. from 6 to 7 per cent. All the ash received in excess of these figures does not belong truly to the coal at all. It is extraneous ash which could easily

be eliminated from the coal at the colliery. In this country we are carrying from 25 million to 40 million tons of ash an average distance of 50 miles, and this engages 10 per cent of our entire mineral traffic. If only a portion of this ash were eliminated, either at the colliery or at some subsequent stage, an enormous saving would be effected which would allow us to pay more for the refined coal without adding to the ultimate cost. I should like to refer in particular to the difficulty of grinding the mineral portion of the coal. I have figures which show that a clean coal would give in the grinders a considerably higher "through-put" than would dirty coal at the corresponding rate. A further advantage would be that the erosion of the burners and also of the firebrick walls of the combustion chamber would be stopped or reduced. From all these points of view I think that it is one of the essentials for a successful solution of the powdered-fuel problem that ash should be eliminated. It is, I feel, rather futile for those who wish to promote the introduction of powdered-fuel installations to endeavour to persuade engineers that they can burn coals with a high percentage of ash. They are doing themselves a great injustice. It would be more advantageous to insist on a high grade of fuel being supplied to them. I believe that if such a reduction in ash could be effected the pulverized fuel would be on a par, or nearly so, with liquid-fuel firing and even with gas firing, and no doubt very great advantages would be realized.

Mr. F. F. Evans: I know from experience that there are very grave disadvantages in dealing with the large number of coals of varying qualities which are continually met with even in any one station. I know also that, even with the most highly organized system and the best type of mechanical stoker, where 19 or 20 classes of coal have to be dealt with it is extremely difficult to obtain highly efficient results. The reason is, to some extent, the want of training of the operators. What has not as yet been mentioned in the discussion is the reason why pulverized fuel is bound, sooner or later, in this country to come to the front as a means of solving a great many important problems. Turbines having capacities anywhere between 15 000 and 25 000 kW are now being made and operated. Taking an ordinary station such as Glasgow, this means that five 60 000-lb. boilers are required, with a sixth possibly as a stand-by. If one lays out a station of, say, 75 000 kW, or even 40 000 kW, it is obvious that the housing of these boilers, together with all their accessories, must involve a considerable capital cost. If, on the other hand, large boilers are installed, it is found at once that the difficulties in connection with mechanical stoking are very great. At Manchester, boilers evaporating from 115 000 to 130 000 lb. of water are at present installed. In connection with each of these boilers there are four mechanical stokers. If the necessity for larger boilers arises, as I foresee it will do in time, about eight large mechanical stokers will have to be installed for each boiler. In other words, the possibilities of a breakdown will be increased eight times. On the other hand, if powdered fuel is used, a system will be obtained by which, even in the event of one of the burners going out of action, the load on the boiler can at once be taken up without the slightest difficulty. It is not likely that the whole of the burners will fail simultaneously. The case for the large boiler will in the future be very definitely established, and from a mechanical-stoker point of view I think that it will provide a very serious problem. At the present time large quantities of grit are being emitted in these mechanically-stoked systems. It is true that the emission of waste matter from a powdered-fuel installation may be greater or less than that in the case of mechanically-stoked systems, but it is not grit; it is a fine flocculent dust. The Medical Officer of Health in Milwaukee has his offices immediately opposite the Lakeside plant, and in the course of four or five years' observation has never had to complain in any way of the emission of either grit or smoke. It will be said at once that the ash must settle somewhere. No doubt it does, but it settles in such a form that it is not objectionable, and its own light flocculent nature and the varied conditions of the wind cause it to be distributed over long distances. I should like to say, with regard to some remarks made earlier in the discussion, that my company are at present manufacturing mechanical stokers 16 ft. in width, and we see no reason why that size should not be increased. No mention has been made of the fact that in a great many stokers the question of riddlings is a very serious matter. My company have been considering the installation of an ash-conveying plant at a London station, and we found that we should have to install in addition a separate system for conveying the riddlings which, we were informed, would amount to 20 per cent of the total amount of coal used in the stoker. This difficulty does not arise in the case of powdered fuel, and the added expense of a separate conveying system for the riddlings is unnecessary.

Mr. W. M. Mordey: In the early part of the paper the author refers to the work of Thomas Russell Crampton. It is very interesting to know that the distinguished engineer who perhaps did more than anybody else in an early stage to recognize the possibilities of powdered fuel, who actually went so far as to put it into practice and conceived many of the important elements necessary to success in practical work, was a member of the Council of this Institution. Although primarily a railway engineer, he was one of the leaders in submarine telegraphs. When the first cable to France failed he designed a new and successful cable and raised the money for it. When he died in 1888, Edward Graves, then our President, described him as the author of the type of submarine cable that had come into use throughout the world.* That was a great achievement. As one of the few here who remember him, it is perhaps fitting that I should remind members of the debt that electrical engineers owe to his memory.

Mr. J. S. Atkinson: It is a matter of regret that the author should have disposed of unit pulverizers in such a few words. I think that as British engineers we are more interested in the European than in the American standpoint, and the unit system has made far greater progress on this side of the Atlantic than has the central system. The author may be surprised to learn that there are over 400 turbo-pulverizers installed and working

* See *Journal I.E.E.*, 1888, vol. 17, p. 421.

in this country and upon the Continent. In addition, there are a number of other types of unit pulverizers now on the market which are giving good results in practice. After Bettington's activities in this country I think that the firm with which I am associated was the first to take up powdered fuel seriously. In the early part of 1918 I paid an extended visit to America to examine the various systems used there, and I came to the conclusion that the central system was better than the unit system. For two years we concentrated on the central system and lost much money and time. We then turned our attention to the unit system and, although we had to face many problems and made many mistakes, I think that we can now say that we have been able to produce a really satisfactory and practical machine. The statement has been made that by reason of the fact that there are no magnetic separators fitted to unit machines, there is a danger of the machine breaking down. Our experience shows, however, that magnetic separators are quite unnecessary; it must be obvious that if an electric separator were a necessary item it could easily be added. The author lays emphasis on the necessity for getting the proper mixture of coal and air; with this I quite agree, but he also makes statements which would imply that it is not possible to get this mixture with the unit system. Practical results have proved that this is not the case. We have had a large number of boiler tests made, many of which show a total efficiency of 85 per cent and higher. The analysis of the waste gases shows that the fuel is burned with not more than 20 per cent excess air, and the unburnt carbon in the ash is well under 1 per cent. I do not think that anyone can expect to get much better results than these. We have never claimed that we can get much higher efficiences with powdered-coal firing under test than can be obtained with good practice in mechanical stokers, but we do claim that we can maintain higher efficiencies under everyday working conditions, and use cheaper grades of fuel than can be efficiently burned with mechanical stokers. It is rather difficult to reconcile the author's present attitude with regard to the unit system with his attitude as expressed in an article which he wrote in the *Iron and Coal Trades' Review* of February 1922.

Mr. P. M. Baker (*communicated*): The author has brought up the subject of boiler-house efficiency, with its corollary of boiler testing, in a new form. Its importance will be obvious to anyone who has read the Electricity Commissioners' annual returns, in which some of the figures are astounding. My first impression was that the author would have done better to have taken the broad view and dealt with all types of pulverized-fuel plant, but further reading convinced me that the course which he adopted, viz. to deal with a particular system and one or two examples thereof, makes a stronger case for pulverized fuel than would otherwise have been possible. The treatment of this particular case is very comprehensive, and the amazingly good results shown in the test tables can only be answered by corresponding figures for mechanical stokers. Unfortunately it is only very large installations that can yield results comparable with those given in the paper, so that very few engineers are in a position to put up a case for the mechanical stoker. I desire strongly to support the author's opinion in regard to boiler tests. An acceptance test should be run under the conditions specified in the contract; the plant should be in the best condition possible, and the test figure should be an optimum. This is not sufficient, however; tests and records should be practically continuous. If we except some of the good and new stations it seems fair to state that the boiler house is still the neglected end of the generating station, and that the instruments installed in it are often covered with dust and cobwebs between tests, which take place at infrequent intervals, when a little careful organization and systematic work would enable a fairly continuous record of the behaviour of the steam-generating plant to be kept, however large or small it might be. The idea that there is no need for the central station engineer to be very strongly interested in the thermal efficiency of his boiler plant may perhaps be responsible for the small attention it receives in some stations, but it cannot be too strongly impressed on all fuel users, of whom the central station engineer is one of the largest, that it is of the utmost national importance that every possible heat unit should be utilized, although it is, of course, realized that a system of stoking which would enable the low-grade fuel hitherto regarded as waste and unusable to be burnt, would justify some loss of thermal efficiency. The author claims that such fuel can be burnt efficiently in a pulverized form. The reply of the users of mechanical stokers as to what their plant can accomplish, particularly in districts in which cheap, low-grade slack is abundant, would go far towards deciding whether we ought to adopt pulverized-fuel firing in this country, for the available coal is likely to deteriorate as time goes on and labour difficulties increase. My own experience, with a very small plant, of dirty and low-grade Indian coal burnt on a chain-grate stoker was not very encouraging. Possibly some station, such as Birmingham (Nechells), would afford very instructive figures, as I understand that much good work is being done there with low-grade slack. The vexed question of the standardization of boiler tests and the Institution of Civil Engineers' Code is again raised in the paper, and in that connection I submit that our Institution is probably much more truly representative of those coal users most concerned with the economical consumption of coal in large quantities than any other, and that we ought to take energetic measures, either in conjunction with the Institution of Civil Engineers or independently, to lay down a satisfactory standard scheme for (*a*) acceptance, and (*b*) running tests, in order to enable fair comparisons to be made.

Mr. J. R. Blaikie (*communicated*): It is interesting to note that the author thoroughly approves of the methods of testing, etc., at the Dalmarnock station, and also that in his opinion the results might be improved by larger combustion chambers and stokers of the "compartmenting" type, and that air-heating alone might raise the efficiency to 80 per cent with a 60 per cent load factor. On the question of combustion chambers the author says on page 400: "One of the chief causes of inefficiency of the mechanically-fired boiler plants in Great Britain is that the tubes of the

boiler are far too near the furnace, so that the flames touch the boiler long before combustion is completed, and the reactions are at once damped down with the escape of unburnt fuel." On page 402 the author quotes from his own personal experience of 400 tests, mostly on boilers of the Lancashire type, individual figures varying from 32½ to 82½ per cent. Is it correct to say that efficiencies of 82½ per cent can be obtained from a Lancashire boiler plant when the furnace is within a few inches of the boiler surface, and, if so, what is the explanation? An interesting point about Dalmarnock is the use of two kinds of mechanical stokers. I should like to know whether one type is intended for a particular class of fuel and the other for another; whether they are in competition on similar fuel; whether it is a case of balancing higher efficiency against extra capital cost; or whether it was simply the result of the lowest tender. The "compartmented" type of stoker, with a positive means of controlling air pressure in different sections to cope with the varying resistance of the fuel bed as combustion progresses, should certainly make an appeal in well-organized boiler houses. Probably the reason that this type is not more extensively used is its high capital cost. Now that this type can be obtained at rates no higher than those in the case of an ordinary chain grate, considerable improvements may be expected in mechanical stoking. I should be glad if the author would give a few test figures of this type to set against the individual boiler tests with pulverized fuel on No. 8 boiler at Lakeside. The author has chosen Dalmarnock as being representative of mechanical stoking chiefly on account of the overall size, which compares with that of Lakeside, but I suggest that the choice might have been better justified for the reasons that the testing department is so highly organized, and that the willingness of this undertaking to supply and make public its records is on a scale which compares with the large-mindedness of American organizations in this respect. The paper is mainly concerned with the thermal efficiency of steam generation. It is true that laudable efforts have been made to obtain the capital costs of pulverized-fuel plants, but the corresponding capital outlay on large-scale mechanical-stoker plant is lacking. On page 416 a comparison of operating costs is submitted in a highly complex form. We are given the net cost, expressed in dollars, per 1 000 lb. of steam at unknown pressure and superheat, to compare with American stoker plant also at unknown pressure and superheat, price per ton, etc., expressed in dollars per ton (American) of fuel. The Dalmarnock figures are expressed in pence per kWh delivered, and the item "Shift Wages and Salaries" seems to cover both engine room and boiler house. Can the author arrive at the cost of, say, 100 000 B.Th.U.'s above the temperature of the raw materials delivered from the boiler house in pence or dollars from this data, or otherwise demonstrate his conclusion No. 8, viz. "The labour costs with pulverized coal are approximately 20 per cent less than with mechanical stoking, but much depends on individual conditions"? Assuming that the difficulties of obtaining information as to capital costs and operating costs are too great, we fall back on thermal efficiency, strictly confined to boiler-house operation. From this standpoint the choice of Dalmarnock which, according to the author, is open to criticism in the selection of stoker plant, stands in need of justification. There is no need to go beyond the boiler unit in size. In this country we have no boiler to compare in size with American boilers, but there are numerous examples of boilers, similar in size to those at Dalmarnock, which may possibly have attained higher efficiency with mechanical stoking. Turning for a moment to the technical data, it is interesting to note that the range of output of the Lakeside No. 8 boiler, at 88·5 and 85·6 per cent efficiency respectively (see Table 7) is from 4·5 to 8·6 lb. of water per sq. ft. of heating surface. It would have been instructive if the tests had gone further to discover the lowest output at which an efficiency of, say, 85·5 per cent can be obtained. This has an important bearing in the matter of load factor. Can the author show what can be done in this direction by the best and latest forms of mechanical stokers? In Table 8 the loss by radiation is given as about 1½ per cent. For Dalmarnock (Table 6) it is given as 2·5 per cent. With the enormous combustion chamber heated to a temperature verging on destruction, a very considerable loss by radiation is to be expected, and I should like the author to comment on this point. In conclusion, I should like to point out that several important stations in America—such as Colfax, Hell Gate and Connors Creek—have no economizers, which fact brings home very forcibly the policy of true commercial efficiency as against that of sensational thermal efficiency.

Mr. W. F. Carr-Hill (*communicated*): The following remarks summarize some of the leading considerations as to the best system of coal pulverizer to adopt for any given requirement. Pulverized coal as a fuel came into serious use in Great Britain about 23 years ago, from which date its use extended rapidly in Portland cement manufacture. In recent years it has been applied increasingly to steam-raising boilers, metallurgical furnaces, etc. For any pulverized-coal proposition to be successful it is essential that the pulverized coal shall not only be ground to the necessary fineness, but that it shall be uniform in quality as regards the distribution of the ash and dirt content in the coal as fed to the furnace. Only some of the systems in use to-day secure this very necessary condition. At the present time three leading systems for pulverizing coal are employed, as follows: (A) Pulverizers giving a finished product to the necessary fineness in one operation; (B) pulverizers which only rough-grind the coal, and deliver it to auxiliary separating appliances, the fines being separated and the rejects returned to the pulverizer for re-grinding; (C) pulverizers of the beater or swing-hammer type, usually of very high speed, which deliver the finished product direct to the kiln, furnace or boiler combustion-chamber. This type usually has a fan combined with the mill to effect delivery of the ground product to the furnace. The relative popularity, uses and operating costs of these three systems may be summarized as follows:—

(A) *Pulverizers giving finished product at one operation.*—There are several types under this heading.

Most of them have a screen fitted to the mill itself and an internal fan device which ensures—

(*a*) The ground product leaving the mill immediately it is fine enough, and not before.

(*b*) Uniformity in the ground product as regards ash content, resulting in the maximum steadiness of flame from the burner. It has been found in practice that this system shows a great advantage over other pulverizing systems which depend on auxiliary separating devices to obtain the necessary fineness of product. These auxiliary methods most certainly result in "selective separation" and stratification of ash content in the ground product due to difference of specific gravity between the coal and the dirt and ash which it contains. This causes a "squally" flame and irregular temperatures in the combustion chamber, with the attendant additional wear and tear, cost of upkeep and loss of efficiency.

The power required is one of the most important items in assessing the relative costs of operating different pulverizing systems, and it can be taken that with the most economical and best type of screen mills the power used will amount to 13–14 b.h.p. per ton of coal ground to a fineness of about 75 per cent passing a 200-mesh screen. (This is about 12½ per cent less power than that mentioned in the paper.)

(B) *Pulverizers depending on auxiliary separators.*—Though these have been used in many plants abroad they have not been so popular in England as the "finish in one operation" mills described in (A) above, for the reasons of non-uniformity of ground product and "selective separation" above referred to. Moreover, this type is usually more costly in power and maintenance, and thus the cost per ton of coal pulverized is higher. The power consumption of this type usually amounts, with auxiliary separators, to about 20–22 b.h.p. per ton ground to a fineness of about 75 per cent passing a 200-mesh screen.

(C) *Pulverizers of beater type.*—The general experience with these seems to be that as the beaters wear quickly, as often happens, it is difficult to keep up the necessary fineness; in fact the fineness falls off badly (which is fatal to perfect combustion and steady temperatures) and the power consumption increases. In an average state of repair, general experience shows that the power required to keep this type of pulverizer running is 40–50 b.h.p. per ton ground to an average fineness of 70–75 per cent passing a 200-mesh screen, varying between the limits given according to the class of coal used.

It will thus be seen that the "finish in one operation" mill containing its own screen as described in (A) above is the most practical and economical pulverizing system to adopt for any purpose, as it secures (1) greatest economy in power and maintenance costs; and (2) the best fineness and uniformity of quality in the ground product (a point of the highest importance for efficient combustion and consistent and economical results).

Mr. F. Clements (*communicated*): The remarks of previous speakers show clearly the need for the paper in order to bring before those controlling the use of large quantities of fuel the considerable progress which has been made with this latest method of combustion. The author mentions the use by the Ford Company at their new plant at River Rouge, Detroit, of powdered coal in conjunction with blast-furnace gas as a fuel for steam generating. I visited the River Rouge plant in 1920, but the combination was not then, I think, installed. I mention this because the usefulness of such a combination has been apparent to me for some years and I was responsible for putting in the first two units of a new battery of Babcock boilers at the works of the Park Gate Iron and Steel Co., Rotherham, on this system. In my opinion this plant pre-dated the Ford installation, but in any case they are the first boilers in Europe using this method of firing. Whilst the plant is in no wise comparable with the Ford plant in size and pretentiousness, yet the experience gained with it proves very definitely the value of the combination and also provides a good indication of the value of powdered coal when used alone. The boilers have each an evaporative capacity of 30 000 lb. per hour at 160 lb. per sq. in. and are equipped with gas burners of new design. The powdered coal is provided by one unit-type pulverizer on each boiler. Each machine is capable of dealing with 2 300 lb. of coal per hour. The combustion chambers are of large volume, and when blast-furnace gas alone is used the full capacity of the boiler can be attained. In the event of the demand for steam increasing still further, the pulverizers are put into service and the jet of burning coal so directed that it finally intermingles with the gas, with the result that the mass in combustion burns with a luminous flame. Under these circumstances it is quite easy to maintain for long periods an output from the boiler of 50 000 lb. of steam per hour. Again, when the furnace gas fails for any reason the powdered coal is used and the boiler evaporation maintained. Naturally with an entirely novel installation, designed without the guidance of previous experience, there are points which would be rectified in succeeding units, but the result on the whole has been so satisfactory that a further extension of the system is certain. Reverting now to the general question of the use of powdered coal, I spent some time during my last visit to the United States in investigating the subject and saw several installations where it is successfully at work. What I learned there, coupled with the experience gained in the use of pulverized coal at the Park Gate works, points to the fact that there is no question as to the superiority of this type of boiler firing. The ease of control of the flame and the perfect combustion attainable renders it equal to a plant burning oil as fuel, and indeed the whole of the summarized advantages of the method, as given by the author, are fully supported in practice. The chief difficulty is the one which the system referred to by the author is designed to overcome, viz. that due to slagging of the ash. This difficulty is not present with all coals because those which have ash in which lime predominates give little trouble, but the possibility is always acutely present. Any system installed for burning large quantities of powdered coal must be guaranteed to have overcome this trouble satisfactorily.

Mr. J. M. Duncan (*communicated*): (1) The mechanical-stoker equipment at Dalmarnock appears to be of conservative design in the light of current American practice. Stoker-width limitations which the sprung arch entail have been removed by the perfection of the flat suspended arch, and full use has been made of this in the successful operation of stokers 24 ft. wide by 18 ft. long. In the Calumet station of the Commonwealth Edison Co. of Chicago, the operation of this stoker has been so successful that six more have been ordered, three Babcock and Wilcox and three Coxe. The original stoker was installed under a boiler of 15 500 sq. ft. heating surface. The removal from each furnace at Dalmarnock of two division walls, with their attendant losses due to uncontrolled air, clinker formation, etc., which 20 ft. wide stokers would permit, should result in an increased economy and a reduced maintenance cost which would place the stoker in a somewhat more favourable position when compared with pulverized fuel. (2) Some station operation figures at Calumet are as follows: Operating 16 Coxe stokers 10 ft. 8⅝ in. wide by 17 ft. long at 300 to 350 per cent of American boiler rating (120 000 to 160 000 lb. of steam per hour) during the day with a monthly load factor of 28 per cent, the number of B.Th.U.'s per kWh for November 1923 is stated to be the remarkably good figure of 17 800. It would seem reasonable to expect an improvement on this figure when the new stokers 23½ ft. and 24 ft. wide are installed. (3) The banking losses at Dalmarnock are extraordinarily low. The actual charge against stokers for banking, if I correctly interpret the figures given on page 400, amount to less than ½ per cent per hour of full-load consumption, a figure which would not be regarded as out of the way for boiler-radiation losses alone, and would indicate that the loss chargeable to stokers for banking and stand-by is nil in this case. The above considerations would indicate that the author's estimate of 5½ per cent better performance of pulverized fuel over stoker firing in a given modern station might be a little high, and a comparison of maximum guarantees for each type as quoted in the paper would appear to me to justify a somewhat lower figure. But the immense advantage which pulverized fuel has in the burning of low-grade fuels of all varieties cannot be overrated, and I am also of the opinion that for continuous operation the ease of control with pulverized fuel will give average operating results for average boiler plants considerably in excess of the 5½ per cent difference estimated by the author, in all cases where the boiler capacity is great enough to warrant the installation of pulverized-fuel apparatus. In conclusion, I should like to ask the author exactly what is included in the figure for "oncost charges" in Table 16.

Mr. C. Erith (*communicated*): The author has practically ignored the direct method of firing boilers with pulverized fuel, although this is the only method which is free from fire and explosion risks. I wish to call attention to the latest development in pulverized-coal firing, for which I have secured the provisional patent. Each direct-firing unit is self-contained and driven by a constant-speed motor; it draws in preheated air for drying the coal during the initial stage of pulverization. It is fitted with an air separator, which returns coarse particles, and therefore it delivers coal in uniformly fine condition to the furnace. The secondary air is preheated, as usual, in its travel through the hollow walls of the furnace. A large modern boiler uses a set of three direct-firing units, thereby assuring a complete immunity from stoppages, as two suffice for normal load. Coming now to the storage systems of pulverized-coal firing described in the paper, we learn that the only British installation is at the Hammersmith electricity supply station, which is very similar to the American systems described but has the added refinement of an air preheater. Although this London installation has been 3 years in use, no figures as to its results are furnished. Despite the enormous publicity given to the Lopulco tests of 3 years ago at Lakeside, Milwaukee, the author tells us that there are still only 9 plants, totalling 43 boilers, using the Lopulco system in America. Referring to the Milwaukee tests, we see that the normal rating of 90 000 lb. of steam was reached on only one of the five tests, when the efficiency, including economizer, was 84·6 per cent, though a dried coal, 11 per cent ash and 35 per cent volatile, was being used. This corresponds very closely to the author's definition of an ideal coal for pulverizing. The author also tells us that a further 91 boilers in 29 other plants are adopting this method, under the remarkably high normal load guarantees of 85 per cent without economizer, 88 per cent with economizer, and 89 per cent with air heater. But in the case of the Vitry plant at Paris the guarantee is only 84 per cent, including economizer, although they will use good coal of 12 600 B.Th.U.'s per lb. as fired. Regarding overload capacity, it is suggested that the greatly increased cost for the Lopulco system as compared with stoker equipment can be offset by getting higher overload capacity. Duties up to 400 per cent nominal rating, say 12 lb. actual steam per sq. ft., are guaranteed, but these can easily be equalled with stoker firing. For instance, the Riley stokers at St. Pancras Electricity Works, London, 3 years in use, can easily give 12 lb. steam per sq. ft. of boiler heating-surface, while the huge boilers of the Buffalo General Electric Co., also fitted with Riley stokers, started 7 years ago, are easily capable of 12 lb. steam per sq. ft.; whereas the Lakeside plant, with the Lopulco system, is limited to 7 lb. per sq. ft. As regards the size of boiler units, I would remind the author that he states in his "Manual of Mechanical Stokers" (page 138) that: "A typical large installation of Riley stokers is that of the Compagnie Parisienne Distribution Electrique power station at Paris, which contains 10 very large water-tube boilers, each of 22 600 sq. ft. heating surface, plus superheater and economizer, each boiler unit evaporating up to 176 000 lb. of water per hour." Returning to American practice, there are 64 central stations, totalling 3 000 000 kW capacity, now under construction; all but five of these will be stoker-fired. Among them is the huge new Kearny plant at New Jersey, where 9 Riley stokers are being installed, each capable of burning 15 tons of coal per hour on a single archless furnace.

Mr. L. M. Jockel (*communicated*): It is unfortunate

that the author has been unable to obtain more extensive data with regard to British power station practice with water-tube boilers and mechanical stokers, and consequently it would seem that the comparisons in the paper are hardly fair to present-day practice in this country, where different conditions obtain. Unless one can afford to spend a considerable time in the U.S.A. studying the applications of pulverized fuel, it is necessary to depend upon reports, such as those of Mr. L. C. Harvey and others, for practical information upon the subject, although the author does not refer to the latest report by Mr. Harvey issued by the Fuel Research Board in 1922. On page 393 the steel-tube economizer is condemned because it fails to withstand for long the corrosive action of the flue gases, but surely this is a mistake, as the trouble with this type of plant is internal corrosion, assuming, of course, that attention is paid to the temperature of the feed-water inlet. If the necessary steps are taken to prevent internal corrosion, such as de-aeration of the feed water and, in the case of high-pressure boilers, a closed-feed system and evaporated make-up, then the steel-tube economizer possesses certain advantages in practice over the cast-iron type. It is very difficult to analyse the data put forward in the paper, but the author is distinctly unfair to the majority of generating engineers when he states on page 396 that an efficiency of 80 per cent, as obtained on an abnormal test, is believed by station engineers to apply to their plant all the year round. If extensive data on present British power station practice as applied to large stations had been obtained, the value of the figures put forward would have been considerably enhanced. The data given for American power stations with mechanical stokers only serve to confirm the opinions held in this country, that the art had never reached such a stage of perfection in the United States before it was arrested by the introduction of pulverized fuel on a large scale. The data for the initial installation at Michigan are not given in the present paper, although the efficiency of 80·2 to 82·7 per cent for boiler and superheater only was at that time a fine achievement. On page 400 the author's attempts to make comparisons between Lakeside and Dalmarnock are rather unfortunate and, as the data stand at present, practically valueless to engineers with years of boiler-house experience. The figures have already been discussed in their true light, however, by one or two previous speakers. It would be interesting to learn what the author considers to be the limiting figure for the efficiency of a modern water-tube boiler plant, as various published tests have shown 89 per cent and over on the "gross or higher" calorific value of the fuel. The data put forward in Table 13 for auxiliary power consumption in mechanical-stoker plants may be true for American practice, but they are not typical of present-day practice in this country, where the figure quoted of 4·86 per cent could in very many instances include the whole of the energy used in the power station for all auxiliary purposes. In commenting upon ash troubles on page 415, the figures for the average ash-contents ejected via the chimney top and deposited in the combustion chamber are given, but no mention is made of the deposited percentage on the various heating surfaces, nor of the methods employed to clean these whilst steaming and the energy consumption and cost of such cleaning. The calorific values of fuel for American tests are apparently remarkably accurate, as the figures quoted actually include the last heat unit, indicating, of course, that the art of calorimetry has reached a state of perfection in the United States quite unknown at present in this country.

Mr. J. E. O'Breen (*communicated*): The author is not quite fair in his comparison between powdered fuel and stokers and he therefore comes to a conclusion that gives a wrong impression of the present situation. He states that pulverized fuel gives an efficiency of 86 per cent, while stokers give 81½. In this connection I would draw his attention to the fact that my firm guarantees for these very best conditions for the Pluto stoker an efficiency of 86 to 87 per cent, i.e. slightly higher than that for powdered fuel. Under ordinary conditions the efficiency will perhaps be slightly lower, due to soot on the boiler tubes, etc., but it can be maintained for stokers as well as for powdered fuel. By installing modern regulating devices as, for instance, the Hagan apparatus, it is possible to control the whole boiler house and all the mechanical stokers from one central point, so that powdered fuel has no advantage in this respect. In the case of mechanical stokers, unburnt fuel in the ash depends largely on the contents of ash in the fuel which is used, and on the melting-point of the ash. For this reason it is impossible to guarantee the same high efficiencies for coal with 40 to 50 per cent ash as for coal with 5 to 10 per cent ash. The guaranteed efficiencies for these low-grade coals will therefore be from 76 to 80 per cent. It is, of course, possible that powdered fuel will give results slightly better than this, although I have never seen tests of powdered fuel where the coal contained more than 15 to 20 per cent ash, and I am not convinced that the Lopulco system will be successful in burning these coals. In any case, the powdered-fuel system has still to prove its superiority for these fuels and for the moment I am not sure that it will even be possible to burn them. I should like to draw the author's attention to the fact that it is quite possible to obtain very favourable results when working mechanical stokers with liquid and gaseous fuels. As far back as 1910 we made extensive tests on the Continent with Pluto stokers and blast-furnace gas, the gas being used for overload and peak loads. On peak loads an evaporation of more than 10 lb. of steam per sq. ft. of boiler heating-surface was obtained. I therefore do not see the advantage of pulverized fuel as claimed by the author under Conclusion 4 on page 416.

Mr. N. Swindin (*communicated*): The discussion on the paper has not brought out sufficiently the scientific achievement of the efforts of the staff responsible for the successful application of pulverized fuel to boiler firing. Much has been said concerning the ability to build power stations in this country, compared with that available in America. This few will deny. What scientifically-trained men in this country complain of is the opportunity to carry out research on basic industrial processes on the scale that exists in America. To anyone conversant with large-scale research, it is evident that no less than £1 000 000 was spent before sufficient data could be compiled to enable the Lakeside plant of

the Milwaukee Electric Railway and Light Co. to be erected and put into commission. The success of the installation has demanded the solution of the following first-class problems: (1) The drying and pulverization of coal at an economic price and with reasonably robust plant; (2) the conveyance of powdered coal as a fluid in pipes without risk of explosion; (3) the correct designing of a burner which can be used for powdered fuel, gas and oil; (4) the manufacture of refractories to withstand the high temperature of combustion, and a design of furnace which keeps the temperature of the walls below that of fusion of the material; (5) the removal of the ash in a continuous manner, and all difficulties due to slagging; and (6) the transmission of an enormous quantity of heat at a high rate of transmission without damage to the boiler. The success of the pulverizing plant is due to the application of the best ore-crushing practice at mines, i.e. the continual screening of the product and the return of the "oversize" back to the mill. In the Lopulco system the screening is done by pneumatic means continuously: the air system being a closed circuit prevents all risk of loss and danger due to "dusting." The transference of powdered substances with air as a carrier is now a well-known process. With coal the quantity of air used must be well below that required for ignition. Ten per cent of the air required for combustion is nearly 1 000 times the volume of the actual dust, and of approximately equal weight. Thus we have practically air passing through the pipes and yet it is not sufficient to ignite the coal. As air must be blown into the furnace, the addition of the fuel adds but little extra resistance to the flow. Stanton has shown that the resistance to flow of a fluid is a function of vd/ν, where v is the velocity feet in per second, d the diameter in feet and ν the kinematic viscosity, i.e. the ratio of absolute viscosity to the density η/ρ. The viscosity of air at 20° C. is 0·000184 C.G.S. units and the density at 760 mm pressure of mercury is 0·0012 g per cm³; hence the value of $\nu = 0{\cdot}000184/0{\cdot}0012 = 0{\cdot}1533$ C.G.S. or $0{\cdot}1533/929 = 0{\cdot}000165$ ft.-sec. units. Now the addition of 1/1 000th part by volume of coal dust would not greatly affect the viscosity but it would double the density, so that the value of ν for dust-laden air would be 0·0000825. If the velocity through a 6-in. pipe be, say, 30 ft. per sec., we have for pure air

$$\frac{vd}{\nu} = 30 \times \tfrac{1}{2} \times \frac{1}{0{\cdot}000165} = 90\,900$$

and for dust-laden air

$$\frac{vd}{\nu} = 30 \times \tfrac{1}{2} \times \frac{1}{0{\cdot}0000825} = 181\,800$$

Referring to the Stanton chart* we find, taking the steel pipe line, the following values:

For pure air $mig/v^2 = 0{\cdot}003$

and $i = 0{\cdot}675 = 0{\cdot}08$ ft. of water per 100 ft. run of pipe.

For dust-laden air $mig/v^2 = 0{\cdot}0027$

and $i = 0{\cdot}6075 = 0{\cdot}1458$ ft. of water per 100 ft. run of pipe,

where m = hydraulic mean depth,

and i = hydraulic slope (head/length).

* N. Swindin: "Flow of Liquid Chemicals in Pipes" (Benn Bros., Ltd.).

With coal as a powder and already mixed with 1 000 times its volume of air, when it passes through the nozzles of a burner it is almost like a gas. The burner is therefore quite a simple piece of apparatus, the flattening of the nozzle enabling the surface to be increased for combustion with the secondary air. The design of the combustion furnace embodies points which the practical man would reject at once. In the first place it is large enough to enable combustion to be completed. The preheating of the air performs two functions: it reduces the temperature of the inner surface of the furnace below that of the actual temperature of combustion and below that of fusion of the material, and it diminishes enormously the loss due to radiation from the outside surface of the furnace; in addition, combustion is assisted and is completed in less time. The life of the brickwork shows that greater attention is paid to refractories than is usual in this country. The treatment of the ash is really a trick. The water screen operates by sudden cooling of the ash slag, so that strains are set up in the slag similar to that in the Rupert's drop, causing the stuff to fly off in a granular form. Besides this, these tubes lying at the bottom of a fierce radiant chamber prevent much loss of heat. The amount of heat absorbed by this screen must be considerable. The chief feature of the furnace, however, is the enormous rate of heat transmission to the boiler tubes. It is usual to express this as so much evaporation of water per sq. ft. of heating surface per hour. Taking the author's figure of 14 lb. of water from and at 212° F. per sq. ft. per hour, we get the enormous figure of 155 kilogram-calories per m² per hour per mean temperature difference between the fire temperature and the temperature of the water in the tubes. This figure is calculated as follows:—

The exact furnace temperature obtained with powdered fuel has never, so far as I know, been ascertained, but I should say that it is at the very least 2 500° F. A furnace temperature of 2 100° F. is given in the paper for a mixture of powdered fuel and blast-furnace gas. Taking, therefore, the fire temperature of 2 500° F., the temperature of the gases leaving the boiler at 430° F., and the temperature of the water from the boiler at 417° F., the mean temperature difference θ_m is found by Grashof's formula thus:—

$$\theta_m = \frac{\theta_1 - \theta_2}{\log_e(\theta_1/\theta_2)} \quad \text{(see Fig. A)}$$

$$= \frac{2\,083 - 13}{\log_e 180}$$

$$= \frac{2\,070}{5{\cdot}187} = 400^\circ \text{ F.} = 222^\circ \text{ C.}$$

$$K = \frac{H}{\theta_m}$$

where H = cals. per m² per hour,

and K = coefficient (cals. per m² per hour per deg. C. difference).

Therefore $K = \dfrac{14 \times 10 \times 537}{2{\cdot}2 \times 222} = 155$

In B.Th.U.'s per sq. ft. per hour per deg. F. difference, $K_1 = 155/4{\cdot}5 = 33{\cdot}4$.

The following values of K have been obtained by similar calculations from representative practice of various types of boilers: For the ordinary Lancashire boiler as ordinarily fired, 20; for a Babcock boiler, 40; for a Bonecourt boiler fired by ordinary coal gas, 80; for Nicholson's experimental boiler, 120; and for the powdered-fuel boiler described in the paper, 155. A careful study of the transfer of heat through plates from hot gases to liquid by conduction shows that it is impossible to obtain anything like this figure except at velocities beyond all practical value. Nicholson's experimental boiler which was designed to increase the rate of transmission by increasing the velocity of gases past the heating surface in accordance with Reynold's law, did not accomplish the rate described in the paper. Only by allowing the radiant heat to flow without hindrance to the boiler can such a transmission be obtained. It is noteworthy that Mr. Stromeyer in a recent paper discussing "The Principles of Boiler Design," dealt with the necessity of screening the boiler surfaces from the radiant energy in order to prevent damage. To one who has long been engaged in studying the mechanism of heat transfer in difficult processes of chemical manufacture, it would appear that the Lopulco system of boiler

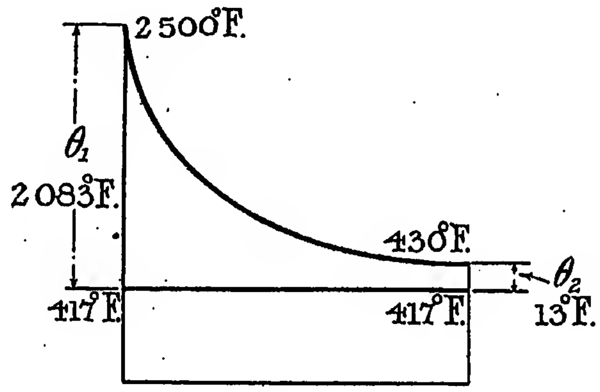

FIG. A.

firing has accomplished most of what modern science has to say on the subject. Improvements may lie in the region of burning the coal mixture under pressure in order to increase the density of the gases in the furnace. In comparing the advantages of the powdered-fuel combustion system with mechanically operated furnaces the size of the modern boiler has put the latter entirely out of court. The Lopulco system marks only a beginning of the real study of the best way to make steam on a large scale.

Mr. E. Kilburn Scott (*communicated*): The most striking piece of evidence of the success which pulverized coal has gained over stoker firing is at the Colfax power station, Pittsburg. This station is situated about a mile from a coal mine owned by the same financial group and it has plant units of 60 000 kW each. When they first started about five years ago, each boiler was fitted with a mechanical stoker and everything was done and every instrument connected up to make the boiler plant as perfect as possible, and it was operated by expert engineers. It is therefore all the more significant that within a few years the consulting engineers and the chief engineer of the power house, and also the financiers who are behind the huge organization that controls Colfax, have been converted to the use of pulverized coal, and the 60 000 kW unit now in hand will be worked on that system. It would have been easier to continue with mechanical stokers, but the decision to change was made after a thorough investigation had been made of what pulverizing had accomplished elsewhere; that is to say, it was not made merely for the sake of change, but from a real conviction. Our boiler-house practice has been in a rut for years and I fear that this is partly due to the habit into which some consultants have got of letting boiler-making firms dictate to too great an extent. Also I am afraid that some of those in charge of power houses know more about electrical apparatus than about boilers and how to burn fuel economically. Yet it is the boiler houses that require the most watching; it is there where supervision is most required and where much of the money goes. Carbon has for years been wasted in riddlings and in clinkers, but the waste has been condoned, or perhaps in some cases not known about, and many who knew have suppressed the fact. The advent of pulverizing will change all that and I believe that the competition will be a good thing for the whole industry of electric power generation. In order to reduce loss of carbon in the ash pit some power station engineers go out of their way to purchase fuel with a highly fusible ash, and select coal in sizes that give low losses by riddlings. Pulverizing does away with all that; station engineers can forget all about low-fusibility ash and sulphur and burning of grate bars, and size of fuel, and need not bother much about volatiles. All fuels are alike when resolved into minute particles, for so long as the particles are given sufficient air in a large enough combustion chamber they will burn satisfactorily. The large combustion chamber has been criticized, but I think that it is well worth the expenditure involved and extra building space, since a greatly increased radiating surface is obtained. Most of the evaporation of a boiler is due to radiant heat waves impinging on the first tubes, and the method of having a screen of tubes at the bottom of the combustion chamber is excellent because it absorbs the radiant heat that goes downwards. Another criticism is that the temperature is so very high, but surely that is all to the good and it is in the right place. By building the combustion chamber of sufficient size and using air flues on the walls and a water-tube screen at the bottom there is no trouble with brickwork. In French practice the composition of the firebricks used is suited to that of the ash of the coal, and in this way slagging of the firebricks is prevented. The much greater size of the combustion chambers of the two new boilers at Hammersmith as compared with the first boiler is very striking. The two burners are 23 ft. from the bottom of the combustion chamber in each of the new boilers, whereas the four water-cooled burners of the first boiler are only 12 ft. from the bottom. Much has been said about the fineness of the ash which results from pulverizing, but a demand is springing up for the very fine ash and I understand that as much as 10s. per ton has been offered for it, and for a good reason. It will be a rather strange position if later on it is found to be a commercial proposition to burn low-grade material partly for the purpose of getting more fine ash to sell.

Mr. J. D. Troup (*communicated*): The author has hardly done justice to himself or to pulverized fuel by emphasizing thermal efficiency to such an extent. In the first place, no comparison between pulverized fuel in America and mechanical stokers in Britain is possible on any common basis, because the fuels are different. In any fair comparison the same fuel should be used in each case. Would the author expect to get Milwaukee results if Dalmarnock coal were used? There is, however, a great deal more to be said for pulverized fuel than merely to claim for it a higher thermal efficiency. We should expect a higher thermal efficiency when using coal in a powdered form, and there can be little doubt that it is attained in practice. A close inspection of the paper shows, however, that there are other advantages in using pulverized coal, some of which may be even more important than securing a higher thermal efficiency. One of these advantages is simplicity of combustion control, and this point becomes one of greater importance when industrial plants are considered, because the skill of the boiler staff is generally not so high as that customary in large power stations. It is necessary also to look ahead in these matters. The boiler unit is already a huge affair, and mechanical stokers on a large scale become a very cumbersome arrangement in the combustion chamber, when the alternative is simply a series of Bunsen-type burners; and if a larger furnace is required it becomes a simple matter of adding burners. Incidentally, the Ford system of centralized control is a significant sign of the times, following the modern movement of all our industrial and business organizations. It would probably be impossible to operate such control with any fuel except that which could be used in some form of burner. Can the author give any indication of the saving in labour effected by such central control?

Mr. J. A. West (*communicated*): I have read the paper with great interest and I regret that in such a lengthy paper the author has dealt only with the Lopulco system. This, I presume, is owing to the fact that he is only dealing with the comparison of the Lakeside and Dalmarnock installations. In this country we have the Holbeck system, which is installed at the Hammersmith Borough Council electricity works referred to briefly in the paper. The first portion of this plant was put in operation in November 1920, so we can really be proud of the fact that the possibilities of pulverized fuel for steam raising were appreciated in this country almost as soon as in the United States. From personal experience I know that the plant at Hammersmith has more than justified its installation and that the Council has been amply rewarded for its progressive policy. Probably in the near future, figures will be available regarding the performance of this plant which, I venture to state, will be found to equal those obtained at the Lakeside installation. Probably one of the main factors that have delayed the use of pulverized fuel for steam raising in this country has been the nominal low price of coal, and no doubt it has been considered that the cost of preparing the fuel for powdered-fuel firing was not compensated for by the efficiency gained. There are, however, many other factors to be taken into consideration which do not warrant hasty conclusions. The power taken for pulverizing and distributing the fuel to the boilers must be credited by the power taken by mechanical stokers. Coal-handling, operating and maintenance costs, capital expenditure, etc., must all be reviewed. There is also another point worthy of consideration, particularly in generating stations, viz. the fact that the pulverizing could be carried out during off-peak periods, thereby reducing the cost of preparation of the coal, as a very much reduced power rate would be in operation. With regard to the author's remarks on the explosion question, I thought that this bogy had, once and for all, been laid by the heels. My personal experience is that with ordinary care there is no more risk of explosion from a modern powdered-coal plant than that existing in a well-designed fuel-oil system. I should like to ask the author if he can state how long the water screen in the furnace has been in operation, and also if any difficulties have arisen in connection with it. Personally, I have found that by admitting air at the bottom of the furnace a result similar to that claimed for the water screen is achieved. I do not quite agree with the author's statement that with mechanical stokers a coal changing from 12 000 to 9 000 B.Th.U.'s would mean a fall in output of 50 per cent and also a fall in efficiency of 10 per cent. This, in my opinion, would only occur where draught was limited and where badly graded coal of very low volatility was being used. With a good ash-handling plant little trouble would be experienced with the ashes. The author's figure of 5 per cent gain in efficiency with pulverized fuel over the best-equipped mechanical stoker is, in my opinion, a correct one, the gain being obtained with a higher proportion of CO_2 and reduced loss in the ash. It may be possible with a few coals burnt on mechanical stokers to have a very much reduced ash loss, but this is rather the exception than the rule. It is incidentally mentioned in the paper that the successful adoption of pulverized fuel for steam raising has necessitated further improvement in mechanical stokers, as manufacturers are being menaced more and more by pulverized-fuel competition, and I agree with this view. An increase in efficiency of 5 per cent with pulverized-fuel firing would effect a saving of 1s. in the £, from which one would naturally conclude that, with coal costing under £1 per ton, the cost of preparation would not be justified, but, as previously mentioned, there are so many factors entering into the case that deeper investigation is necessary for comparison before deciding what would be the most economical plant to install. From a purely coal-conservation point of view, pulverized fuel is the only system and, in conjunction with low-temperature carbonization plants, we should be taking full advantage of the valuable products that our country offers. Engineers should give very serious consideration to the whole question when installing new plant.

[The author's reply to this discussion will be found on page 460.]

Mersey and North Wales (Liverpool) Centre, at Liverpool, 10 December, 1923.

Mr. J. Hamilton: I should like to ask if the Lopulco system is the only one at present developed which overcomes the slagging difficulty, and if it can be depended upon to do this consistently when dealing with the varying fuels used in this country, which are mostly in the form of slack. I am in agreement with the author's statement on page 400 in regard to the lack of combustion space in our present-day mechanically fired boilers, and I think that it is fairly common practice nowadays to add moisture to the coal as fired to enable combustion to be completed before the fire reaches the ash doors. This is often difficult to ensure while maintaining the output from the boiler, due to variation in the fuel. I assume that feed-water regulators are in use on the boilers in conjunction with automatic control on the feed pumps at the River Rouge plant. Table 9 is interesting but is apt to be misleading. In considering the claims of pulverized fuel, the cost of labour is one of the largest items from the operating point of view, and the number of men required to operate the plant must be taken into consideration. In the table the author gives a total of 86 men for boiler room and pulverizing house, with a total number of hours worked of 11 554, which gives an average of approximately 134½ hours per man per month. I understand that labour is much more "flexible" in the United States than in this country, and it would be interesting to know how this total of 86 men would compare with, say, the number of men necessary for a similar plant in this country, each man working 48 hours a week on his own particular duty in connection with the plant. I assume that the figure includes the men on repairs and maintenance, as otherwise it appears unduly high compared with the total of 84 on operative work at Dalmarnock, where this figure includes turbine-room operation also. With reference to the wear and tear of brickwork mentioned in the paper, I should be glad if the author would say whether carborundum bricks have been tried and, if so, with what results. One would have thought that no soot would be formed by the combustion of pulverized fuel, but I notice that soot blowers were fitted to the boilers shown on the lantern slides and I take it that they are fitted to deal with lodgments of fine ash. Can the author say if any attempt has been made to reduce the ash from the chimney by centrifugal action of the gases at the base of the chimney? It is stated on page 417 that the ideal coal for pulverizing contains from 33 to 40 per cent of volatile matter, and on page 418 that pulverizing lends itself particularly well to low-temperature fuels containing from 8 to 12 per cent of volatile matter, and it would therefore appear that practically any fuel is suitable and may be used in pulverized form. If this is so, and burners are now designed with an adjustment to cover all conditions efficiently, a point has been reached beyond the range of mechanical stokers. One of the chief essentials in maintaining a continuously high boiler efficiency is to keep the plant up to a high standard of overhaul and cleanliness, and difficulty is experienced on old plants where there may be a large number of small units all in service at times of heavy demand. A higher efficiency can be expected from a modern lay-out, especially in its earlier days.

Professor G. E. Scholes: It is evident that furnace design has been given very careful consideration in the paper, and one outstanding feature of the boiler installations mentioned has been the cubical capacity of the furnaces used. Believing that large furnaces tend to increase the boiler efficiency, I calculated the amount of pulverized coal burned per cubic ft. of boiler furnace in 11 plants now being installed in America by the Combustion Engineering Corporation. The boilers are of several different makes and the average furnace volume per boiler horse-power rating is 5·6 cubic ft. At Cahokia the furnace volume per boiler horse-power is 7¼ cubic ft. Assuming that the normal load on the boilers is equal to a 300 per cent rating and that the evaporation from and at 212° F. per lb. of coal is 10 lb., the average coal burned per hour per cubic ft. of furnace volume in these boilers is 1·84 lb. The author's figure of 1 cubic ft. of furnace volume per 3 lb. of coal burned per hour is thus a conservative one, and the tests given on page 404 in connection with the Lakeside station show 1·39 lb. of coal burned per hour per cubic ft. of furnace volume when the boiler is working on a 215 per cent rating. Boiler manufacturers in America using mechanical stokers are increasing the volumes of their furnaces, and three recent installations show that the rate of burning coal is respectively 2·33, 2·0 and 3·37 lb. per hour per cubic ft. of boiler furnace with the boiler working on a 250 per cent rating. Can the author give similar figures for large boiler installations in this country similar to that of the Dalmarnock station? He has pointed out the great importance attached to the provision of a water screen in the base of the furnace, and it is evident that with the high furnace temperatures involved—which are probably of the order of 3 000° F.—the question of refractory material for furnace linings is of great importance. At the Cahokia station at St. Louis, water screens are used in the front and rear of the furnace in addition to the bottom, and Foster radiant superheaters are being fitted to the side walls of the furnaces in two of the boilers. By these means it is hoped to lengthen the life of the furnace linings by reducing the temperature in the locality of the screen and superheater tubes. Can the author say whether the maximum amount of moisture of 2 per cent which is allowable is adherent or inherent? I gather that the coal is crushed to pass through a ¾-inch ring, and is then taken through a vertical drier. It does not seem likely that the inherent moisture would be affected by this process. The author refers to the high efficiency obtained by the Edgemoor 4-pass boiler, and suggests that this efficiency is probably due to the gases passing the tubes four times. It is interesting to note that the latest Edgemoor boiler is a baffleless single-pass boiler, and that very high efficiencies are anticipated. Pressures in steam boilers

are increasing rapidly; some American boiler manufacturers market boilers for working pressures of 600 lb. per sq. in., and designs are in hand for pressures of 1 200 lb. per sq. in.

Mr. F. R. Maxted: In considering the case of pulverized fuel, I have chiefly concerned myself with the question for and against adopting the system in this country on plants now working with mechanical stokers. It seems to me that the first point of importance lies in the price at which a suitable fuel can be purchased. A recent quotation which came to my notice for coal, suitable in every way for powdered fuel, was 9s. 3d. per ton. What will be the price of this fuel in a year or so's time when a demand has been created for it? A particular boiler plant in which I am interested is to consist of six Babcock boilers, four of which are now installed, and these will presently consume 100 tons of coal per boiler per week, i.e. 500 tons of coal per week on five boilers working out of the six. The fuel to-day costs 21s. 7d. per ton, and, on account of the heavy duty on the boilers, it has not been found possible to use a cheaper-grade coal, nor does it seem likely that we shall be able to do so in the future. I have taken this particular plant and examined the cost of installing coal-dust firing and the economy that would result. The boilers are fitted with every modern appliance and instruments for the scientific control of the boilers and continuous testing. On week-in, week-out tests, the average efficiency of the plant is 75 per cent, and when it is considered that the average boiler plant in the country has an efficiency, as the author has told us, of just under 60 per cent, it would not at first appear that a case could be made out for powdered fuel. The chimney issues black smoke at intervals and gases pass away at 400° F. There is a loss on the refuse heap equivalent to 5 per cent of the fuel fired, which amounts to a loss to the ash heap of 1 300 tons of coal per year. The labour in the stokehold to-day on the four boilers is from two firemen per shift, and I estimate that with coal-dust firing this labour can be halved, thus saving approximately £400 a year. The type of coal grinder selected as being most suitable is the turbo-pulverizer manufactured by the Powdered Fuel Plant Co. This machine appears to be the lowest in first cost, occupies very little floor space and cuts out the heavy initial cost of coal driers, magnetic separator and fan. One of these machines would be installed on each boiler, and the power required to operate them would be 25 h.p. per machine. After adding the cost of grinding to the price of the fuel, adding 3d. per ton for maintenance and deducting 10d. per ton, which is the cost of running our existing mechanical draught, and assuming that the 9s. 3d. per ton mentioned above would probably be increased to 12s. in the course of time, allowing for grinding, etc., the cost at the boilers on this same fuel would be 14s. 3d. per ton. On a basis of heat units per 1d., we have the following comparison: To-day we obtain 106 000 B.Th.U.'s per 1d. on stoker firing, and with coal dust, the cost, after allowing for grinding, etc., works out at 1d. per 123 000 B.Th.U.'s. Assuming an 80 per cent efficiency, and allowing 10 per cent for interest and depreciation, the saving in favour of coal dust works out at £4 700 per year, and pays back the cost of alterations in approximately 1 year and 9 months. A few days ago I had an opportunity of inspecting two Babcock and Wilcox boilers, each of a capacity of 30 000 lb. per hour, fitted for burning coal dust and blast-furnace gas. This plant was fitted with one turbo-pulverizer, which supplied fuel for the two boilers. On the firing floor there was not the least appearance of coal dust or coal, and one man only was in charge of the complete plant. The iron content of the blast-furnace gas had the effect of fusing the ash, which fell to the bottom of the combustion chamber as a molten slag. I was told that the cleaning out of this slag was done at week-ends only, when there was a layer of about 12 to 14 in. There was said to be no difficulty in breaking this slag up and removing it. From Monday morning to Saturday night no labour was employed other than the one man mentioned. The turbo-pulverizer machine had been in use for two years and had given no trouble. The whole appearance of the plant was most pleasing, and it was very easy to control. The turbo-pulverizer made very little noise and seemed to have practically no vibration. There was no smoke at the chimney except a light grey vapour which was lost to view at about 10 ft. from the chimney top. The chief points in favour of coal-dust firing seem to me to be: (1) The ability to burn a low-grade fuel; (2) the ability to follow fluctuations of demand; and (3) the elimination of arduous work on the part of firemen, entailing extreme physical fatigue. In regard to the type of pulverizer selected for the 6-boiler installation referred to, it is probable that a central grinding plant would make the change-over too costly to be considered, and, in addition, it is probable that a case for coal-dust firing could only be made out for this particular job when employing a cheaper-grade fuel.

Mr. G. P. Dennis: I have been following with interest a pulverized-coal system manufactured in Liverpool which does all that the Americans claim to do, but with less initial expense and with lower operating costs. This method is known as the Buell system and possesses several novel features. It comprises a special burner which enables a very low grade of fuel to be used. The burner is a marked advance on any other, because it enables the operator to obtain such an intimate mixture of air and coal that any grade of fuel can be efficiently burned, and, at the same time, the length and shape of the flame can be changed as desired. This flame control enables a much smaller combustion chamber to be used than that required in the United States. A further advantage is that the Buell electric control automatically regulates its own steam pressure. When the correct head of steam is raised, the flame is regulated so that a constant pressure is maintained. Sudden demands for increased pressure are instantly met, and it is possible to work the boiler at 100 per cent overload. It is possible with this system to use lignite—an extremely low-grade fuel—on a Cornish boiler. In Australia this system is more successful than any other, and four Babcock and Wilcox boilers with a normal capacity of 1 425 h.p. are now successfully running in Melbourne. The

difficulty of the successful pulverization of coal with a low power factor has already been solved by the use of the Buell-Milloyd unit, which works at the low grinding cost of 7 kWh per ton ground, while its life is considerably longer than that of American pulverizers used for this purpose. While America has made considerable progress in the adaptation of pulverized coal, I am glad to say that England is in no way lagging behind in the manufacture of efficient apparatus for burning it.

Mr. H. W. Hollands: I feel that there is very little left to say regarding the principles of powdered-coal firing, but on many points I cannot agree with the author's application of those principles. I am convinced that the unit system is the only one worthy of consideration in this country. The author states that he has not included any reference to this system because "in the first place this is more applicable to smaller boiler plants and not so much to large power station work, while general furnace work is also disappointing." I would ask members to bear in mind that it is nearly impossible to make any sort of useful comparison between the power stations of America and those of this country, but there is no power station in Great Britain, either built or contemplated, to which the unit system could not successfully be applied. At the present time there are running, on boilers alone, 160 turbo-pulverizers burning a total of 146·2 tons of coal per hour, while for furnaces the figures are 288 and 92·1 respectively. It may therefore be agreed that this system has certainly gone beyond the experimental stage and has, in fact, taken a much greater hold on engineers in Europe than has any other form of central station firing. The author states that with crushing or grinding mills of the Fuller or Raymond type the coal has to be dried down to at least 2 per cent and preferably 1 per cent of moisture. With the unit system it is easily possible to use coal containing 8 per cent moisture, while, by passing preheated air through the machine with the coal, moisture contents as high as 15 per cent have been dealt with. In an article in the *Iron and Coal Trades Review*, February 1922, under Mr. Brownlie's name, it was stated that "if coal can be pulverized without drying it would be an enormous improvement, but up to the present time it has always been considered necessary to dry it to within 1 per cent moisture—a formidable operation for most coals." I am in entire agreement with this view. Driers are, at the best, costly additions to a plant; they are inefficient and are, on account of their great radiant heat, unpleasant to work near. With any form of central station practice or, in fact, with any system which stores powdered coal, there is a very real danger of explosion or spontaneous combustion, and a number of appalling accidents due to these causes have taken place in America. As the author points out, the risk has now been largely overcome, but this has entailed special bunkers, special buildings, and altogether considerable unnecessary expense. With the unit system the coal is burnt as it is pulverized; none is stored and there is therefore no possible risk of fire or explosion. The author deals very fully with the ash-slagging question, including the water screen designed to overcome any such trouble. Such a screen is an unnecessary luxury, since a proper design of combustion chamber will always result in the ash being deposited in a perfectly dry state. At Hammersmith Corporation Electricity Works—where three boilers burning powdered coal are evaporating 130 000 lb. of water per hour—no trouble due to ash slagging has been experienced, and the same remark applies to almost every unit plant in the country. The combustion chamber should be so designed that there is a vacuum at the base, balanced pressure in the middle zone, and a slight plus pressure at the first pass. The ingoing cold air cools the ash and prevents the formation of slag. It might be suggested that such an arrangement would lower the efficiency of the plant, but that this is not the case is convincingly shown in the two following extracts taken from recent tests on boilers fired by means of turbo-pulverizers. The first is a Babcock and Wilcox boiler having a heating surface of 5 760 sq. ft. and which, using a coal (Durham splints) having a calorific value of 9 550 B.Th.U.'s per lb., has been running with a constant overall efficiency of 83 per cent. The second case is also a Babcock and Wilcox boiler with a heating surface of 2 690 sq. ft. and which, using a coal having a calorific value of 10 788 B.Th.U.'s per lb., has been running with a constant overall efficiency of 86 per cent. In dealing with the troubles due to wear of brickwork, the author makes little or no reference to a point which, to my mind, is of the highest importance, i.e. the velocity of the powdered coal in the pipes and through the burner. Most of the early troubles were due to too high velocities, the result being serious impinging on, and consequent scouring of, the brickwork. That fact has now been recognized and it is not uncommon with unit pulverizers for a plant to run for 18 months without any repairs to the brickwork being required. To sum up, I would say that, while the unit system is giving results quite as good as those obtained on any other system, the difference in cost is enormous, the space occupied is very considerably smaller, while the risk of fire or explosion is entirely eliminated.

Mr. R. G. Devey: The author refers to boiler plants in this country working at 60 to 70 per cent efficiency. I venture to say that what is required is not altogether the installing of pulverized-fuel plant but the introduction of scientific control on the boiler plants which are working to-day. I should like to ask the author how he proposes to deal with the present boiler plants. A number of new ones having recently been put down, does he suggest scrapping these to make room for pulverized-fuel boiler plants? Assuming that with mechanically fired boilers the efficiency is from 78 to 80 per cent, to scrap existing plants would mean providing a sinking fund and adding interest at the rate of 5 per cent to the working cost if the pulverized system were introduced. It appears that to obtain a higher efficiency equal to, say, 85 per cent the saving in fuel would hardly warrant the scrapping of existing mechanically fired plants which are at present scientifically controlled. If this is so, then pulverized plants are a good proposition only when a new installation is

being put down. In comparing American and British plants, it is rather unfortunate that the author had to deal with plants having load factors of 60 and 34 per cent respectively, as a low load factor cannot compare with a high one on boiler plants. I should like to suggest that for boiler plants the steam load factor should be compared and not the power station load factor, as there are a number of variables in the power house which differ in efficiency, such as turbines, generators, vacuum, water temperatures, etc. I should be glad if the author would state if suitable furnace linings are obtainable in this country to withstand high temperatures.

Mr. E. Moxon: The paper is of great value to power station engineers, particularly as it has been presented at a time when everyone is striving his utmost to obtain the highest possible efficiency in the generation of electricity. The past few years has seen an enormous advance in the demand for electricity for all purposes, and to cope with this many generating stations of large capacity have been designed and put into commission, whilst a large number of the old generating stations have been modernized or enlarged. Although very large boiler units have been erected, with the adoption of higher pressures and temperatures the method of firing the coal has been chiefly by means of mechanical stokers. It is somewhat astonishing that more stations have not equipped at least an experimental plant using pulverized coal for firing purposes. One can, however, quite understand that the smaller station requiring extensions of its boiler plant hardly dares to adopt pulverized-fuel equipment, on account of the capital expenditure involved being greater for this type of equipment than for mechanical stokers. Furthermore, the small amount of data available from independent and unbiased sources has perhaps tended to impede progress in the direction now recommended by the author. The engineers of smaller electricity undertakings have to be very careful that any plant that they adopt must be reliable and capable of giving regular service when required, and this view might even outweigh the advantages of more modern plant able to give a higher efficiency of a few per cent, chiefly on account of the fact that smaller stations have not, as a rule, the amount of spare plant that larger stations have. Again, later additions of plant are generally larger units, which often constitute a fairly large percentage of the total equipment; hence the necessity for the utmost reliability of the later units installed. Referring to the efficiency obtainable, a small generating station can to-day, with coal costing 17s. per ton delivered, generate 1 kWh for, say 0·23d., with a 20 per cent load factor, the steam generating plant having an all-the-year-round thermal efficiency of over 12 per cent, i.e. on units generated. One is inclined to think that on account of the extra expenditure involved in obtaining a very slight increase in the thermal efficiency of the steam-raising plant, given equal expenditure on other sections of the undertaking, the financial gain would be greater from a commercial point of view. I am rather afraid that firing pulverized fuel will, unless the draught is very carefully regulated, result in the emission of fine particles of dust and grits from the chimney, and I know from experience that this can be, in the case of mechanical firing of very fine fuel (commonly called "dant" or pit-heap coal), a great nuisance to neighbouring properties. Dust or grit extractors are not very effective, but perhaps the more common use of pulverized fuel has brought in its train an efficient remedy. My personal opinion is that the greatest value could be obtained by using pulverized fuel at generating stations close to large collieries for making use of the "dant" from coal washeries and pit-heap coal that has been deposited at the pit head for years, and any other low-grade fuel that may be available. This should be purchasable in large quantities at very low rates, and as the transport charges would be almost negligible the coal costs per unit would be very low indeed. Furthermore, the dust problem would not be of any consequence. I consider that the very great overload capacity of a boiler fired with pulverized fuel, stated in the paper to be 100 per cent, taken in conjunction with the speed at which a boiler so fired can be brought into and taken out of action, will make the use of a certain portion of the boiler equipment of this class of great value to meet peak-load requirements. I should like to ask the author whether the efficiency figures given for stations using pulverized fuel are calculated on the weight of fuel fired as dried or on the weight received in the bunkers.

Mr. E. W. Hall: I should like to ask the author if he has any knowledge of the pulverized-fuel system being applied to marine practice, and if, in his opinion, its adoption would entail alteration to the existing boilers, whether of the Scotch or of the water-tube type. Also, does he think that the noise caused by the operation of the pulverizers would make the system unsuitable for passenger liners?

Mr. A. E. Malpas: In the latest practice the vertical-louvre type of drier is adopted. I take it that the moisture evaporated from the crushed fuel escapes with the chimney gases. The temperature is supposed to be continuously maintained at 215° F. in order to drive off the hygroscopic water, leaving about 2 per cent combined water which can only be driven off at a somewhat higher temperature. Should the temperature rise above 215° F., however, there will be some tendency for volatiles to be driven off and so lost in the chimney, and I should like to know how the temperature is controlled.

Mr. H. S. Rowe: Many of the advantages claimed for pulverized fuel are as much due to scientific control as to the fuel itself. As the accuracy of the author's figures for the average efficiency of steam generation in this country and elsewhere have never been seriously disputed, it is interesting to note—in regard to the statement made at the foot of page 397 as to the efficiency of water-tube boiler plants—that an increase in the average efficiency of 70 per cent to the attainable efficiency of 80 per cent would result in a saving of one-seventh of the total fuel consumption. In a plant consuming 300 tons per week this would represent a saving of about 2 200 tons or, say, £1 700 annually. Such a result demands close and accurate attention and will justify the payment of £500 per annum to

a suitably qualified engineer who would obtain it, although this is a proposition which many owners of boiler plants would not consider. High efficiencies are claimed for other methods of steam generation. As much as 88 per cent is claimed for steam generation on marine boilers fitted with forced draught and air preheaters, and I should be glad if the author would state if he has any knowledge of such a figure being actually obtained. No claim was made in this case for using poor quality fuel, such as is frequently made by advocates of pulverized fuel. In spite of such claims made on page 389 and elsewhere, it will be noted that the guarantees quoted on page 396 regarding the Vitry installation do not refer to low-grade fuel, whilst the fuel used in the Dalmarnock station (see page 399) is of a quality inferior to that used in the tests on the Lakeside plant (see page 404). There seems to be some divergence of opinion as to the best size of combustion chamber required for use with pulverized fuel. This is evidenced even in the paper itself, as figures given on page 404 indicate that about 1·62 lb. of fuel are fired per hour per cubic ft. of combustion space at normal working, whereas on page 400 it is stated that 3 lb. of fuel are fired hourly for each cubic ft. of space, whilst on page 407 the description of the River Rouge plant shows that about 1 cubic ft. per lb. of coal per hour is required, assuming that the boilers relied entirely on coal. The amount of power required for pulverizing is claimed to be exceptionally low and, although in the case of the Vitry power station the power consumption is guaranteed not to exceed 1 per cent of the steam production, this involves the production of power at an expenditure of 1·15 lb. of coal per kWh, an exceptionally low figure. From the figures quoted on page 400 it would appear that the total power consumed at Dalmarnock station is between 4 and 5 per cent of the total amount generated, and although on page 397 the author states that 1·5 per cent of power is used as an auxiliary to the production of steam in the most efficient boiler plants, yet the figures quoted on page 401 show that in one case 9 per cent and in another case 4·3 per cent of the power generated at Dalmarnock is consumed in the boiler house during test periods. The figures quoted on page 405 for losses in unburnt fuel in ashes can only be described as illustrative of the general carelessness in these matters, and the Dalmarnock figures quoted on page 401, showing only 1·07 per cent loss in this respect, demonstrate what can be done with care, this figure being less than the 2 per cent quoted by the author as being the best stoker practice. Whatever may be the thermal efficiency of steam generation it is the ultimate aim of engineers to produce steam as cheaply as possible. From the figures quoted on page 416 the average cost of the fuel used works out at between 26s. and 27s. per English ton, and steam is then produced with pulverized fuel at a cost of about 21·2d. per 1 000 lb. The cost of steam at Dalmarnock, arrived at from the figures given in Table 16, may be fairly estimated, after allowing 20 per cent for capital charges, as about 19·26d. per 1 000 lb. At a local power station and a factory steam is produced at a less cost than at the American plant mentioned, and it may be that the heavy charges for fuel and labour in America make it worth while to follow up the small higher efficiency obtainable from pulverized fuel in order to reduce steam charges to a minimum. The author has made out a case for the careful attention by British engineers to the claims of pulverized fuel where heavy demands for steam are to be met.

Mr. E. Cook (*communicated*): Whilst the author has undoubtedly made out a good case for pulverized-fuel stoking, considerable improvement could be made on existing mechanical stoker plant efficiencies, without entailing additional capital outlay, by a closer supervision and a greater appreciation of boiler plant economics by the engineers in charge of steam-raising plant. The figures quoted of the Dalmarnock station were obtained under a very complete system of record keeping and testing, indicating the close attention to details which is absolutely necessary. The fact that figures approaching those of Dalmarnock are not obtained on the average station to-day with mechanical stoker plant is, in my opinion, largely due to inattention to the above-mentioned points of testing, record keeping (with the intelligent use thereof) and details of firing. If a station of average capacity, say 10 000 to 20 000 kW, is to-day operating, with mechanical stoker plant and an average calorific value of fuel of 9 500–10 500 B.Th.U.'s, at a boiler-house commercial efficiency of less than 75 per cent, then there is something radically wrong either with the plant or its operation. The author's main arguments appear to be based upon stations of large capacity. The majority of engineers are, however, probably interested in stations of medium capacity, say 10 000 to 20 000 kW, and the question arises as to the advisability of installing pulverized fuel plant in such stations. If a figure of not less than 75 per cent commercial efficiency can be obtained—and it certainly ought to be on such medium-capacity stations—can the additional 5¼ per cent efficiency be obtained by pulverized-fuel plant, and is the capital expenditure and maintenance warranted? On the other hand, is it not a better proposition to operate existing plant more efficiently by expending a portion of this outlay on efficient apparatus and continuous technical supervision of boiler-house operation? This would undoubtedly produce a definite return, whilst the installation of pulverized-fuel plant, unless accompanied by the necessary efficient apparatus and supervision already mentioned, might conceivably yield no return at all. In Table 5 the author quotes a calorific value of the coal as fired of 9 905 B.Th.U.'s, with an ash content of 12·74 per cent of the total coal. This seems to be an abnormally low ash content for such a calorific value, and unless the coal contains an unusually high percentage of moisture it seems difficult to account for the discrepancy. The foregoing remarks are based on the assumption that the plant is a modern one of the ordinary type met with in medium-capacity central stations, without air-heating and with a station load factor of, say, 35 to 40 per cent.

[The author's reply to this discussion will be found on page 460.]

Scottish Centre, at Glasgow, 11 December, 1923.

Mr. R. McLaren: The paper is the best summary of the position of the operation of pulverized fuel that we have had since Mr. Harvey's Report to the Fuel Research Board in 1919. I propose to confine my remarks to one or two of the more important points in the paper. As regards thermal efficiency, the author can hardly expect us to accept the figures given in Table 2. If they were correct, it would reflect more on those operating the plants than on the plants themselves. On the other hand, the efficiencies given for pulverized-fuel plants are based on one of the most scientifically operated stations in the world. It is futile to compare such a plant with a badly run station which happens to be served by mechanical stokers. It is stated in the paper that the efficiency of the Lakeside station is, year in and year out, 85–86 per cent, and a figure of even 89 per cent has been attained. The author very justly draws attention to the great difference that exists between the results obtained in day-to-day working and those obtained on test. If he can get 85–86 per cent efficiency in day-to-day running, why is it that only 84 per cent is guaranteed for Vitry on test? It would appear that the author's optimism is not shared by the Lopulco Company, because one would naturally think that if it were possible to get that efficiency on regular service, the test figure would be, if anything, higher. Mechanical-stoker engineers will guarantee 84 per cent under penalty. Such efficiencies could not, however, be obtained if the author's figures of the percentage of unburnt carbon in the ash from mechanical stokers were correct. He says that this is about 35 per cent, but in a well-operated station it should not exceed 10 per cent. It is possible that the author's views in regard to the efficiency of mechanical stokers have been formed without knowledge of the great improvements that have been made in them recently. For instance, he says that air-heating is not a common thing. Air-heating is, however, very important if high efficiency is required, and during the past two or three years my firm has supplied air heaters for a great number of boilers both in this country and abroad. Air-heating is a recognized method of improving the efficiency of mechanical stokers. The next point is in regard to flexibility, in the sense of the power to deal with a wide range of coal, and I differ from the author when he claims that fuel which is pulverized before being burnt gives the greatest flexibility. To burn pulverized coal there must be a certain minimum content of volatile matter in order to get free ignition and to maintain combustion. When I was in the United States last year, I was told that in several cases where pulverized coal was being burnt it had to be mixed with bituminous coal owing to the want of sufficient volatile matter in the fuel, and also in some cases auxiliary means of maintaining combustion had to be applied. That is, of course, very inconvenient. It is stated in the paper that the ideal fuel for pulverizing is one having 30 to 40 per cent volatile matter, although it is mentioned later that it can be burnt down to 5 per cent. There need be no such limitation with mechanical stokers, where any range of fuel having any volatile content or any amount of ash can be burnt. At the Birmingham municipal station I believe that 800 tons of coal are burnt daily, the coal having a heat value of between 8 000 and 9 000 B.Th.U.'s and 24 per cent volatile matter. The stokers burning that coal were tested a short time ago to ascertain how they would burn coke breeze having only 5 per cent volatile matter, and it was found that this could be burnt equally well with no alteration except as regards adjustment and regulation of the feed. We recently burnt some "unscreened metallurgical coke" which had a calorific value of 8 470 B.Th.U.'s and 1·75 per cent volatile matter. It was burnt on a stoker on which we burn Bothwell singles having a heating value of 12 000 B.Th.U.'s and about 25 per cent volatile matter. The author mentions low-grade fuel, but I do not call fuel of 12 000 B.Th.U.'s such as that he refers to at Milwaukee a low-grade fuel. I apply that term to fuel having less than 9 000 B.Th.U.'s, and there is no information in the paper as to how pulverizing would affect such a fuel. Another point is that, as shown by Mr. Harvey in his Report to the Fuel Research Board, the cost of pulverizing increases very much more rapidly than the percentage of ash, and to burn coal with a large amount of ash will add considerably to the running cost for pulverizing. The Lopulco plant appears to consist of a feeder and mixer, a new drier (which apparently has not yet been thoroughly tried), and the water screen, about the last-named of which the author is very enthusiastic. My firm has made two of these water screens, but only on the distinct understanding that we took no responsibility whatever for them. The author criticizes the steel-tube economizer and alleges that it will not last, but I put it to him that it will outlast the water screen. Referring to the remote control at the Ford plant, where one operator controls four boilers, or is shortly going to do so, by merely manipulating switches, there seem to be great differences in American practice, because according to Table 9, which deals with the Lakeside station where the author says there are six boilers at work, 63 men, excluding those in the pulverizing house, are employed. It certainly is not necessary to employ 10 men per boiler with mechanical stokers.

Mr. J. Train: The question of burning pulverized coal seems to be one of furnace design, and from the results presented in the paper the Lopulco system seems to have overcome the difficulty in connection with brickwork, etc. My firm tried pulverized fuel on a boiler some time ago, but unfortunately this boiler was designed for use with mechanical stokers with the result that the brickwork lasted about three days. It is therefore imperative that a combustion chamber designed for pulverized fuel only should be installed. I think that one of the main reasons why this method of burning fuel has not been adopted extensively in this country, is that only half measures have been taken when it has been tried. To be a success, it would seem that full measures are required

to obtain satisfactory results. It seems at present that the best results are obtained when the coal is burnt at the rate of 1 to 1½ lb. per cubic ft. of combustion surface per hour. As the author has mentioned the Ford plant, I should like to mention that my firm is at present installing two boilers each of 8 215 sq. ft. heating surface to be fired with a combination of pulverized fuel and blast-furnace gas. I would mention, however, that the pulverized system being installed is the unit system. I note that one of the principal claims for powdered fuel is the fact that varying grades of fuel can be burnt without difficulty. Opinions on this matter seem to have altered, as it was lately held that only fuel of good quality was suitable. As it is admitted that the system described in the paper is only economical when used with large central power stations, I would suggest that as these are usually some distance from the collieries it is advisable to use fairly good fuel on account of freight charges, etc. The best place for the pulverized-fuel plant would appear to be at the colliery, where there is a large surplus of fuel which is difficult to sell, and this fuel could be used by the colliery company under water-tube boilers to generate power for their own requirements. As the usual power station at a colliery is not large enough to justify the installation of the multiple system on account of capital cost, it would seem that the unit system is the more suitable. With this system, however, difficulties due to moisture arise, as if the free moisture of the fuel exceeds 4 to 5 per cent, choking of the discharge pipes takes place, and if the moisture content increases beyond that stated, the power required increases out of all proportion. I would suggest that to overcome this difficulty it would be a good proposition to add a vertical drier, such as that described by the author, to the unit pulverizer. With this addition I think that it would be possible to burn fuel for which there is no ready market, and which is available at collieries. In connection with the efficiency given by the author in Table 2, I think that it is in the smaller power stations, which cannot afford the capital outlay necessary with the multiple system, that the lowest efficiency occurs. As it is stated that the water screen is one of the principal reasons for overcoming the difficulties in connection with pulverized fuel, it is a question of using pure or distilled water. It is only at the largest stations that water of this kind is available, as in many stations it is not economical to put in evaporators for this purpose, owing to the large amount of make-up required. It would seem, therefore, that if water screens are barred on account of the quality of the feed water, we should concentrate on designing a furnace which does not require water screens, and this I think will be done as experience is gained in actual velocities in the combustion chamber and with air-cooled and hollow walls. The evaporations given in the paper for various plants are obviously not in connection with stoker plant, and here again pure water is essential to prevent trouble. It is regrettable that no mention is made of the actual work done by the water screen itself, or if this heating surface is included in the boiler heating surface when data are given regarding evaporation per sq. ft. If the actual performance of the water screen could be stated separately, it would give a much better idea as to the performance of the boiler itself and a better basis for comparison with stoker-fired boilers. I would suggest that this water screen has a greater effect on the performance than appears to be the case at first sight. For instance, it is stated in the paper that the water screen for the new boilers for Milwaukee has 320 sq. ft. heating surface per boiler. As this screen is subject to a very high temperature it is generally admitted that the evaporation at normal load will be in the nature of 41 lb. from and at 212° F. per sq. ft. of heating surface. This amounts to 13 120 lb. per hour. Taking, say, a boiler suitable for 50 000 lb. normal evaporation per hour, the water screen is responsible for approximately 24 per cent of this evaporation. If this figure is applied to the guaranteed evaporation per sq. ft. of boiler heating surface it reduces this figure considerably and gives a much better idea of the actual performance of the boiler. I should be glad if the author would give more information regarding the high evaporation and the amount contributed thereto by the water screen. The data for the repair bill for the pulverizer are unfortunately given for a case where good-quality fuel is being continuously used. It would be interesting to have the figures for the repair bill where the percentage of ash in the coal varies, and also the effect of various grades of coal on this item.

Mr. W. Ross: The paper will, I am sure, act as a basis for comparisons in costs and working efficiencies for some years to come. One is inclined to ask whether the boiler designer has no share in the increased efficiency obtained by the use of pulverized coal. Table 7 gives the highest evaporation per sq. ft. as 8·6 lb., the efficiency as 85·6 per cent, and the temperature of the stack gases as 272° F. These figures compare with the guarantees given for the new boiler plant at the Central Electric Supply Co.'s station, London. Of course the figure of 85 per cent efficiency for the London boilers is the test figure, but if banking losses are excluded is there any reason for supposing that the powdered-fuel boiler will keep cleaner than the other? I have mentioned the London station, but I think that when the several large boiler plants which have been laid down during the past few years are in full working order they should show efficiencies close to the 80 per cent mark, and that without putting in excessive heat-recovery surface, either in the economizer or air-heater. The figure of 77 per cent given in the paper for Dalmarnock is the average for the year with a load factor of 32 per cent, and the average stack temperature is 400° F. The coal used for banking at this station is about 5 per cent of the total, and if air-heaters or larger economizers were put in to reduce the stack temperature to, say, 250° F., then by eliminating the banking losses the efficiency would be about 87 per cent. It is, of course, admitted that with pulverized fuel the air supply is under better control, but I think that the big feature is the reduction of banking losses. My point is that the performance of an up-to-date stoker plant, combined with a heat-recovery surface sufficient to reduce the stack tempera-

ture to about 250° F., will compare favourably with that of a pulverized-fuel plant at 100 per cent load factor and a much smaller capital cost. Boiler plants do not run at 100 per cent load factor, however, so that some means would have to be adopted to overcome this handicap. I have had some experiments carried out on a 30 000-lb. C.T.M. type Babcock and Wilcox boiler with an oil burner fitted across the arch close to the fire door. The oil flame, which is only in service for about 15 minutes, takes the place of the arch until the coal is ignited and the arch hot. By this means it was possible to get a boiler on full load from cold in 30 minutes. This method appears to me to be worthy of further investigation, as although it might not be good practice to raise steam so quickly from cold, it might take the place of the banking of boilers over light-load periods. On page 417 the author gives the analysis of the ideal coal for pulverizing, and it will be noted that the ash should be less than 10 per cent. Now good washed singles and pearls supplied to Dalmarnock generally have about 14 per cent ash, and advocates of this system, when pulverized fuel is being discussed, usually make a great point of the fact that almost any sort of coal can be usefully and cheaply utilized. I should be glad if the author would say what would be the limit of ash percentage suitable for pulverizing in comparison with stoker gear. On page 411 he gives a summary of the auxiliary power required to operate a pulverized-fuel plant, and it is rather surprising to find that the fan power is given as 3 kW per ton of coal. On page 394 it is stated that 10 per cent of the air necessary for combustion is supplied at the burner at a pressure of 12 in. water gauge. To do this alone would take 22 kW, to say nothing of the separating fan at the pulverizers, and if the figures given on page 411, with the above corrections, are applied to the test given on page 401 under induced draught, then the electric feed pump in the one case and the conveyers in the other will be common to both, and the figures would be, for 8·3 tons per hour :—

	Dalmarnock	Pulverizing plant
	kW	kW
Induced-draught fan	68·3	—
Stoker drive	8·3	—
Electric feed pump	75·0	75·0
Conveyers	8·3	8·3
Pulverizing mills	—	99·6
Vertical driers	—	22·4
Pulverized-coal feed	—	6·65
Fans	—	22·00
Total	159·9	233·95

It will also be noted that the pulverizing plant does not allow for drawing the remaining 90 per cent of combustion air into the combustion chamber and passing it up the stack. In regard to the author's point that as the American engineers have done a great deal of experimenting and proved the system to be a success, it only remains now for the British engineer to start putting down plant and depend on the results obtained in America, I would remind him that quite a short time ago the multiple-retort stoker was quite the fashion in America and very fine results were obtained from it, but I have still to hear that the same type of stoker has been a great success in this country.

Mr. J. Bruce: It is claimed as one of the advantages of pulverized-fuel firing that the combustible in the ash can be kept to a value in the neighbourhood of 0·40 to 0·74 per cent of the total coal consumed. These figures can also be obtained on a competently operated mechanical-stoker unit. It will be noted on page 401, in the report of the tests carried out on boilers Nos. 9 and 10 at Dalmarnock, that under balanced-draught conditions the combustible in the ash is negligible. Actually it was below 0·5 per cent. On another test carried out a week ago on a single boiler unit at the same power station, this item in the heat balance was 0·53 per cent, the average rate of combustion being approximately 31 lb. per sq. ft. of grate area per hour, equal to a heat-liberation rate of 320 000 B.Th.U.'s per sq. ft. of grate area per hour. The furnace efficiency in this instance was slightly over 99 per cent. I am aware that values of this order are an exception in the case of the average mechanical stoker plant, but they show what can be obtained with the assistance of modern scientific instruments and an intelligent operating crew in the boiler room. Undoubtedly, as the author points out, the rate of combustion with pulverized fuel lends itself to very flexible control, and that with comparatively little difference in efficiency. While the control of combustion rates with pulverized fuel is more flexible, it is surprising the little effect that changes of load or the quality of the coal will have on the overall efficiency of a mechanical-stoker unit if competently and intelligently handled. On tests of large water-tube boiler units I have found it possible to obtain an overall efficiency in the neighbourhood of 80 per cent at all loads from $\frac{3}{4}$ full load up to, in certain cases, 40 per cent overload. These again are exceptions to general mechanical-stoker practice, and the credit is due not so much to the equipment as to the intelligence and adaptability of the boiler-room operating staff. One of the early objections to the use of pulverized fuel was the rapid deterioration of the furnace and combustion chamber refractories. A similar difficulty is occasionally experienced with mechanical-stoker plant when operating at high rates of combustion under balanced-draught conditions. I understand that refractory troubles at Milwaukee have been successfully overcome without any sacrifice of efficiency, and it would be of material benefit if the author in his reply would say how this was accomplished, and describe the nature or type of the firebrick used. Very great improvements have within recent years been effected in the design of mechanical-stoker plant, but the benefits derived from these improvements can only be realized if the plant is intelligently operated. Again, there are cases where stoker plant has been installed and unjustly condemned, due to the fact that in the first place no attempt was made to determine the correct combinations of grate area, arch length, and combustion-

chamber volume. In one case that I know of, the furnace efficiency of a mechanical-stoker plant was improved by from 6 to 7 per cent by re-designing the ignition arches. There is still room for improvement in mechanical-stoker design, especially in the direction of simple and accurate methods of scientific control. In my opinion, instruments for the measurement of coal, air, and flue-gas constituents should be looked upon as a part of the stoker equipment, and it is here that room for considerable improvement exists. More co-operation is required between the stoker manufacturer and the instrument maker, and there is a great field for valuable research work in this direction. Generally speaking, the author puts forward a very good case for pulverized fuel, but while such a system may be considered and adopted in the case of large new plants, I do not think that the benefits to be derived would warrant the scrapping of the mechanical-stoker plants at present in operation. A modern mechanical-stoker installation using preheated air and handled by an efficient operating staff should produce results not very far short of those obtained on pulverized fuel, and, taking into consideration the difference in capital cost, I think that pulverized fuel will find the mechanical stoker a strong rival for some time to come. The adoption of preheated air, the elimination of banking losses, and a general all-round increase in the efficiency of the majority of operating staffs, would go a long way towards bringing the efficiency of mechanical-stoker plants nearer to the average efficiency obtained with pulverized fuel. It is pointed out in the paper that quite a number of large power stations at present being erected are installing mechanical-stoker units. Is the author aware of the reasons that finally decided this course? The greatest factor influencing the economical combustion of coal and the generation of steam is the human element, and what is needed, equally as urgently as new and improved plant, is the education and all-round increase in status of boiler-room operatives. Taking the mechanical-stoker plants in operation to-day, I think that not 90 per cent of them are as efficiently operated as they could be. The same result would occur if pulverized fuel were adopted. Possibly 5 or 10 per cent of the plants would be operated in an efficient manner, the remainder falling into the class at present occupied by the majority of mechanical-stoker plants, and not until we reduce the effect of the human factor shall we be in a position to utilize efficiently new methods of burning coal. From the point of view of the chemist also, pulverized fuel does not offer the solution to the problem, inasmuch as it still entails the total consumption of the coal in the raw state, there being no provision for the extraction and recovery of the valuable by-products. The objection to the chemists' schemes of low-temperature carbonization, gas-fired boilers, and by-product recovery, is the enormous ground space required for the gas-producer plant. For instance, in the case of Dalmarnock something like 250 gas producers, with their accompanying auxiliary plant, would be required to supply steam for the present capacity of the station. It is my opinion, however, that cheap steam, the abatement of smoke, a cleaner atmosphere, and healthier industrial communities will only be obtained by a compromise between pulverized fuel and low-temperature carbonization, the boiler plants being fired by a combination of gas, and the pulverized coke from the producer plant, the coke not required by the generating stations being supplied for household consumption. A great amount of hard work must be done by our pioneers of science and engineering before the dawn of such an era, but steps should in the meantime be taken to make everyone in general, and engineers in particular, realize more fully that the black smoke polluting our industrial centres represents the prodigal squandering of civilization's greatest inheritance.

Mr. J. W. L. Jones: We ask ourselves why is it that so little progress has been made in what undoubtedly does represent a much better plant when dealing with a big installation, i.e. the use of powdered fuel. I think that it is perhaps to some extent due to the fact that manufacturers of powdered-fuel plant have been rather anxious to make a start in this country and are not sufficiently careful in the selection of the plant on which they are going to work, with the result that they have been putting installations into existing boilers where the setting is low and consequently the combustion chambers are too confined. Inevitably they have found themselves confronted with problems that are practically impossible to solve, with the result that purchasers have become disgusted with the experiments and progress has therefore been retarded. The paper states that the Americans have spent stupendous sums of money on the development of the powdered-fuel system, and this is undoubtedly true. My opinion is that powdered-fuel plants will not come into great vogue in this country except for large stations, where the large capital expenditure would be warranted. The paper does not give much information about the unit system, and I should be obliged if the author would say what is the difference in results attained by the two systems. With reference to Mr. McLaren's remarks as to what stoker practice had done, it is perfectly true that the development of stokers has gone on from year to year, and low-grade fuels, both anthracite and bituminous, present no great difficulties. Stokers have, however, definite limitations in certain directions. Stokers cannot burn efficiently low-grade fuels that are high in moisture content beyond 28 to 30 lb. per sq. ft. of grate, unless hot air is adopted, whereas with such powdered-fuel plants as are described in the paper there is practically no limit to the amount that can be burnt. It is merely a question of feeding into the furnace a sufficient quantity to obtain the capacity required.

Mr. R. B. Mitchell: It is rather remarkable that the Dalmarnock station makes a good basis of comparison with Lakeside so far as capacity is concerned; in fact, the two stations are very similar with respect to size and running conditions, the one exception being load factor, which at Lakeside is 60 per cent and at Dalmarnock 34 per cent. The author has made out a very strong case for pulverized fuel, and the figures which he puts forward are very striking. It is a most desirable thing to have a boiler-house efficiency of 86 per cent, and in the case of Dalmarnock an improvement

from 76 per cent to 86 per cent would mean a saving of £12 000 per annum. I think, however, that the hesitancy which the engineers in this country have shown in adopting pulverized fuel is due to the fact that they recognize that pulverized fuel is passing through a transition stage. In the development of everything new there is a stage in which changes are very rapid, and what is up-to-date to-day may be obsolete in a few months' time, and I think, therefore, that it is quite right that conservatism should be shown in this way. For instance, it is not yet certain whether a form of pulverized-fuel plant such as that put forward by the author is the right thing. I know that experiments are being carried forward in America with a design of furnace which is much smaller in proportion than that described in the paper; and the velocity of the furnace gases is very much lower. That form of furnace might be followed up with interest and compared in time with that described by the author. The problem of the emission of ash from the chimney is certainly one that would require serious consideration, especially in a station situated—as Dalmarnock is—in the midst of a closely populated district. Where a station is situated in the outskirts of a town there may be no difficulty, but a town station is different. The reference in the paper to low-temperature carbonization in conjunction with pulverized fuel is very interesting. I did not realize that such a thing was possible, and it is well to know that the residual from low-temperature carbonization can be burned in pulverized form with high efficiency. I agree with the author that it is vital that the utmost should be made of the fuel resources of the country.

[The author's reply to this discussion will be found on page 460.]

North-Western Centre, at Manchester, 18 December, 1923.

Mr. A. B. Mallinson: Within the last month I have been through some of the typical pulverized-fuel stations in the United States, where pulverized fuel has made enormous strides during the last two years. I must admit that what I saw at Cahokia and at the River Rouge plant of the Ford Company was wonderful. Take the Union Electric station at Cahokia, St. Louis. Quite apart from the question of pulverized fuel, that station impressed me as being a wonderful monument to American "push." A station with two 30 000-kW turbo-generators in it had been virgin ground in June 1922; the first pile on the bank of the Mississippi was driven in that month; when I visited the station on the 18th November, 1923, they had been generating for over a month, and the whole of the concrete sub-foundation work and condenser pit had been put in for another two 40 000-kW sets. They told me that for many months they had had 2 200 contractors' men working on that station, and the day I was there there were 1 600. There are 8 Babcock boilers each of 17 800 sq. ft. heating surface. It is almost uncanny to see the simplicity of operation at that station. What is called the Quigley system is used for moving the pulverized fuel from the pulverizers to the bins. It is dropped from the pulverizer into a vessel which holds, I think, 6 000 lb. of coal, and then the operator "shoots" it by compressed air first to one boiler bunker and then to another. There has been a lot of talk about the danger from explosion. Incidentally I should like to know whether the author has heard of the very onerous conditions which the National Fire Protection Association Committee a short time ago drafted at their annual meeting in Chicago. At Cahokia the pulverizing plant backs on to the boilers, and they have taken care to put a strong reinforced concrete wall right up from top to bottom, and the other side is all glass windows, the reason being that if there is an explosion they want it to go outwards. I was told that so far they have not experienced any trouble with the plant. After that I saw the plant of the Ford Motor Co. at the River Rouge, Detroit. That plant was different from the Cahokia station in that the station had been some time in operation and was in a practically finished condition. The author is quite right in what he has said about the number of the staff. What he did not mention is that everybody in the boiler house at the station is dressed in a white duck suit, and there is no sign whatever of coal dust or ash on the floors, or the tops of pipes, or anywhere. When I saw it the station was using just under 70 per cent of blast-furnace gas, and the remainder was pulverized fuel. The pulverizing plant is in a separate building, and the pulverized fuel is brought up by screw conveyers to the hoppers or bunkers over the tops of the boilers. The author gives figures in regard to the size of these stations. The remarkable thing is that they do not look big, owing to everything being symmetrically proportioned. The chimneys at Cahokia and River Rouge are all over 300 ft., but they looked no higher than an English power station chimney. I think that the author has rather run down the Englishman and, in making comparisons between modern British practice and modern American practice, has taken as his basis data which he has collected in this country during the past 10 or 15 years from plants many of which we know cannot be regarded as typical of plants which rely for their existence upon the generation of electricity for profit. In many cases they are simply part and parcel of a big works equipment. With regard to the question of ash, the Ford station is reasonably clean outside, but in the paper it is admitted that $17\frac{1}{2}$ per cent of the ash goes out of the top of the chimney. I wonder what a Manchester smoke nuisance inspector would say about that. The high chimneys must undoubtedly carry the dust some distance before it is deposited; that is well known in the paper trade. I cannot quite understand Table 8. I was told in the States that no carbon was left in the ash from these plants—at any rate it was under 1 per cent; but in the heat balance we get 0·5 per cent in the first instance and 0·9 per cent in the last. Further up that table under "Ash and refuse" we see figures of 3·6, 6·26 and 0·45 per cent, which added together total 10·31 per cent of carbon in the

ash. Is that burned effectively, or has it to be handled over and over again before it goes back to the boiler? The automatic control at the Ford works is certainly wonderful, but I do not think that it could be adopted anywhere else. The chief engineer of the Lopulco Company said that the Company are not keen on the automatic system. Incidentally, I heard that the Bailey meter was giving wonderfully good results with the automatic control. At Cahokia 4 of the 8 boilers were to be automatically controlled. On the question of maintenance, both at the Ford works and at other works where other systems were in use the maintenance of the pulverizers is not a big matter. In Mexico with similar pulverizers for pulverizing rock, I find that the maintenance question is not a big matter if the plant is correctly installed. I saw another system working at Chrome, New Jersey, where one could hardly see the pulverizer for dust. The plant, which was quite small, had been running 3 years like that and they had never attempted to clean the pulverizer. Handling 200–300 lb. of Pennsylvania bituminous coal per hour, a set of paddles lasts here for 1 600–1 700 tons, or about 1 400 working days.

(*Communicated*): From the paper one would consider that the development in the United States is practically entirely confined to the somewhat complex Lopulco system. The self-contained unit systems, however, are being developed in the States and elsewhere just as rapidly. Unit systems are extremely simple in comparison, and must effect a very material saving in capital outlay—both in plant and buildings. A properly designed unit pulverizer will not only pulverize the fuel but will also introduce continuously and uniformly the desired mixture of air and powdered fuel into the furnace. The impression which I formed in the States was that for plants under, say, 10 000 kW no case at all could be made out for the Lopulco system. The following data are for two typical cases where the "Aero" unit system is used.

Kansas City Southern Railway.—This plant comprises a battery of Heine boilers, each rated at 350 h.p. One boiler was at first fitted and, after experience of operation, four other sets have been put in.

PITTSBURG POWER PLANT WITH PULVERIZED FUEL, SEPTEMBER 6, 1922.

Test run (8 a.m. to 4 p.m.)	8 hours
Total coal burned	19 443 lb.
Total water evaporated (actual weight)	157 932 lb.
Average boiler pressure	114·6 lb. (gauge)
Average steam temperature	340° F.
(NOTE.—Superheater was blanked off during test, and while this temperature shows slight superheat it was disregarded in this test—only dry heat assumed.)	
Average feed-water temperature	168·5° F.
Average room temperature	92° F.
Average amperes at pulverizer motor	128
(NOTE.—Motor is a 50-h.p. 50° motor, and at the above load is only 57 % loaded.)	
Average voltage of circuit	220

Analysis of coal burned (on basis of coal as fired):—	
Moisture	1·28 %
Volatile	31·36 %
Fixed carbon	44·54 %
Ash	22·82 %
Sulphur (in volatile percentage)	5·27 %
B.Th.U.	10 953
Factor of evaporation	1·087
Lb. water from and at 212° F.	171 672
Average rating of boiler	177·5 %
Combined efficiency	78·4 %
Lb. water per lb. of coal (from and at 212° F.)	8·8 lb.
Average h.p. (elec.) of pulverizer motor	38
(On basis of 20 lb. steam per horse-power and allowing 5 % line loss, 95 % generator efficiency and 95 % mechanical efficiency.)	
Per cent steam used as generated by boiler at 177·5 % rating	4·1 %
Average CO_2	14·5 %
(No oxygen or CO readings were obtainable on this test.)	
Average fall of draught through boiler	0·15 in. water

The Wheeling Steel Corporation.—The units here are fitted to Connelly boilers. The tests were not special in any way, and the comparison with the stoker-fired adjoining boilers agrees closely with the comparisons made with Dalmarnock and Milwaukee by the author.

Mr. S. L. Pearce: This subject has always had a fascination for me. When I visited the States in 1920, things were just beginning to move; at any rate I had an opportunity of seeing the original plant put in at Oneida-street by Mr. Anderson. Milwaukee—Lakeside—had not started up at that time; it started up a couple of months later. I also had conversations with the chief engineers of the various stations which have been referred to this evening. What seems to me most remarkable is the complete change of opinion which apparently has come about in the States in the matter of pulverized fuel. In 1920 there was hardly an engineer other than Mr. Anderson who had a good word to say for it. To-day the facts speak for themselves. Whatever we may think about the question, several prominent engineers in the States are convinced that there is sufficient in it to warrant them putting down plants. When I came back from America one of the first things I did was to obtain estimates for the application of what are known as the "central" system and the "unit" system to existing plants in Manchester. I was prepared to admit, for the purpose of calculation, that a possible saving of 5 per cent in efficiency was obtainable. But even on that basis, and on the capital estimates submitted, I could make out no case whatever for the application of pulverized fuel to existing plants. Of course at that date the central system, at any rate, was extremely complicated; it involved the installation of a great deal of plant which is now eliminated, and the capital cost was necessarily high. I am prepared to admit that there has been a material improvement in

designs, but I still think that it is very difficult to make out a case for applying a pulverized-fuel installation to existing boiler plant; I am inclined to think that in the majority of cases the capital costs will still outweigh the savings. Therefore I feel that it is essential that the question of pulverized fuel versus mechanical stokers should be tried out if possible on a new job. Without attempting to throw any discredit or doubt upon the figures which have been sent over to this country from America, I should like to see the question settled in a British boiler house with boilers working under identical conditions. I am inclined to agree with the author that the utmost gain we can expect to get from the adoption of pulverized fuel, as compared with the present mechanical appliances, is 5 per cent. I think that is an absolutely outside figure. I see that the Milwaukee results are given as 85–86 per cent. These, I take it, are not the efficiencies for the individual units but the efficiencies for the boiler house as a whole. I think I read in the last publication of the Prime Movers Committee of the National Electric Light Association, U.S.A., that Mr. Anderson claimed that during the last 12 months he

TESTS ON POWDERED COAL AND STOKER-FIRED CONNELLY BOILER AT THE CREEK PLANT OF WHITTAKER-GLESSNER CO.

	Powdered coal	Stoker fired
Date of test	22nd Aug.	23rd Aug.
Fuel-burning equipment	Aero Pulverizer	Underfed Stoker
Heat balance:		
Loss due to moisture in coal	0·22 %	0·24 %
Loss due to burning of hydrogen	4·13 %	4·40 %
Loss due to moisture in air	0·25 %	0·28 %
Loss due to heat in dry flue gases	9·30 %	13·20 %
Loss due to carbon in ash	0·00 %	4·22 %
Loss due to radiation (assumed)	5·00 %	5·00 %
Total loss in heat	18·90 %	27·34 %
Efficiency of boiler and stoker	81·10 %	72·66 %

The heat balance was calculated on the basis of coal analysis as submitted by the Pittsburg Testing Laboratory, viz.:—

		Powdered coal	Stoker fired
Ultimate analysis of coal by weight	Hydrogen	4·74 %	4·72 %
	Carbon	68·08 %	67·84 %
	Nitrogen	1·33 %	1·26 %
	Oxygen	7·07 %	7·19 %
	Sulphur	4·87 %	4·84 %
	Ash	13·91 %	14·15 %
B.Th.U. per lb. dry coal		12 647	12 623
Analysis of ashes:			
	Carbon in ashes	—	29·83 %
	Ash	—	68·22 %
B.Th.U. per lb. dry ashes		—	4 699

The average of the principal results obtained during the test is as follows:—

	Powdered coal	Stoker fired
Total water evaporated, lb. for 24 hours	1 108 756	1 205 000
Total coal used, lb. for 24 hours	105 352	125 567
Equivalent evaporation from and at 212° F. per lb. coal, lb.	11·2	10·2
Boiler efficiency corresponding to above	86·1 %	78·3 %
Average rating developed during test period of 24 hours	172 %	186 %
Flue gas analysis, by volume: CO_2	14·4 %	13·7 %
O_2	4·0 %	4·4 %
N_2	81·6 %	81·9 %
Temperature of feed water	208° F.	212° F.
Temperature of flue gas leaving boiler	470° F.	649° F.
Room temperature	77° F.	85° F.
Average steam pressure (gauge)	190 lb.	190 lb.
Average superheat	27 deg. F.	20 deg. F.
Moisture in coal	2·08 %	2·25 %

It will be noted that there is a difference in the figures of efficiency as calculated from water credited as evaporation and as given in the heat balance. These figures are:—

	Powdered coal	Stoker fired
Efficiency from water measure	86·1 %	78·30 %
Efficiency in heat balance	81·1 %	72·56 %
Efficiency difference	5·0 %	5·74 %

had been able to improve the Milwaukee figure from 85 per cent to 88 per cent. I am not quite clear to what he refers. If it means a general boiler-house efficiency of 88 per cent it is truly an astonishing figure. If, on the other hand, it refers to individual boiler units, we might expect that the general boiler-house efficiency would be as high as 85 or 86 per cent. I want to compare that with the results which we are getting at Barton to-day. We have had given to us in the paper the figure from Dalmarnock, which is taken as a typical modern station. It is 76·5 per cent, with a 34 per cent load factor. I should say, first, that the guarantee we have got from the boiler manufacturers for individual units at Barton is 85 per cent on full load. Whether we shall get that figure or not I am not at present in a position to say. What I can say is this, that the average boiler-house efficiencies, week in, week out, vary from 81 to 82 per cent. That means there is an improvement of at least 5 per cent over Glasgow. I understood the author to say that the figure for Connors Creek was 75 per cent, and that there was an American station which showed 81 per cent; perhaps it was Delaware. The point I want to make is that the Barton results of 81–82 per cent (and we have had a week with 82·5 per cent, and I think that even that figure is capable of improvement) apparently set up a new standard, at any rate for British boiler-house practice. These results have been obtained with coal of a calorific value of 11 000 B.Th.U.'s and a 45 per cent load factor. In passing, I should like to refer to the Vitry (Paris) figures. They seem to be remarkable. How much of it is due to pulverized fuel I cannot say. The boilers are easily the largest in Europe, judged from the evaporation point of view. On the other hand, the heating surface of the Vitry boilers including economizers is about 1 400 sq. ft. less than that of the Barton boilers. Their evaporation is 140 580 lb. with 12 000 B.Th.U. coal, against the Barton figure of 100 000 lb. with 10 000 B.Th.U. coal. Even making the correction for the higher calorific value, the greater output of the Vitry boilers compared with Barton will be seen. This problem of pulverized fuel is divisible into two parts, the question of preparation machinery and the question of combustion. I am inclined to agree with the author that we need not trouble ourselves very much about the preparation of the plant: I think that problem is solved; but in regard to the question of combustion, success can only be obtained by correct design of the furnace. In that respect one is very interested to hear what the author has had to say about the necessity for adopting the circulating-water screen and the hollow side-walls and bottoms of the furnaces. In connection with a proposal which I made to the boiler makers at one of our stations in Manchester, I put forward this circulating-water screen arrangement, and asked for their opinion. They were decidedly opposed to it, and went so far as to suggest that they did not think a boiler insurance company would insure a boiler with that attachment. When it was pointed out to them that the design was identical with one of those in successful operation in the States, as shown on the screen to-night, it made no difference to their view. This subject is of far too great importance to power station engineers to admit of any unfair or too critical attitude. Savings in power station costs are mainly to be made in the boiler house. I think everybody will agree with that. Therefore we have got to keep an open mind on this question, and I appeal to the boiler and stoker manufacturers, and to all interested, to approach these questions in a proper and progressive spirit. If a case can be made out for pulverized fuel in this country, whichever method is adopted, either the central or the unit system, I hope that no hostile interest will be allowed to stand in the way of its adoption. I have seen some very bad examples of what can take place through slagging resulting from incorrect design of ash chambers; and I emphasize this, that the combustion end of the problem is the serious one that wants tackling.

Mr. W. Eccles: On pages 402 and 403 it is stated that under most modern conditions pulverized fuel is working at 86 per cent efficiency and mechanical stoking at 81½ per cent efficiency; and that the resultant saving of 5¼ per cent in the coal bill is due to pulverized fuel. This may or may not be correct, but the figures given for Lakeside and Dalmarnock most certainly do not uphold the statement. According to the table given on page 403 the maximum efficiency of Lakeside is at about 170 per cent rating. At full load the average efficiency is 88·5 per cent, and it drops to about 86 per cent at the long overload rating. The only corresponding figures for Dalmarnock are those given on page 401, and of these only the balanced-draught test is a fair but very unsatisfactory comparison. I say "fair" because balanced draught is a standard method of operation, and "unsatisfactory" because a 3-hour boiler test cannot be a reliable one for efficiency. However, as the author has left me no other choice, I must take the efficiency for mechanical stoking as 83·5 per cent. This shows the Lakeside plant to be from 2·5 to 5 per cent more efficient than the Dalmarnock plant, which approximately corresponds to the author's comparative statement of efficiency figures which I have just mentioned. I should like, however, to draw attention to the fact that this difference in efficiency has nothing at all to do with pulverized

	Lakeside	Dalmarnock	Efficiency in favour of Lakeside
(1) Combustible in ash	5 %	Negligible	0·55 %
(2) Per cent of CO_2	14·6 %	14·5 %	+ 0·05 %
(3) Extra power required	100 b.h.p.	—	— 0·8 %
(4) Coal required for drying *	1 %	—	— 1 %

* The coal required for drying might fairly be neglected as this drying is done by flue gases in the more recent plants.

fuel; in fact, on examining the test figures on pages 401 and 404 (Test No. 2) it will be seen that if Lakeside had been fitted with the Dalmarnock stokers and burning Dalmarnock coal a higher efficiency would have been obtained than was actually done with the pulverized fuel used. Let us first take the factors directly affected by the method of stoking, which are as stated in the table on page 443. These figures show that the method of stoking at Dalmarnock is more efficient than that at Lakeside. The reason that the overall boiler-plant efficiency shows Lakeside to be a better plant than Dalmarnock is clearly seen from the following factors, which are not affected by the method of stoking:—

	Lakeside	Dalmarnock	Efficiency in favour of Lakeside
(1) Chimney gas CO_2	11·9 % *	14·5 %	(Included in temperature correction)
(2) Chimney gas temperature	196° F.	414° F.	+ 4 %

* The drop in the amount of CO_2 at Lakeside from 14·6 to 11·9 per cent indicates a leakage of air into the boiler of approximately 0·30 per cent of the air required for combustion, a state of affairs which should be explained especially in view of the stress laid on the importance of keeping down the excess air to a minimum.

This temperature difference is partly accounted for by the air leakage and completely when the following comparative facts are noted for the same B.Th.U.'s transferred:—

	Lakeside	Dalmarnock
Feed water temp. ..	129° F.	158° F.
Boiler heating-surface ..	165 sq. ft.	100 sq. ft.
Economizer surface ..	125 sq. ft.	100 sq. ft.

Summarized, the facts are:—

	Per cent
Comparative loss at Lakeside due to pulverized-fuel firing	1·3
Comparative loss at Dalmarnock due to remainder of plant	4
Net gain of Lakeside over Dalmarnock..	2·7

This very closely approximates to the difference in efficiencies (87·1 %–83·56 %) when allowance is made for the extra power required by Lakeside.

Is there any need to explain further the reason why Lakeside is more efficient than Dalmarnock? The Lakeside boiler is obviously more expensive than the Dalmarnock boiler, and this brings me to the point that it is not thermal efficiency that matters, for that can usually be improved by buying more expensive plant; but the point is, what efficiency does it pay to buy? I have no doubt it paid Lakeside, on their 60 per cent load factor, to buy 87 per cent, nor do I doubt that on their 34 per cent load factor Dalmarnock were justified in buying 83·5 per cent. One small point which I noticed in going through these figures, is that the air leakage at Lakeside, between the furnace and the chimney, amounts to about 30 per cent. There does not seem much object in reducing the excess air to 22 per cent at the expense of brickwork troubles, etc., when it might as well have been 50 per cent if the leaks were stopped, without reducing the efficiency of the plant. I come now to the author's conclusions on page 416.

Efficiency.—I hope that his opinions here are based on something better than the figures which he has submitted; otherwise the case for pulverizing falls rather flat on the grounds of efficiency. Personally I feel that there is some extra efficiency to be gained by pulverizing, but the facts presented by the author do not prove it, although he claims 5¼ per cent on this account. In view of this miscalculation I do not see how we can possibly accept the statement that under ordinary conditions the saving would be 9 to 10 per cent and in most existing stations 15 to 20 per cent, and I think that we must agree that in this respect the author's case is not proven.

Unburnt fuel in the ash.—Again the Dalmarnock and Lakeside figures are contrary to the claims made, but it is possible that with a fusible ash the pulverized fuel might prove to cause the lesser loss.

Stand-by and banking losses.—This is a 2 to 5 per cent gain for pulverizing, but why? I cannot see any particular reason one way or the other, when all the dampers are closed. Can the author give us any comparative figures on this point? No doubt heat can be lost by careless banking, but we are comparing good practice in each case.

Ease of scientific control.—This apparently implies central control by a highly-skilled person who has long-distance CO_2 and temperature indicators besides him; and although a great deal more could be done in this direction with mechanical stokers than is done at present, it is possible that pulverized fuel lends itself more readily to this than do mechanical stokers.

Labour costs.—I do not understand how it can be that under similar conditions there is less labour involved in pulverized-fuel plant than in stoker plant. Water, coal (apart from pulverizing), ash and fan services require the same attendance in each case, and surely a chain-grate stoker cannot require more attendance than a pulverizing mill and drier. Again it seems to be a case of capital expenditure versus labour.

Auxiliary power consumption.—Here again the feed water, coal- and ash-conveying and fan services are common to both systems and the power for pulverizing must be in excess of that required to drive stokers. Naturally, if the amount of power required is expressed as a percentage of the total boiler output, it is a very

small amount; but my point is that the pulverized-fuel plant requires more power than the stoker plant.

Maintenance costs.—I note and agree that it is usually very difficult to get such information for comparison, but in this respect I have in my possession complete detailed costs for each piece of apparatus in a station, including—general; brickwork; stoker; soot blower; piping and valves; forced-draught fan and ducts, etc.; economizer; induced-draught fans; coal bunkers; ash hoppers, etc., for the year 1922, of a similar large station in America using mechanical stoking; and whilst I feel that I am not at liberty to publish this information without referring to the manager concerned, I have no doubt that permission could be obtained if the author would produce similar detailed costs for a pulverized-fuel plant, such as Lakeside, which he refers to on page 396 as being "run on thoroughly modern and scientific lines both of control and costing."

Ash troubles.—I note that, according to the tests mentioned, Lakeside apparently discharges from 30 to 50 per cent of the total ash, and at Dalmarnock about 30 to 45 per cent of estimated ash seems to be unaccounted for.

Capital costs.—Here again I think that the author is very optimistic as regards pulverized fuel, but I think he need not have been so vague in the matter, for the bill for material, different in each case, could easily have been stated, from which it could have been seen how he arrived at his statements.

Mr. E. H. Hutchinson: The title of this paper is rather misleading; it should rather be a description of the Lopulco system, and it would have been interesting to hear something about other well-known systems of pulverized coal, such as that of the Powdered Fuel Co., Ltd., the Holbeck Engineering Co., Messrs. Alfred Herbert, Ltd., Messrs. Fraser & Chalmers, Ltd., and the Société Anonyme pour l'Utilisation des Combustibles of Paris, with whom are associated Simon-Carves Ltd. of Manchester. The plants installed by the last-named company have a capacity of $1\frac{1}{4}$ million tons of coal per annum. It is rather surprising that the author should lay so much stress upon American figures when this French Company already have over 100 pulverized-fuel plants at work in France, of which 60 are applied to boilers. I might mention the plant installed by them at the Citroën motor-car works in Paris. These works were fitted up with pulverized-fuel apparatus by this French Company, and during the war they were pulverizing lignite and peat, with which mixture they were firing the whole of their boilers and reheating furnaces dealing with billets up to 5 in. square. Another example is that of the Mines de Bruay in the North of France, where they have installed a central power station from which electric current is supplied to outlying districts extending as far as Calais, which is some 80 miles distant. Here there are two boiler houses, each having a battery of 16 boilers. Considerable trouble was experienced with the refuse coal that had to be burned and the Bruay Company experimented with every kind of mechanical stoker and chain grate and also designed stokers of their own, but in no case were the results satisfactory. Ultimately it was decided to experiment with pulverized fuel on one boiler only, by means of a unit machine. The results obtained from this one boiler were so satisfactory that one battery of 16 boilers was equipped with a central pulverizing plant. At this colliery there are two boiler houses - one equipped with mechanical grates and stokers and the other with the Simon-Carves system of pulverized-fuel firing and for the same quantity and quality of coal burned the boiler house fitted with pulverized fuel produces 50 per cent more evaporation, the coal burnt containing 25 per cent of ash. The results from this boiler house have been so efficient that the Bruay Company have recently placed an order with this French Company to equip 8 new large water-tube boilers at the same colliery, with another central pulverizing plant. Another installation just carried out by this French Company is a central pulverizing plant for the Cie des Mines d'Anzin, having a capacity of 42 tons per hour, and I think it will be agreed that this is by no means a small plant. I might mention also a central pulverizing plant installed at the Cie du Nord-Ouest Electrique (Centrale d'Abbeville), dealing with 12 tons of coal per hour. Why is it that we do not see a single Lopulco plant at work either in this country or in France? I think that Mr. Bell stated last week that with the extension of the pulverized-fuel plant recently installed a saving of about £5 000 had been effected at Hammersmith after working the boilers 9 months. That is a statement of fact and should be considered very carefully because, although the author talks of efficiencies, he has given no figures as to the actual savings effected in the plants mentioned by him. Another point that requires careful consideration is the water screen used with the Lopulco system to prevent the ash slagging. With the earlier pulverized-fuel plants considerable trouble was experienced owing to the fused ash having a deteriorating effect on the brickwork of the combustion chamber. The patent combustion chamber and ash pit used with the Simon-Carves system of pulverized fuel has obviated all difficulties. With this system about 40 per cent of the ash is fused, flows down the sides of the combustion chamber and is cooled whilst falling into the ash pit, and does not adhere to the brickwork of the combustion chamber in any way. The ash pit only requires clearing about once in 6 hours, and the slag taken out occupies about one-tenth the volume as compared with the clinker taken from chain-grate stokers; or, in other words, for every 10 trams of clinker from chain-grate stokers we get about 1 tram from pulverized fuel. The brickwork of the combustion chamber is a very important point, and the above French Company have experimented for some years in order to find a brick that would resist the fluxing action of the slag, and they now use such a brick which has a melting point in the neighbourhood of 3 350° to 3 400° F. I have seen combustion chambers which have been in continuous use for 18 months and are in almost as good a condition as when they were first started up. If, as the author says, in the Lopulco system the ash is brought down in dust, it would appear that the greater part of the ash in the coal cannot be fused. In a combustion chamber fired with pulverized fuel with a sufficiently high temperature, there is a fused ash deposit all over the combustion chamber, not only on the bottom but on the sides, and

it is difficult to understand why, if the ash is fused, the sides of the combustion chamber used in the Lopulco system should not have a deposit of fused ash on them. I think that the author gives the temperature in the combustion chamber of the Lopulco system as about 2 100° F. With the Simon-Carves system the temperature in the combustion chamber is about 2 700°–2 800° F. A temperature difference of 700 degrees F. must have a remarkable effect on the efficiency of the boiler. It has been proved by experience that the efficiency of the boiler itself is much higher with pulverized fuel, and this is shown by the fact that the degree of superheat is much lower and the temperature of the waste gases entering the economizer is about 90–100 degrees F. lower, as compared with a boiler fired by mechanical stokers or grates. In my opinion, boilers fired with chain-grate stokers leave much to be desired as regards efficiency, when we consider that in firing a boiler fitted with chain-grate stokers we have only a certain time in which the coal may be burned, and in order to burn the coal in the time available we require an induced-draught fan giving a suction of $1\frac{3}{4}$ in. to $2\frac{1}{2}$ in. With this high suction a large volume of air at a very high velocity is pulled through the fire (in fact, far too much air) with a consequent reduction in temperature and percentage of CO_2. I think that if we take many of the power stations in this country we shall find that the percentage of CO_2 in boilers fitted with chain-grate stokers over a month (not 8 hours or 24 hours) is somewhere in the neighbourhood of 7 to 8 per cent, and not 14 to 15 per cent as is obtained continuously with boilers fired with pulverized fuel. With the Simon-Carves system of pulverized fuel a suction of only $\cdot 1\frac{1}{2}$ in. to $\frac{3}{10}$ in. water gauge is required, and it is partly due to this low suction that so very little dust is emitted from the chimney. To any one conversant with the handling of air and gas and the collection of dust, the dust difficulty could easily be overcome, and it is quite possible to install a plant with a guarantee that not more than 5 per cent of the dust would be discharged from the chimney. The bulk of the dust produced with the Simon-Carves pulverized-fuel plant never reaches the chimney, but is caught in hoppers in the economizers and the main flues. As to the question of power absorbed by central pulverizing plants, this is considerably lower as compared with boilers fitted with chain-grate stokers and balanced draught. In one particular case dealing with a plant of four boilers each evaporating 50 000 lb. of water per hour, there was a saving in running costs of 80 h.p. per hour. The author does not refer to the unit type of pulverizer. Although more costly in power this type has certain advantages over the central plant, in that the fuel does not require drying. In a well-designed machine, coal containing 10 per cent of free moisture can be pulverized, and this has been done in this country. In one plant fitted with unit machines the saving of coal per boiler, compared with others fitted with chain-grate stokers, is 25 to 30 tons per week. The author states that the unit machine is not capable of fine regulation. This machine is, however, being applied very extensively to metallurgical furnaces, which require a much finer control than a boiler plant. We have reheating furnaces at work with pulverized fuel with an output of 40 tons per hour.

Mr. T. R. Wollaston: I am not a believer in firing boilers direct with coal, which I think we must now agree is more or less crude, nor yet with pulverized coal, which is, however, a step in the right direction; I hold that raw coal should be turned into the ideal fuel, viz. gas. The author and other speakers have suggested as good practice 50 per cent excess air and 12 per cent CO_2 when working with ordinary stokers; and it has been stated that with pulverized fuel one can work with 20 per cent excess air and something like 14 or 15 per cent CO_2. I know from long experience that with gas one can work with no excess air, and it can be done continuously with from $17\frac{1}{2}$ to 18 per cent CO_2 in chimney gas. Some few years ago —about 1917, I think—several papers were written touching upon boiler firing by recovery gas. We have heard to-night that all these remarkable results have been obtained with pulverized fuel within the last four or five years. Certainly the progress is wonderful, but there has also been considerable progress in connection with gas firing. I hope that I shall not appear to be arrogant in claiming to have proved, upon a sufficiently large scale, advances in producer-gas firing potentially as great as those accomplished with pulverized fuel. Five years ago one could regard the recovery gas producer as capable of working at less than 70 per cent thermal efficiency (cold gas) and the gas-fired boiler as at 82 per cent efficiency, an all-round thermal efficiency of under 60 per cent. To-day these figures might be 80 per cent (cold gas) efficiency for the producer and probably 92 per cent for the gas-fired boiler, an all-round efficiency of at least 73 per cent for the combination. These combined efficiencies are below those which the author has given us, but one would ask: Do we want high thermal efficiencies wholly for scientific reasons or mainly as a means towards generating electrical energy at the lowest possible cost? The general public is more concerned with cost. The author has mentioned some remarkable points in pulverized-fuel firing as regards, for instance, ease, certainty, and consistency of handling and burning, range and condition of raw material, facility for remote control, cleanliness, and so on. I say with conviction that gas firing possesses these features in a much greater degree. I believe that there are three all-important conditions in the choice of site for a power station:—(1) Cheap central location. (2) Abundant cold water supply. (3) Easy access for fuel. As water can be piped over long distances comparatively cheaply it may be regarded as being the least important. I would point out that gas can be piped even more cheaply, particularly if the mains be laid simultaneously, so that with gas firing, coal delivery, storage and handling may be centralized miles away from the boiler house. The latter may be as clean, light and open as the turbine house, and there will be no smoke, grit or ash handling. I have been much encouraged to-night in noting the boiler house sections including pulverizing and storage plant as shown on the author's slides. I roughly estimate that with gas-fired boilers every one of these boiler houses would be reduced in cross-sectional area (or cubic content)

by at least 50 per cent, and the capital cost in even greater proportion, due to reduced excavation and foundation work. In short I think that the total capital cost of a gas-fired boiler house with remote gas plant and gas mains would not greatly exceed that of the stations shown on the slides, and that the running costs, having in view the use of the cheapest fuels, would not be higher. So far I have not referred to by-product recovery, which may safely be regarded as showing a net rebate of 4s. per ton of coal. I am now engaged upon a careful analysis of the subject, the results of which I hope shortly to publish. My case is that, had the same skill and energy been given to producer-gas firing during the last 10 years as has been given to the utilization of pulverized fuel, the former would have shown results in every way more economical, hygienic and scientific.

Alderman W. Walker: I agree with Mr. Pearce that everything on this important subject of pulverized fuel should be received not with hostility but with an earnest desire to learn what has been done and what are the results. I had not read the paper very far, however, before a feeling of opposition was aroused, because it was borne in upon me that the paper did not deal with the burning of pulverized fuel as a principle or as a general system, but merely with one particular method. It would have been better if the author had obtained information as to what other people in the United States have been doing and what other plants have been installed, rather than confine himself to one type only. I think that if he had put before us the advantages of pulverized fuel in general, explained the principal systems, how and where they differed and what he considered to be the strong and weak points of each, so as to assist us to come to a decision on the matter, the paper would have been more valuable. He suggests the idea all through the paper that there is no other method than the particular one to which he has confined his remarks. We have to consider one point in connection with this system which will be likely to cause a lot of trouble to power stations in this country, namely, the question of the disposal of the ashes from the chimney. Taking the higher figure on one of the slides which the author has shown to-night, it would mean that 50 per cent of the ash would go up the chimney, and, taking the lower figure, it would be 25 per cent. Remembering the situation of a large number of the power stations, can we consider depositing anything approaching 25 or 30 per cent of the ash from the chimney without at once causing trouble with the local authorities, complaints from the residents of the district, and applications for injunctions to stop it? That is one of the points which will have to be faced in connection with the system. I notice that on page 385 the author refers to the unit system, which he says is not applicable to large plants. I should like to know something about that. I find on making inquiry that there are quite a number of other plants at work and that those who have them are quite satisfied. I do not think, therefore, that the other methods ought to be turned down as has been done by the author on page 385, because information could have been obtained from the users and makers of these, both in the United States and elsewhere, just as easily as from those who are putting forward the one system described. In addition to the single plant which he says is being installed in France, there are already 40 or 50 plants of other makers installed. I hope that the author will give us through the Institution or through some technical paper a description and figures which will enable us to judge what are the advantages and disadvantages of the various systems of burning pulverized fuel.

Mr. A. Stubbs (*communicated*): Facts of a divergent nature are placed side by side in the paper whilst the obvious inferences are far from being substantiated. The Lopulco system as described appears to be the outcome of a certain amount of "dog logic." "Dog logic" results in action being taken on the spur of the moment without reference to many of the surrounding factors. The system provides for what looks like an overgrown furnace with mechanical stoker removed, and this development has presented difficulties of wall temperatures and ash disposal. Air cooling for the walls and a water screen for the ashes readily provides the solution, but the plant has a very makeshift appearance. It is easy to imagine that a more general survey would have resulted in a different arrangement, e.g. it might be possible to arrange the boiler surface like the surface of a truncated cone or the walls of a blast furnace and, should it be necessary to have refractory material to give the high-temperature radiation in order to support combustion, this would be suitably placed. The feature to be brought out is that any such outlook must involve the boiler manufacture and the combustion engineers. Co-operation between these two parties is not particularly evidenced by the Lopulco system. Boiler construction is so far from being standardized to-day that it does seem possible that users may be able in the future to buy units of surface capable of being arranged in any manner to suit the particular problem, which would of course leave the initiative largely in the hands of the combustion engineers. The list of plants installing pulverized-fuel equipment, as published by the Combustion Engineering Co., makes it very obvious that there must be some advantage. I have looked for this in the paper, but much of the talk regarding efficiency is like that of the misinformed salesman, who will persist in putting forward electricity on the score of efficiency even in those instances where no case could be made. The really important features are lost sight of because of his anxiety to stress the question of efficiency. The facility of control is probably one of the most important features of a pulverized-fuel plant. It would be very desirable to be able to govern the prime-mover output by means of the fuel valve rather than by the steam valves. I would ask the author whether the Lopulco system provides for the fuel to be shut off in emergency and at the same time for water to be supplied to the furnace instead. The question of control is the more important the larger the plant. I understand that some months ago water sprays were being fitted over the underfeed stokers for use in emergency at Gennevilliers. Referring to the author's statement of advantages up to the year 1920 (page 389):—

(1) Efficiency figures mean very little, for we can obviously get anything we wish by paying for it, and indeed the figures for pulverized-fuel plant seem to be low compared with those now being mentioned in connection with plants in this country. I was recently concerned with tests on a number of 30 000-lb. boilers in which the efficiency was 85·3 per cent. Certain boiler plants with mechanical stokers and air-heaters on the North-East Coast are stated to be capable of running at 86 per cent, whilst when visiting the Gennevilliers station I was told that the Stirling boilers were operating at 88 per cent.

(2) It is now the usual practice to return the riddling for combustion in connection with mechanical stokers.

(3) The high temperature of the flame seems to be a disadvantage so far as the walls and the ash problem are concerned. I should like to ask the author whether it has been considered to take air from the cooling towers for combustion in order to keep the temperature down. Water injection was put forward with internal-combustion engines for similar reasons.

(4) The transport question is increased with the pulverizing plant, but the convenience within the boiler house is probably greater. The Lopulco system, however, still provides for massive bunkers which obstruct the light and increase the cost.

(5) Whilst there would seem to be considerable scope for pulverizing under this heading, it does, however, seem that different coal requires different treatment. Some inconvenience was experienced at Gennevilliers with the mechanical stokers when the Ruhr coal supplies were cut off and it became necessary to get coal from Scotland, Wales and elsewhere.

(6) and (7) are probably notable advantages to be obtained by using pulverized fuel.

(8) There appears to be some doubt as to ease of scientific control as shown in the remarks under heading (6) on page 390, although it is difficult to see why this should be.

Disadvantages up to 1920.

(1) Any of the figures here quoted for the cost of preparation when made as a charge against the efficiency of the pulverized-fuel plant would be sufficient to condemn it upon this score.

(3) The cooling of the furnace by inlet air as now put forward is obviously inefficient, as this heat should be derived from a low-temperature source and not from the highest temperature of the system. Such practice limits the possibilities in connection with preheating the air by the chimney gases or exhaust steam, etc. Every temperature-rise of 100 degrees F. on the chimney temperature means reducing the efficiency by 4 per cent.

(7) The lighting system as invented by Prof. Thornton for use in coal mines might be of interest to the advocates of pulverized fuel. This system provides for electric lighting from a fairly high-frequency supply (approximately 160 cycles) at a reasonably low voltage, and it is claimed that it is quite proof against any possibility of causing an explosion.

(8) It appears that any hope of being able to pulverize with a higher degree of moisture content in the coal must be discounted on account of the danger from spontaneous combustion.

(9) More will be heard of the ash problem when pulverized fuel is introduced into the large English cities. Recently one of the large London stations operating with mechanical stokers had an injunction issued against them by the people on the opposite side of the Thames, and necessary action had to be taken in order to prevent the ash passing through the chimneys.

On page 392 there seems to be a point worthy of some considerable notice, namely, that the Lakeside station was completed and put in operation within 12 months. Similar progress on the civil engineering work on this side of the Atlantic does not appear to be usual. With regard to the Dalmarnock figures, I should like to ask the author whether he is in a position to state that with the two types of stokers in operation at this station, there is 4 to 5 per cent difference in the efficiency of the plant.

[The author's reply to this discussion will be found on page 460.]

North-Eastern Centre, at Newcastle, 14 January, 1924.

Mr. J. W. Jackson: The supply undertaking with which I am associated agree in general with the remarks made by the author under the heading of "Boiler Plant Efficiency." We have been able since early in 1920 to make investigations for ourselves with a powdered-fuel plant on one 20 000-lb.-per-hour boiler burning a very low-grade fuel. This fuel is so difficult to handle that with some types of chain-grate stokers it is commercially impossible; but with a pulverized-fuel plant the burning of the fuel is quite easy. The boiler subjected to this treatment gives the maximum evaporation of any of the 12 boilers installed in the station, while its maintenance charges both in the furnace and mechanically are considerably lower than those of the ordinary chain-grate stoker. The efficiency and heat transference are at least as high under commercial operation as it is usual to obtain with a boiler of this type and size under chain-grate-stoker conditions on official tests where the manufacturers' representatives are required to secure the guaranteed efficiency. Although on many boiler trials efficiencies as high as 83 and 84 per cent have been claimed for boiler and economizer, we are at the same time quite satisfied that the author is much too generous towards the chain-grate stoker in Table 2, when he admits that 5 per cent of travelling-grate stokers under service conditions may reach 81·9 per cent. efficiency, while in the second column he points out that 85 per cent of boilers may be showing a working effici-

ency of 69·2 per cent. We, on the other hand, express the opinion that the efficiency of the finest and best-manufactured chain-grate-stoker plants under service conditions does not exceed 73 per cent for boiler and economizer, and in the majority of plants is as low as 65 per cent. As already indicated, we secure under commercial operation the high efficiency of approximately 83 per cent, it being very easy to secure a CO_2 reading in the boiler exit gases of 16 per cent with just a trace of combustible gas, and the temperature of the exit gases is on the average 50 degrees F. lower than that of a chain-grate stoker when dealing with the same load. Any station engineer admitting the presence of a large amount of CO_2 in the exit gases of a chain-grate-fired boiler would know, or would very quickly know if he attempted to continue this for more than three or four hours at a time, that the furnace arches would be quite unable to carry their own weight, even where the arches are ventilated, owing to the high temperature to which the brickwork was subjected, and, further, that the metal of the grate would become so hot that operation would be uncomfortable and would lead to early breakdown and acute wear. The plant with which we have been experimenting is of the single-unit type and deals with about 30 tons of fuel per 24-hour day. We find it possible to deal with coal containing as much as 5 per cent of moisture. The manufacturers claim 7 per cent. We can say quite definitely, however, that if 4 per cent of moisture is exceeded the output of the plant is noticeably affected. We are, however, in a peculiar position in that our plant is close to a colliery. The coal is crushed on the power station site and is normally delivered quite dry so that it is quite possible for us, even under difficult conditions, to get all the coal into our bunkers with no more than 1 or 2 per cent of moisture. We agree that the pulverized-fuel system gives great flexibility as regards variety of coal. In our case, however, we find that with a lower grade of fuel there is a tendency for the ash to be deposited on the walls of the furnace and then, when a change with a higher-grade fuel is made, for the ash to be melted off, fall to the bottom of the furnace in a liquid state, and come down sometimes at a greater rate than will enable it to be conveniently dealt with as molten slag, thus causing choking. Even then, the question of handling ash under these conditions on a submerged conveyer is preferable to that of dealing with clinker under similar commercial conditions from travelling-grate stokers on the pneumatic ash-handling system. We normally run our pulverizer on full load and we seldom desire to run it at anything else. During about $3\frac{1}{2}$ years' operation we have not lost one boiler tube. We know, however, that it is quite easy to run the pulverizer at half load and secure good conditions. We also find that stand-by and banking losses are greatly reduced. It is a simple matter to shut the plant down and put it on load again. This cuts out the expensive banking arrangements that are so necessary on travelling-grate stokers. To get our plant on load, we have a torch made of asbestos mounted on the end of a pipe. To this pipe is connected a paraffin supply. Just before starting up the plant, the torch is lighted and placed in the coal stream. The plant is then started up and after about 7–15 minutes, depending upon the grade of coal and its state of dryness, the boiler is able to support combustion, and in less than 5 minutes from that time the furnace has attained full heat. We are of the opinion that it is possible for one man properly to supervise a very much larger steam output from a pulverized-fuel plant than with travelling-grate stokers. There are no furnace slides to slice and keep in order, no gears to grease, no back ends to dump and, in fact, no laborious work whatever in the boiler house. The figures given under the heading of "Power Consumption in the Proportion of the Fuel" appear to us to be abnormally high, as our charges for pulverizing and getting the fuel into the boiler amount to 10d. per ton. We think that it would be more economical to dry fuel before it is put into the furnace, than to pass it into the furnace in a wet state and evaporate the moisture there. It would be interesting to hear what boiler manufacturers have to say as to the treatment to which boilers are sometimes subjected when coal burnt under them contains a high percentage of moisture. In our experience with pulverized fuel, which extends over a period approaching four years, we have been able to carry a load approaching 15 per cent higher on the pulverized-fuel-plant boiler than on other boilers in the station, while some of the travelling-grate stokers are only able to deal with 60 per cent of their normal rating. Provided the dust-fuel plant is considered in the way which it should be and all pipes are properly jointed, the pulverized-fuel plant can be kept in every way as clean as any other plant, and we think that there are no difficulties whatever in the way of preventing this plant from being kept as clean as any other. As regards proper temperature control, the important point to aim at appears to us to be that the furnace must be of very large capacity in relation to the size of the boiler; it is then as easy to regulate the temperature and other conditions as any stoking arrangements can be. We understand that special precautions have to be taken to prevent the danger of explosions with pulverized fuel. We should like to hear what the author has to say under this heading. As may be surmised from the statements already made on the single-unit plant, we have never had the slightest sign of an explosion, or apparently any danger of one. If we withdraw the asbestos-paraffin torch from the furnace before the furnace has got sufficiently warmed up, we have found over and over again that the fire goes out and will not restart itself even when continuously supplied with dust fuel and air in apparently a correct explosive mixture. Our difficulty therefore is to obtain ignition. The author states that it is not convenient to store coal in a pulverized state to a depth of more than 5 or 6 ft. This is about half the depth to which it is safe to store ordinary rough small coal, whether in bunkers or in heaps in the open. We should like the author to confirm this figure. When this plant was first installed, we had trouble due to the dust adhering to the boiler tubes. These boilers being of the horizontal type naturally allow the dust to accumulate very readily. It is probable that the vertical type of boiler would be much more desirable from this point of view. We, however, installed a dust-blowing plant and by turning on the

steam and blowing the dust clear we are able to keep the boiler in a far better condition than is the case with average boilers fired by other methods. The figures for capital costs put forward by the author are very much higher than those with which we have had to deal. On the single-unit plant we find that the capital costs were on the right side compared with stoker gears. The pulverizer to give a duty of 30 tons per 24 hours cost £1 725 at the beginning of 1920, and an electric motor to drive it cost £90. Costs have, of course, been very much reduced since then. We agree with the author that cast-iron economizers are the best. On page 394, the author deals with the question of firing the powdered coal to the bins. We have heard tales of the pipes choking up, thus allowing the fires to go out and, when they have been got away, of the danger of explosions, and the author further points out that the coal is now delivered to the bins by means of screw conveyers. We should be glad to know whether the author thinks that there is any truth in these reports. On the same page he deals with the question of hollow air-column furnace walls. We should be glad to have some details as to the manner in which the air is caused to circulate and whether auxiliary fans are required to force the air in; also what percentage of the total air used for combustion in the furnace is circulated in this manner. We should also be glad if the author would say in his reply if the single-unit plant at Vitry is being installed for each boiler, and, if so, what are the reasons that have led to its adoption. On page 403 the author refers to the high efficiency of 81 per cent, which includes the comparatively heavy stand-by and banking-up losses. We are of the opinion that such a figure as this is quite unattainable. On the same page he sets out the reasons why pulverized fuel gives the decidedly higher efficiency. Among other things, it appears to us to be due to the fact that furnaces are now designed to have a very large capacity, and when a piece of coal 1 cubic inch in size is broken down to pass through a 100-mesh screen and so becomes one million cubes of coal, it will naturally be exposed and so can be brought into contact with the air that is available for combustion much more quickly and readily than can possibly be the case with the travelling-grate stoker. The idea in the past seems to have been to make the furnace as small as possible and to keep the tubes as near to the fire grate as to allow of barely working clearance. Travelling-grate stokers have progressed somewhat since then, but furnaces are still very small. On page 405 the author refers to the unburnt fuel in the ash. Our own experience fully confirms the statement made, that the carbon contained in the ash can be kept to, say, 1 or 2 per cent of fuel contained in the ash. In the succeeding paragraph the author deals with the question of riddlings from travelling-grate stokers. On some such stokers the percentage of riddlings has amounted to as much as 35 per cent of the total coal fired. In the last paragraph on page 405 the author states that mechanical stokers are largely dependent within fine limits on coal of good quality. We would add that some stokers are more dependent than others. On page 414 the author refers to the necessity of using distilled water as far as possible to secure reliability of service. Plants that use distilled water from service condensers are kept in reasonably good order. We have had experience with feed-water evaporators for a period of many years and have found them of great benefit. On the same page the author refers to the risk of the coal taking fire in the horizontal type of revolving drier. We have heard of fires taking place inside the tube mill and of the mill being stopped with the idea of putting out the fire, but before the fire could be got under control the entire mill had collapsed. This would seem to require some explanation.

Dr. J. T. Dunn: I am particularly interested in the circumstance that the very complete installation at Lakeside has been designed as the result of careful scientific investigation into the question. Lakeside is not the first power station of the Milwaukee Electric Railway Co. They had before that a station in Oneida-street, part of which, not originally designed for powdered-fuel firing, was altered and adapted for it. The working of powdered fuel there was subjected to continual close observation and record, and to scientific variations of conditions; and it is as the result of these careful experiments that the Lakeside power station has from its beginning proved such a complete success. Take, for example, the matter of grinding. It used to be stated in the early days of powdered-fuel firing that it was necessary to grind the fuel until at least 95 per cent of it would pass a 100-mesh sieve, and 85 per cent a 200-mesh sieve. This was the usual grinding at Oneida-street; but several tests were run in which the percentages passing a 100-mesh sieve varied from 93 to 89, and those passing a 200-mesh sieve from 70 to 64. With this fuel the efficiency of the boiler and the completeness of the combustion were not distinguishable from the results attained with the normal grinding. The importance of this is seen when we consider the power required for fine grinding. In a number of experiments with the Raymond pulverizer, the ratio of the power required to pulverize a given quantity of coal, first so that the percentages passing the 100-mesh and the 200-mesh screen were 99 and 95, and next 95 and 82, varied with the different sizes of machine from 1·3 to 1·65; and Mr. Atkinson, of the Powdered Fuel Plant Co., found with another type of machine that it required $1\frac{1}{2}$ times as much power to get the percentages 96 and 82, as it did to get 94 and 75. Again, in the matter of drying it was formerly believed that it was necessary to dry the coal down to about 1·5 per cent of moisture, in order to get good results. But at Oneida-street, where the coal was usually dried down to 1·5 to 3·5 per cent, a number of tests were run with the undried coal containing 7·7–8·2 per cent of moisture. In these cases the combustion was quite as complete as with the dried coal, and the loss of efficiency amounted to about 0·7 per cent, a quantity corresponding almost exactly to the amount of heat theoretically needed for the evaporation of the additional moisture. As far as the economy of evaporation goes, it would seem to be more economical thus to evaporate the surplus moisture in the furnace than to use a drier, for the efficiency of the rotary drier at Oneida-street was found to be not more than 25 per cent; but there are, as the author

points out, other considerations, which, in some cases at least, make it advisable to dry the coal. The early driers were all of the rotary type, using a coal-fired furnace to dry the coal, and for the most part a fan to draw the necessary air through the drier. They formed a weak spot in the installation, because without careful and constant supervision there was always the possibility of the coal becoming overheated and either firing or losing some of its volatile combustible constituents. Of late these driers are being superseded by gravity driers similar to that described by the author. These are heated by the flue gases themselves on their way to the stack, and not only prevent the danger of fire or loss just mentioned but also save the whole of the coal (amounting to 1 to 1·5 per cent of the coal dried—say 2 000 tons at Lakeside during the period March 1921 to May 1922, mentioned by the author) used in the furnace of the rotary drier. Experience has shown that the danger of fire or explosion is negligibly small if reasonable care is taken in working. Practically all the explosions which did occur in the earlier days were due either to great carelessness or to want of thought, or occurred in experimental work. Mr. Jackson has told us how difficult he found it, not only to explode but also to ignite his mixture of powdered coal and air; and although it is true that the powdered coal which he uses has so much ash and hence so little volatile matter in it that it approaches the composition of those coal dusts which are allowed to lie on the roadways and on the walls of coal-mine workings, yet the same thing has been shown to be true with coals that are much more readily combustible. I agree with the author as to the confusion which exists due to the lack of definiteness in the expression of units in records of numerical tests. It is greatly to be desired that the use of the so-called "net" or "lower" calorific value of combustibles should disappear, for it has no useful significance. I would go further than the author here, and say that we shall never have satisfaction in this respect until our cumbrous British units have disappeared and all our records are kept in metric units. The author refers to the radiation from the heated particles of ash in the furnace. This is really an important aid to the ready transmission of heat to the boiler tubes; and where blast-furnace gas is used along with powdered coal, as in the large Ford installation described in the paper, and as at the Park Gate steel-works at Rotherham on a small scale, the transmission of heat from the blast-furnace gases is found to be sensibly increased by the presence at the same time of the ignited powdered fuel. In regard to no-load losses, there is a very interesting record from the Oneida-street tests, in which the boiler ceased work at 9 p.m. and work was not resumed until 7 a.m. the next day. The loss of pressure during that time was only from 175 to 155, or 20 lb. per sq. inch, although between 9 p.m. and 11 p.m. the safety valve was released for 15 separate minutes. A great deal has been made of the nuisance caused by the ash from powdered-fuel installations, and of the difficulty of dealing with it. At Lakeside and in other installations this difficulty has been altogether overcome; and in different ways, as Mr. Jackson has stated, the same difficulties have been surmounted elsewhere. Where a large quantity of the ash escapes from the chimney it is in such an extremely minute state of division that it falls exceedingly slowly, and is distributed by the natural currents in the air over such a wide surface before it reaches the earth that it is never discoverable. The emission of this fine dust from a chimney is entirely different from the emission of grits (even though these may be completely burnt) such as are ejected from the chimney in the case of mechanical-stoker firing, and the dimensions of which are enormously greater than those of the particles of ash from powdered fuel.

Mr. A. R. Clemitson: If the system of powdered fuel becomes established in this country then mechanical stokers will not be required, and while water-tube boilers with horizontal tubes may be used with this system it is obvious that its application is more readily adapted to vertical-tube boilers. As the correctness of figures is so important in making comparisons of efficiency I should like to draw the author's attention to the following: In Table 7, Test 1, the efficiency of boiler and superheater is stated to be 83·3 per cent and with the economizer 86·3 per cent, a difference of only 3 per cent, while the temperature of the gases leaving the boiler are 434° F. and after the economizer 168° F. This drop in temperature should account for about three times the above difference. In Table 8, test 1, item 36, the temperature of the gases leaving the boiler is given as 434° F. and entering the economizer 338° F. What is the reason for this big loss, as apparently the gases enter the economizer immediately after leaving the boiler? In item 38 the temperature of the gases leaving the economizer is very low and in one case only 168° F. If this is correct what effect has this low temperature on the economizer tubes, and does the moisture present any difficulty? On page 400 attention is drawn to the enormous size of the combustion chamber required for powdered fuel, and it is stated that at least 1 cubic foot of space is required for every 3 lb. of coal burnt per hour. This figure appears to be a very conservative one and provides a combustion chamber area very little larger than should be provided in a well-designed chamber with mechanical stokers. I should have considered that 0·8 to 1 cubic foot per pound of coal would have been more desirable. On page 405 the author points out that a high percentage of CO_2 can be obtained with powdered fuel, "which means a continual high temperature of combustion averaging over 2 000° F.", but surely he does not consider this temperature high for powdered fuel, as it would be considered low for mechanical stokers and could not give the high-efficiency results claimed for either system. The figure should be nearer 3 000° F. The author has made out a very good case for powdered fuel, and against the many advantages of this system the only extra cost is the power required for crushing the coal. The principle of admitting air through the brick walls is a good one as it must increase the life of the brickwork while at the same time reducing the radiation losses and adding considerably to efficient combustion. This method could not be so satisfactorily applied to mechanical stokers. With reference to the drying of coal, it would appear to be a more reasonable method to remove

the moisture outside the furnace than within. In the latter case it is evaporated by the heat from the coal and goes away with the gases as superheated steam which is all lost heat. The system of drying the coal with waste gases adds considerably to the overall efficiency of the plant and eliminates the dangers of some of the other methods of drying. The utilization of waste gases for heating the air for mechanical stokers has been applied, but it cannot be considered to be a great success with most stokers as the burning of the bars is excessive. The trouble with ash from the chimney and the large amount of dust which finds its way into the boiler tubes requires consideration. No doubt some form of collector could be satisfactorily arranged in the chimney, if necessary, but it is not likely that there will be more trouble from this than in the case of mechanical stokers, where a great deal of grit and smuts is emitted from the chimney. I do not readily understand the author's preference for the central system over the unit system. With the latter the capital cost is much less and brings it into favourable comparison with mechanical stokers, while the dangers from explosions and fires would be entirely eliminated. While it may be contended that the danger from this source with the central system is not frequent, yet it should not exist at all if it can be readily avoided, as it can be in the unit system. It is a much simpler arrangement to deliver the powdered fuel direct to the boiler, as in the case of the unit system, than to pass it through a separator, then into a bunker and then to feed it into the boiler, an arrangement which is unnecessarily complicated. I should be glad if the author would state whether coke alone can be used with the Lopulco system; whether the system has been adapted for boilers on board ship; and whether it is suitable for this purpose. The desirability of coming to the right decision on this subject is most important and it is unfortunate that we have not a national system to investigate these methods, as it is only by extensive tests with coal used in this country that we can expect to find the best system for our own particular use.

[The author's reply to this discussion will be found on page 460.]

East Midland Sub-Centre, at Loughborough, 29 January, 1924.

Mr. E. G. Phillips: I should like to know if means have now been provided to prevent the pulverized coal from taking on the "liquid" form and passing through the feeding screw conveyers as though no impediment existed. In the cement industry, where this class of fuel has been used for 20 years, this trouble occurs without warning. I have known everything to work satisfactorily for months, and then suddenly, without any apparent reason, the whole of a 50- or a 100-ton bunker will be emptied in a few minutes by the whole of the material passing through and over the screw and dumping itself on the ground. Has the graduated pitch of the conveyers shown on the screen been designed to overcome this trouble? In view of the entire absence of any British information, I should like to know if the author can give any information of the one fairly large pulverizing plant in this country, i.e. Hammersmith, which has now been running for a sufficient period for some data to be available.

Mr. T. P. Wilmshurst: I am disappointed that the author refers to only one system of burning pulverized fuel and confines himself to very large plants, whereas plants of, say, 20 000 to 40 000 kW are much more common in this country. I consider that the comparison of the large boiler plants at Rouge River and Lakeside with their boilers of 26 470 and 13 060 sq. ft. heating surface respectively, with the Dalmarnock boilers of 6 948 sq. ft. is hardly fair; further, the American coal contained 12 000 to 13 000 B.Th.U.'s as against Scotch coal of 9 900 B.Th.U.'s. There is also the difference in the combustion chambers and the use of preheated air to consider. I should prefer to hear less of the overall efficiency of the boiler, and more of the total commercial cost of running per unit generated or sent out—such figures to include all capital charges and the cost of running auxiliaries. I recognize the excellent features of the pulverized-fuel plant, and have a perfectly open mind. In this connection I may say that in Derby we shall shortly put down two or three large boilers, each of 60 000 to 80 000 lb. evaporation, and any thoroughly commercial scheme will receive the most careful consideration.

Mr. G. H. Rutland: Can the author give any information as to the application of the pulverized-fuel system to marine work? I believe that experiments were made some years ago. The fuel was, I think, pulverized on shore and stored on the ship. This necessitated special bunkers and I believe that the fuel absorbed moisture from the air and clogged in the conveying system. With regard to the question of the wear on the burners, there must be a good deal of grinding action and it would seem that the smaller portions of the burners would rapidly enlarge and so lead to inefficient burning of the fuel. I raise this point after experience with unfiltered oil in oil-fired boilers. In this case the wear due to grit in the oil rapidly throws the burner out of adjustment when the high-pressure system is used. The question of the ash ejected as dust would appear to be worth considering. We know that even an impalpable powder can be used in some grinding processes, and surely the fine ash that is ejected into the air may cause trouble in other works' plants if not in the immediate vicinity of the station. With oil-fired boilers we are sometimes troubled with what is called the organ-pipe effect. A pulsation in the air admitted to the furnace sets up powerful vibrations in the whole of the gases in the combustion space and uptakes. A small change in the oil or in the uptake or in the amount of air may or may not stop the trouble. As the pulverized system of firing is very analogous to the oil-fuel system, I should like to know if any similar effect has been noticed with this system. If it did occur the vibrations would possibly have a very serious effect on the water screen which is a feature of the

Lopulco system, especially if the period of the screen were in tune with that of the air. The size of the boilers used to generate the power is spoken of with pride, but I would suggest that there seems to be a good deal of space wasted. In marine practice it is common to find boilers which can deliver 43 000 h.p. at the shafts, together with all their fuel and water pumps, forced-draught fans, etc., stowed in a total space of 100 ft. × 29 ft. × 18 ft. Site value should be worth considering and, in my opinion, steps should be taken to see what economies in space could be made with power station plant.

Mr. F. Nicholls: In his comparison of Lakeside and Dalmarnock the author gives the difference in the average CO_2 percentage obtaining in the flue gases as 15 to 17 per cent at Lakeside and 10 per cent at Dalmarnock, and I would suggest that the large difference is due not so much to using powdered fuel as to the much larger combustion chambers in use. Operating engineers in this country know that with the mechanical stoker when aiming for more than 13 to 14 per cent CO_2 there is danger of CO formation and consequent loss of temperature and efficiency, and I suggest that without pulverizing, given greater combustion space, the correct fusion of air and combustible would take place before striking the tube surfaces, as is at present the case. Preheating the air supply at Lakeside is an added factor towards its higher efficiency, and it would appear that boiler-makers in this country will have to tackle this question, as it is certain that higher temperatures can be used. I was particularly interested in the final exit gas temperatures obtaining at Lakeside, and on one test the figure of 168° F. struck me as being remarkably low for the corresponding water temperature. I should be glad if the author would state the size of economizers in use in America. One great advantage of powdered-fuel firing would appear to be the quick response to any alteration in conditions, also the ease of control of excess air admission, thus following on the lines of oil-fuel firing. I would suggest that the comparatively low efficiency figure quoted by the author for boiler plants in this country, viz. 69 per cent, is largely due to scale formation in tubes, and that the more extended use of distilling plants for making up losses will obviate this with a consequent increase in efficiency.

Mr. S. J. R. Allwood: Owing to the inability to obtain the desired superheat with the usual type of integral superheater, there has been designed a radiant-heat superheater in the form of cast-steel headers built in the furnace wall. I should like to know if the author has had any experience of these, and, if so, what kind of trouble is experienced with them. I suggest that the water screen, unless particular attention be given to the purity of the water, introduces a very weak point in the boiler. I consider that the author has made out a very good case for the efficiency and flexibility of this method of firing, but not so convincing a one on the question of the comparative cost.

Mr. D. Rushworth: On page 393 the author refers to the question of steel versus cast-iron fuel economizers. In this connection Sir James Kemnal at the London meeting said that in his opinion "the cast-iron economizer has been an excellent servant, but the pressures that are common nowadays render it less suitable." Also, "there are too many cases of cast-iron economizers being replaced by steel economizers for the author's assertion to be taken as representing altogether the facts of the present day." Speaking as an engineer who has had 38 years' practical experience with the Green-type cast-iron fuel economizer, I agree entirely with the author's statement and disagree with Sir James Kemnal's remarks. In the first place it would be interesting to know why the important power stations run by the Corporations of Birmingham and Leicester should have decided within the past few months to install cast iron as a protection against the corrosion which has taken place with the steel-tube economizers of which they have had experience. I could give numerous instances of steel tubes having failed after a few years' working. As the author points out, cast-iron economizers can now be made to withstand the highest pressures, thanks to improvements in their construction, either by the method advocated by the author or in the method of manufacture. It is without doubt that cast iron has proved to be superior to any other material for economizer construction, and economizers have been known to be in service after working 35 years: no steel economizer could lay claim to such a record.

Mr. J. Cauthery: The figures of running efficiency obtained at Lakeside are certainly very remarkable, and are a challenge to the mechanical stoker. It is, however, necessary to have, as pointed out by Mr. Wilmshurst, figures showing the price at which this efficiency has been obtained, with all costs and charges taken into consideration. Reliability—by which is meant freedom from breakdown and continuity of running—comes first, and it is desirable that more and fuller particulars should be given on this point. The author mentions a boiler being run for 9 months on end with pulverized fuel at the Ford works. Is such a run a common feature with boilers fired by powdered-fuel plants, or is it a sort of feat and so not to be taken as an average? Having regard to the number of stages through which the fuel has to go before it is ready to be blown into the furnace, and the mechanisms and storages on the way, it would seem that in the nature of things there must be a greater liability of breakdown at one point or another than with mechanical stokers. The water screens may increase the possibility of trouble by overheating, contraction and expansion, and it would be well to know if any trouble has resulted from them. The rupture of one of these tubes and the sudden emptying of one of these mammoth boilers might result in a considerable disaster. The last word has not yet been said with regard to the mechanical stoker. Test efficiencies of 85 to 87 per cent have been obtained with them, and there seems no reason why with the improvements now being made a much higher day-in and day-out efficiency should not be obtained.

Professor C. H. Bulleid: I should be glad if the author would give some information as to the application of the system to small stations and small boilers. In the aggregate these account for a very large part of the total amount of coal burnt per annum. With

regard to the fine ash blown out of the top of the chimney, whilst agreeing that it is not an immediate nuisance I should like some information as to its ultimate effect on vegetation, and should be interested to know if it chokes up rain-water spouting. In connection with the trouble found in connection with the fusing of the ash, is it not possible to make a virtue of necessity and arrange that the ash should fuse completely and should then be run out through a slag hole?

[The author's reply to this discussion will be found on page 460.]

South Midland Centre, at Birmingham, 30 January, 1924.

Mr. F. Forrest: The undoubted success which has attended the use of pulverized fuel for the firing of steam boilers is really due partly to the pulverizing of the fuel and partly to the large combustion chamber which it has been found desirable to install when using this class of fuel. In Table 2 the author is rather unfair to the mechanical stoker, in so far as he has compared the results obtained when using pulverized fuel in an ample combustion chamber, with those obtained on the old type of mechanical stokers having cramped combustion chambers. It would be interesting if he could give results obtained with pulverized fuel used on a boiler fitted with smaller combustion chambers of the size usually put in when mechanical stokers are used, so as to show to what extent efficiency depends upon furnace design and to what extent it depends upon pulverizing. This question of large combustion space has not hitherto received the attention that it deserves, and I suggest that every boiler installation should be compared on the basis of the cubic feet of combustion-chamber space provided for each pound of coal fired to the grate per hour; in other words, we should compare the space provided for the complete combustion of a certain quantity of gas per hour in the two systems respectively. The following figures obtained from various large power stations using water-tube boilers fitted with mechanical stokers show how this figure varies in this country and abroad:—

	Lb. of coal burnt per hour per cubic foot of combustion space
Average British practice	3·6 to 6·2
Dunston (Yarrow boiler)	3·5
Gennevilliers (Paris)	1·93 to 3·05
Philadelphia (U.S.A.)	1·22
Calumet (U.S.A.)	1·52

With pulverized-fuel plants the figures are as follows:—

	Lb. per cubic foot
Lakeside (U.S.A.)	0·85 to 1·39
River Rouge (Ford)	1·49
Figure recommended by Kreisinger .	1·0 to 1·5
Maximum recommended by author .	3·0

The compartment type of mechanical stoker is a very great improvement on anything produced hitherto, and such a stoker combined with ample combustion space would give a flexibility in the choice of fuel and a furnace efficiency approaching that obtained with pulverized fuel. With such a stoker full duty has been easily obtainable with gasworks coke-dust burnt alone, the fuel having a calorific value of about 10 000 B.Th.U.'s per lb., with only 5 per cent of volatile matter. The author does not state to what extent the size and cost of boiler-house building would have to be increased in order to accommodate the pulverized-fuel plant, as compared with the figures for mechanical-stoker plant. It seems to me that a larger and more expensive building would be necessary with the former, and this additional capital expenditure should be taken into account when comparing the total cost of steam generated in the boiler house with the two systems. The highest boiler-house efficiency is not, however, the only consideration. What is of greater importance is the lowest cost of steam per unit generated, including all fuel costs, operating and maintenance costs, and capital charges. With ordinary unwashed slack coal at less than 15s. per ton delivered, it would be very difficult to make out a case for a pulverizing plant, but the burning of more expensive fuels in pulverized form would probably show a saving over the usual method of burning it on mechanical stokers. Can the author mention a really satisfactory CO_2 indicator or recorder for use in the boiler house? We have tried in Birmingham almost every type made, and the only one that is at all satisfactory from the point of view of continued accuracy and with the minimum of time-lag between taking the sample and indicating the result, is the electrical type of indicator produced by the Cambridge and Paul Instrument Company, and even this requires further improvement before it can be regarded as an accurate and robust boiler-house instrument.

Mr. F. C. Platt: In Great Britain we appear to lack courage in the steam-raising department, although in the engine room we have not hesitated to keep well up to the practice of less conservative countries. We cling to the comparatively small boiler, and rows of such boilers with their attendant ranges of steam and feed piping are necessary to make provision for the large steam demand in a modern station. We should strive to replace all these small units with large units capable of being kept under steam for very long periods, and sufficiently reliable to be kept in commission from one annual inspection to another without serious breakdown. The problem of firing such boilers seems to call for drastic action. In my opinion, to ensure the reliability and length of operation previously mentioned we must, for one thing, get rid of the ponderous mass of machinery which mechanical stoking involves. Even our comparatively small boilers, evaporating, say, 50 000 lb. per hour, require the chain-grate stoker to be divided into three parts, whilst the somewhat larger boilers at Gennevilliers have to be fired from both sides. With pulverized fuel vast quantities of heat can be generated in the combustion chamber of the boiler, with an entire absence of machinery at the boiler itself.

Perry, in his book on "The Steam Engine and Gas and Oil Engines" (1904), states that "the fixed carbon needs to be scrubbed with air." With the mechanical stoker we are accustomed to burn very finely divided coal, and the quality known as "washed fine" is very popular. Here is an attempt to utilize the idea outlined by Perry, but with pulverized fuel we can achieve in a practically perfect manner the scrubbing of each particle of fuel with air. An important aspect of pulverizing plant is that it can be worked at a load factor irrespective of the boiler load factor at any given time, i.e. the load factor of the pulverizer plant is independent, within limits, of the load factor of the boiler which it serves. The amount of storage capacity would also give a 10–15 hour period for repairs to be made to the pulverizing plant, whereas if the mechanical stoker is not in operation there is no steam. The objection on the score of fine ash emitted from the chimneys of boilers using pulverized fuel is of little moment, as far worse results are obtained with chain-grate stokers burning fine slacks. In one plant under my charge, one chimney discharging gases from two 20 000-lb.-per-hour boilers, which work at full load only for an eight-hour day, has rendered necessary the cleaning out of all the gutters in an extensive area of roof adjacent to the power station, after the short interval of five weeks.

Dr. W. Lulofs: The general impression which I have gained is that the author exaggerates the advantages and attributes to powdered fuel virtues which it cannot strictly claim. The manner in which he attempts to prove the superiority of the powdered fuel system over the chain-grate stoker by comparing the practical results obtained in various stations is open to criticism. A direct comparison of the nature of the two systems leads more directly to the same results. Bearing in mind that the combustion of the coal is merely a chemical reaction between the oxygen of the air and the carbon, hydrogen, etc., of the coal, the conditions under which this chemical process takes place must be far less ideal in the case of the mechanical stoker. As the coal burns away steadily on the mechanical chain grate while it is being carried through the furnace, leaving only the ash at the end, the thickness of the layer of coal along the grate gradually diminishes towards the back and the quality of the fuel diminishes correspondingly. The effect of this is—assuming an equal draught over the whole stoker—that the ratio of quantity of air per lb. of combustible matter varies considerably along the grate, causing an excess of air at the end of the stoker. In addition, the stoker at this end has to deal with very inferior quality of coal containing no volatile constituent, and an increasing percentage of ash, theoretically up to 100 per cent. This results in a low percentage of CO_2 at this end of the stoker (on an average not more than 5 per cent) and a great difficulty in burning the coal completely. There are thus two sources of loss. First, the uneven distribution of air makes it impossible to run at a high average of CO_2 without CO; indeed, this is the explanation of the fact that, as mentioned by the author, with the mechanical stoker not more than 13–14 per cent of CO_2 can be obtained without CO, whereas with powdered fuel 16–17 per cent may be obtained. The other loss is a certain percentage of carbon left in the ash, also due to the cooling effect which the boiler has on the grate, 5 per cent of carbon on an average being a low figure. Owing to the defects inherent to the mechanical stoker much skill is required to operate it efficiently, and the extra attendance necessary adds to the loss. In addition, there are extra stand-by and starting-up losses on account of the lack of adaptability of the chain-grate stoker to variations in the load and the considerable period that elapses from starting up to an efficient running condition. The manufacturers of chain-grate stokers have brought out devices to counteract these defects. In consequence the compartment stoker has been evolved which allows for the regulation of the air, in sections, underneath the stoker. This enables the amount of air per lb. of fuel to be regulated throughout the length of the stoker. Adjustable dumping bars or dams have been designed in order to bank up the fuel at the back of the stoker, thus causing a thicker layer and by this means decreasing the excess of air. A back arch has been constructed for increasing the temperature in order to assist the combustion of this poor fuel. Although improvements have thus been obtained, they have tended to camouflage rather than eliminate the original defects, and therefore the system of powdered-fuel firing remains superior. On the other hand, the advantages of powdered fuel over chain-grate firing are not so considerable as to cause existing chain-grate stokers to be completely superseded, especially as the changing over to powdered fuel would necessitate a much larger combustion chamber and therefore a complete re-setting of the boilers. In view of the enormous number of chain-grate stokers in daily use it may prove of value to point out how the adoption of powdered fuel in combination with existing mechanical stokers can reduce the above-mentioned principal defects and so bring the mechanical stoker more up to the standard of powdered-fuel firing. At the same time this combination may overcome some of the difficulties met with in the latter method of firing. The Underfeed Stoker Company have effected this combination by inserting a number of small burners (or jets) of powdered fuel at the back of the stoker in such a manner that a row of small flames from these burners is directed almost parallel to the mechanical grate but pointing slightly towards it. This results in three distinct advantages over the mechanical stoker alone, viz. (A) increased efficiency, (B) increased boiler evaporation, and (C) increased adaptability for a varying load. As regards (A), (1) the row of small flames acts as a perfect form of back arch with all its advantages and none of its disadvantages, especially in respect to the upkeep and repair of brickwork. (2) The amount of excess air at the back of the mechanical stoker is utilized for completing the combustion of this powdered fuel by regulating the amount of air supplied in the mixture to the burners. (3) As the flames from the burners are at right angles to the flames from the mechanical stoker a whirling motion is set up in the combustion chamber and brings the excess air and combustible matter into close contact with one another. As regards (B), increased evaporation is

obtained, due not only to the increased amount of B.Th.U.'s set free from the combustion of the powdered fuel but also to a higher temperature in the combustion chamber. In addition, more fuel can be burnt per sq. ft. of grate surface. The boiler is enabled to absorb these extra B.Th.U.'s because of this higher temperature, which also accounts for the fact that the temperature of the superheated steam is not increased by the higher temperature in the combustion chamber. Actual tests have proved that with a 20 per cent increased evaporation the rise in temperature of the exit gases from the economizer was practically negligible. A 30 per cent increase of evaporation was reached but could not be continued because the boiler commenced to prime. As regards (C), by this means the evaporation can be instantaneously adjusted by regulating the supply of powdered fuel, and further, the boiler takes considerably less time to start up because the powdered-fuel flames, once started, raise the temperature of the brickwork and the combustion chamber very rapidly. On the other hand the mechanical stoker will assist the powdered-fuel firing, because the ignition is always certain and because the ash from the latter falls on to the mechanical stoker which then removes it. It will be obvious from (B) and (C) above that the adoption of powdered fuel has the further advantage that the steam production of an existing boiler house may be thus increased without any extension of boilers being necessary. In this connection I should like to mention a further advantage of powdered fuel in general which the author does not appear to emphasize sufficiently. The development of station design tends towards the use of ever-increasing sizes of boiler units, and the bigger the boiler the greater the difficulty of supplying adequate grate surface (which I regard as the heating surface of the boiler). One of the many things which one is taught in theory and discovers later to be wrong in practice is the manner of describing the various functions of the different parts of which a boiler unit is composed. In my opinion the boiler proper has only a cooling surface, the heating surface of the boiler being the grate surface and, therefore, for a certain boiler the heating surface must be such that it can produce that number of heat units which that particular boiler is capable of absorbing. Since the number of heat units which a square foot of grate surface can liberate is limited, there must be a fixed proportion between boiler cooling-surface and grate heating-surface. Where the cooling surface of the boiler is not, as is the grate surface, restricted to the floor space, it is obvious that by increasing the cooling surface of the boiler the difficulty of providing adequate heating surface increases accordingly and is ultimately insurmountable. Here the adoption of powdered fuel comes to the rescue. First, the heating surface is now no longer restricted to floor space and can therefore keep step with the increase in cooling surface of the boiler; and, secondly, the temperature of the combustion chamber can be raised through which the cooling surface of the boiler becomes more efficient, which means that for a certain duty the dimensions of the boiler unit can be decreased.

Mr. W. Wilson: The system of pulverized firing described by the author is interesting for several reasons. The process seems to be very well thought-out and to be in every part exactly suited for its functions. The pulverizing of a soft material such as coal, even to the fineness of a 200-mesh screen, need not be an expensive matter if suitable apparatus is employed, as is instanced by the economy of the cyanide process for the extraction of gold from quartz. The roller mill and conical separator employed in the plant described in the paper remind me forcibly of the usual apparatus employed in the case of the gold ores; and the method exhibits every probability of doing the work efficiently and economically. The beauty of the pulverizing principle is that it converts the fuel into a form that can be treated as a gas and can be consumed in a Bunsen burner. The completeness of the combustion obtained by the latter device is proverbial, and should render it possible for this mode of boiler firing to achieve maximum efficiency. It is not unnatural that such a method has not been developed in this country, since good coal is available for practically every power station. In some countries, however, lignite and other poor forms of coal are the rule rather than the exception, and under these conditions pulverized combustion will show to greater advantage. In this connection I should like to ask the author if peat has been so treated, as there are large and valuable deposits of this fuel in Scotland that should be open for utilization in this form. Two of the drawbacks of the system that have been mentioned do not appear to me to be serious. It is not correct to say that powdered coal is explosive, at any rate in the same way as gunpowder. The coal needs to be mixed with air before an explosion is possible, and it is only necessary to prevent leakage of the powdered material in order to render it safe. Ordinary wheat flour suffers from exactly the same drawback, and serious explosions have been caused in the past by carelessness in handling it. Finally, ash in the chimney gases should not be troublesome in practice, since the particles of coal are already reduced to a fineness of about 1/200 in., and after they have been burnt all but between 2 and 5 per cent is removed in the majority of coals. Thus the resultant particles should not be larger than about 1/1 000 in., a size comparable with that of the motes which are seen floating in every sunbeam.

Mr. C. H. Petford: The author refers to the great difficulties in the way of comparing two entirely different systems of firing, i.e. pulverized fuel and mechanical stoking. In view of this statement it is surprising to find that he has rather added to the difficulty of comparison by dealing with English test-results in English units and with American test-results in American units. I consider that the author could have made Table 9 much clearer if, instead of dealing with the operating costs of the American plant in American units, he had applied English rates of wages as are at present being paid in this country. He should have had no difficulty in this direction with his knowledge of the class of man required to carry out the various classes of work demanded on a pulverized-fuel station. Had this been done, a direct comparison of labour charges on the two different systems of firing would have resulted, and it would have brought to light a point which requires

some little explanation, for in Table 9 the author gives the pulverizer-house operating charges as 18·8 cents per American ton (this includes all conveyer attendance, etc.) and on page 410 it is stated that 0·465 dollar per American ton corresponds to 25d. per English ton, on the basis of American wages, and that this would equal 14d. per English ton on the basis of English wages. 18·8 cents per American ton on the American wage basis would then be equal to 5·66d. per English ton on the basis of English wages by the author's own method of comparison. If this cost of coal-handling is compared with the coal-handling charges for Dalmarnock referred to in Table 16, one sees that for Dalmarnock for the month of March 1923, over which period a little more fuel was handled than referred to with regard to the American pulverizer-house charges—therefore forming a fairly rational comparison—the coal-handling plant-operating charges were 0·0052d. per unit delivered, and, by calculation from the other data given in the table, the fuel-handling charges at Dalmarnock become equivalent to 5·87d. per ton, so that it costs more in labour charges for Dalmarnock to unload the fuel and convey it direct to the bunker than it does for the Americans (on the English basis) to unload the fuel, convey it to a coarse coal bunker, grind it, convey it to the powdered-fuel bunker, and from thence to the boilers. This would suggest that there is either something wrong with the systems of handling fuel in this country, or that some satisfactory explanation should be provided. The author's method of comparison on the wage basis is not entirely satisfactory. The average wage for the class of man required in a pulverizer house in this country could, I think, be taken at the outside as 15d. per hour. Working on this basis, complications resulting from rates of exchange and relative wage basis are avoided, and taking from Table 9 that 4 567 hours (total) are worked in the pulverizer house on 13 670 tons (English) then at an average rate of 15d. per hour the pulverizer-house charges in this country would be equal to 5·0d. per ton of fuel handled. This makes the comparison with Dalmarnock considerably worse. The author's statement with regard to the high efficiencies that could be obtained with pulverized-fuel firing is, I think, universally agreed by engineers, but efficiency is only one of the factors necessary for economy and in many cases the straining after the higher efficiencies often results in lowering the overall economy, due to additional charges. Here we have less charges and higher efficiency, however, but I fail to see how the handling charges of the fuel for the many operations required in the pulverizing plant can be less than the charges for direct conveyance to bunker. Dealing with fine ash blown into the atmosphere, the author states on page 415 that on the average about 17½ per cent of the ash seems to be discharged from the chimney top. On this basis, then, Dalmarnock for the month of March, 1923, with powdered-fuel plant installed would have sent out about 360 tons of fine dust into the atmosphere, and, although it may be in the state of a fine powder, I am afraid that the medical authorities in this country would not look upon it with favour. I cannot altogether agree with his statement that there should be no more difficulty in preventing the emission of this fine ash from the chimney than with any other method of firing, for I think that the very fineness of the particles will in itself increase the difficulty of trapping it. With regard to the statement that on the recent careful test in the United States it was discovered that with mechanical stoking no less than an equivalent of 3 per cent of the coal fire was discharged from the chimney top, it seems difficult to believe that such a thing could possibly be taking place in this country, for 3 per cent with a fuel which contained on analysis 15 per cent of ash would mean that 20 per cent of the ash was ejected to the atmosphere, in this case in the form of detectable grits. With regard to furnace brickwork, it would be interesting to know what is the relative cost of the brickwork in a pulverized-fuel plant as compared with that used in mechanical-stoking practice. The initial cost in the former, due to its considerable size and possibly special bricks, will be high, and, although it may last for three years without any renewals, what will the cost of such renewals be? It would appear that in the long run the renewals will be a much more expensive item than is at present the case with mechanical stokers.

[The author's reply to this discussion will be found on page 460.]

North Midland Centre, at Leeds, 5 February, 1924.

Mr. M. Wadeson: Although the author gives the reasons why he has dealt only with the Lopulco system, I think that the value of the paper would have been increased if a description of other pulverized-fuel systems had been included. There is no doubt that pulverized fuel can be most efficient; combustion is, after all, a chemical process, and no effort to combine a solid and a gas can be so efficient as when the former is reduced to an impalpable powder. Moreover, the large combustion chamber is a further factor tending to efficiency, but efficiencies equivalent to that obtained by the use of pulverized fuel can be obtained, and already have been obtained, by other methods, e.g. the gasification of the fuel before burning. The author states that the paper is essentially a comparison between a pulverized-fuel station and a mechanical-stoker station. He has taken Dalmarnock because he was able to get the figures for that station, but Dalmarnock has not the highest boiler-house efficiency of stations in the United Kingdom. Many details of the process of pulverized fuel can be applied to mechanical stoking, e.g. as the heating of air and the use of a large combustion chamber, and I think that the adoption of such portions of the pulverized-coal process will undoubtedly raise the efficiency of mechanical stoking somewhere in the neighbourhood of the pulverized-fuel process. The author mentions that only 5 per cent of the stations in the British Isles had an efficiency of over 75 per cent, but I am of the opinion that this is a low figure. He gives 85 per cent as the realized efficiency

for pulverized fuel, and quotes high guaranteed figures which have not yet been realized. As he points out, however, efficiency is not the only factor. I take it that the author does not suggest that the power stations in the British Isles should scrap their plant, but rather that pulverization should be adopted in the new stations where circumstances warrant. As to its adoption in new stations, it would depend entirely on whether the stations were of sufficient size to warrant the use of pulverized fuel, and also on other questions in connection with it. The author states that the actual costs are considerably greater in small stations. That must be obvious, as is shown at the end of the paper where the height of the boiler house in one station is given as equivalent to the total height of the chimney in the other. The height of the chimney in the pulverized-fuel station is about 2¾ times the height of the chimney in the mechanical-stoker station. The author states that the drying temperature is regulated at 215° F. I should like to know how that regulation is carried out. If the boiler is forced, the temperature of the exit flue gases will be higher and more air will have to be admitted to bring down the temperature to the requisite amount. I believe it to be a fact that fine dust accumulates in the boiler tubes, and it is often of advantage to use a dust blower at frequent intervals. The author appears to assume throughout the paper that the British engineer is backward and conservative against his own interests. It is a charge which has been levelled many times. In connection with large turbines I believe it was said that the British engineer was backward and conservative, but I strongly dissent from this view. The British engineer may be cautious, but I do not think that he is over cautious.

Mr. J. W. J. Townley: I do not think that anyone will disagree with the contention that pulverized-fuel firing will give more efficient combustion and can be more easily controlled than any other system of burning coal, but in considering this matter I would suggest that the question is not one of thermal efficiency alone. Thermal efficiency is not necessarily commercial efficiency, and a 1 per cent improvement in boiler thermal efficiency may not be thought worth while when the cost of obtaining this is taken into consideration. The first problem that one usually has to consider is the case of the existing plant and whether it is worth while to change over from stokers to pulverized fuel. I have studied this matter recently, and have considered the conversion to pulverized fuel of a battery of three 35 000 lb.-per-hour boilers. These boilers are equipped with chain-grate stokers and burn a rough slack costing (at present) 17s. per ton. The actual efficiency upon a series of 10-hour tests averaged 81·5 per cent, based on the gross calorific value of the coal as fired. The actual total amount of coal burnt per annum is 18 000 tons, the load factor being 33 per cent. If by the adoption of pulverized-fuel firing we can obtain an increase of 4 per cent in the overall efficiency, then the saving in fuel would be 900 tons, which at 17s. per ton is equivalent to £765 per annum. The cost of a 7-ton-per-hour pulverized-fuel plant (including alterations to combustion chambers) based on recent quotations would be £16 000. Annual charges (interest and sinking fund) assuming a 20-years' life, would be £1 315, or a net extra cost for capital charges alone of £550. The power required by the auxiliaries would be slightly greater for the pulverized-fuel plant but not sufficiently so as to have any material effect upon the above results. Secondly, the case when stoker replacements are due may be considered. The cost of six stokers completely equipped and erected would not exceed £6 500. Annual charges would amount to £535, as compared with the capital charges of £1 315 for the pulverized-fuel plant. The difference, £780, would more than cancel the saving in fuel of £765. It can be seen, however, that in this case there is a very narrow margin, and that the choice of firing plant may be decided by such factors as variability in the quality, low calorific value, and cost of the fuel which is available. It would appear, too, that it is possible to maintain a higher annual efficiency with pulverized-fuel plant than with stoker plant, owing to the ease of control. Most users know only too well the very great difficulty in maintaining a high efficiency of stoker plant at times of light load. I do not agree with the author that the actual cost of current for auxiliaries for the pulverized-fuel plant is the same as that for mechanical stokers. It is generally agreed that the power required for the operation of the pulverizing and drying plant amounts to from 20 to 25 units per ton of fuel. That is equal to 0·55 per cent of the boiler-plant output, assuming 15 lb. of steam per kWh. Comparing this with a forced-draught chain-grate stoker, I find that the forced-draught stoker takes only 3·5 units per ton on normal load, equal to 0·1 per cent of the output, or, allowing for light loads, say 0·15 per cent. The other auxiliaries are common to both systems, although the power required for the induced-draught fans may be considerably reduced owing to the smaller amount of flue gases in the case of fuel firing. Some of the comparisons in the paper are not quite fair; for instance, in the particulars given of the tests made upon the Colfax boiler plant, no reference is made to the fact that this plant is not fitted with economizers, and the comparison between Lakeside and Glasgow is affected by the much lower load factor at Glasgow and the larger heating surface of the Lakeside units. Our principal source of information with regard to pulverized-fuel firing for steam boilers is the United States, but American engineers are not by any means of one mind regarding this method. In a list of 37 plants under construction given in *Power* (31 July, 1923) 29 of these are being fitted with stokers and 8 with pulverized-fuel plant. In the 1923 Report of the Prime Movers' Committee to the National Electric Light Association there is a statement by the Puget Sound Power Company that their pulverized-fuel plant costs 3¼ cents more per 1 000 lb. of steam than another station fitted with chain-grate stokers, although in the case of the former the cost per ton of the fuel used is 29·3 per cent less. They state that the thermal efficiency is higher, but this is offset by the high cost of preparing the fuel and the high maintenance charges on the plant. I do not suggest that this is a representative case, but it shows that there is another side to the question. The adoption of pulverized fuel by the Detroit Edison Company is mentioned in the paper. In this connection I would

refer members to what the chief of the Research Department of the Detroit Edison Company said in a recent paper which was published in *Power*.*

Mr. C. P. Henzell : I am not prepared to quarrel with the efficiencies given in the paper, but the chief point to a station engineer is the question of cost. Efficiency is to be sought for, but the important figure is the cost per unit. I have seen no figures that one could compare in the same way as the efficiency figures. It is stated that one advantage of pulverized fuel is that heavy overloads can be obtained from the boilers. That is all very well at Lakeside or some of the modern plants equipped with evaporators, but in the majority of stations I do not think that that could be done for long periods without causing trouble. The cost of pulverizing seems to vary. Some authorities give it as 3s. per ton, including power, maintenance, etc. Although chain-grate stokers have certain limitations, I do not think that enough attention is given to preparing or selecting the fuel for them. If crushers are installed in order to reduce large coal down to the most suitable size, and suitable sprayers employed for wetting the very fine coals, much better efficiencies would be obtained. With a washed slack, which is, in a way, a prepared coal, excellent results can be obtained on a chain-grate stoker. The figures given for maintenance costs at Lakeside are very good indeed, but it is possible that, after two or three years and with not quite so much skilled attention, these figures might rise. The author mentions the difficulty of obtaining data relative to the maintenance of mechanical stokers. With chain-grate stokers the maintenance cost is approximately 2d. per ton of coal burned. This figure applies to stokers that have been operating for two or three years.

Mr. F. Dransfield : I do not think that the author has been quite fair in comparing Dalmarnock with Lakeside. The exit temperature at Dalmarnock is in the neighbourhood of 400° F., while that at Lakeside is 200° F., which is remarkably low. On a rough calculation the difference means a 5 per cent difference in efficiency. That difference should be credited to the boiler design and not to the pulverized fuel. It therefore brings the Lakeside efficiency down to 81 per cent, which compares reasonably well with the efficiency of a good chain-grate stoker. The author says that the furnace temperature is greater than with stokers. I have taken a great number of tests on furnace temperatures, and I find that the average is in the neighbourhood of 2 500° F. The author gives a figure of 2 000° F. Firebricks of the best grade melt at approximately 3 000° F. If the temperature is increased from 2 500° F. up to, say, 2 800° F. there is a great danger of the firebricks running. This running is accentuated by the fact that some ashes have a tendency to flux the bricks. How does the author propose to get rid of the 20 per cent of ash deposit in the boilers? It is rather unfortunate that the higher the quality of the firebrick the softer it gets. A really high quality of firebrick crumbles in the hands, and there is therefore likely to be a great deal of wastage in the pulverized fuel due to the erosion of the ash, since a great deal of it is blown through the boiler. With regard to water, the author says that a steel economizer cannot be used owing to the corrosive action of the flue gases. I have been studying the water question for two years and my opinion is that the corrosion is mainly due to the dissolved gases in the water. There is, in addition, a little danger from flue gases.

Mr. W. A. Wordley : Representing, as I do, more the industrial works with their smaller plant than the central stations, I am more concerned with the possibilities of pulverized fuel on plants consisting of, say, 2 or 3 Stirling boilers each of 25 000 to 30 000 lb. per hour normal capacity, and with ranges of from 4 to 10 Lancashire boilers each 8 ft. 6 in. × 30 ft., and evaporating 9 000 to 10 000 lb. per hour. The Stirling boilers can no doubt be converted from mechanical firing to pulverized-coal firing and prove very efficient, but is the cost of conversion and running of these smaller plants justified by the increased efficiency? In other words, does the interest on capital invested justify the expenditure? In considering the Lancashire boiler plants one has to decide which type of combustion chamber best meets the requirements, the external (or Dutch oven) or the internal or firebrick-lining type. Personally, I do not think that either type can prove a great success. The former introduces new sources of heat loss and the latter is not, according to the basis of 1 cubic foot per lb. of coal per hour, of sufficient capacity to ensure complete and perfect combustion. With regard to the cost of installing pulverized-fuel equipments on plants such as I have already mentioned, I have come to the conclusion that it is not a commercial proposition. Certain savings in fuel, labour, etc., would probably be effected, but when one compares these credits with the debits represented by running costs, interest, depreciation, etc., one is forced to conclude that good mechanical-stoker firing still holds the field in industrial works' plants.

Mr. L. E. Hendry : How does the author arrive at a really reliable heat balance? It is very unlikely that the same calorific value can be obtained at each test. After sampling coal most carefully in the orthodox manner, and taking two separate samples, I have found as much as 10 per cent difference in the calorific value. These tests were most carefully taken in a properly equipped chemical laboratory and not in one usually attached to an ordinary plant. As regards mechanical stokers on the Babcock and Stirling boilers and induced draught, I have on 8- and 10-hour tests got up to 86 per cent, and on the whole plant on varying types of boilers, induced draught, some of the boilers with economizers and some without economizers, an average efficiency of 76·6 per cent over the whole year, with about 35 per cent load factor, including all losses. The author does not state what system of draught is used on the Lopulco system. I should be glad if he would say how all the foreign matter (bricks, clay, etc.) in coal which is delivered at power stations is got rid of.

Major H. Bell : Many of the speakers in the London discussion seemed to take exception to the attitude taken up by the author, and suggested that he was championing American practice. I, personally, agree with the author in saying that anything which can contribute to our knowledge of the better combustion of

* Vol. 58, No. 5.

fuel is something that must of necessity be to our advantage, no matter in what form it is put before us. Looking generally at the question of powdered fuel, one realizes that the problems in connection with it can be properly divided into two distinct parts, preparation and combustion. Dealing with the latter first, it seems to me that there cannot be very much doubt as to whether it is not better accurately to prepare a fuel so that by the time it is introduced into the furnace it is in a form in which it can be controlled with a very much greater degree of refinement than can ever be the case with solid fuels of such varying ranges of quality and size as we have been subjected to during the last four or five years. From that point of view I feel that the author is no prophet, and that before very long powdered fuel will be a very serious competitor of the mechanical stoker. In 1919, before the operations of that particular Corporation with whose process the author is so familiar, comparatively little had been done, and the tremendous progress which he outlines has all been achieved within the past four years. The designers of the Milwaukee plant, after going all over the Continent with the object of ascertaining which is the most effective and economic way of consuming coal, decided upon the powdered-fuel process. This installation has been followed by a large number of other plants, the most notable possibly being the Ford plant in Detroit, followed by the same firm's Canadian plant at Walkersville, and others too numerous to mention. The process in connection with cement and steel-works is well known, but I should like to know which particular process is the correct one for steam raising. There is undoubtedly a great diversity of opinion about the various components which have to be introduced into a successful pulverized fuel; for instance, as to whether drying should be introduced or not. This seems to turn upon the amount of moisture which has to be dealt with. It is clear, as the author shows, that there are a number of very large plants which have been operating for a considerable time, in most of which drying is a feature. It is equally true to say that there are a number of smaller plants which have been working for years without any drying, and, of course, at first sight it would seem that if one can eliminate this comparatively troublesome component of the scheme something very material has been accomplished in the way of improving the chances of powdered fuel. One of the greatest of the arguments that have been raised against powdered fuel is dust. I am one of those who subscribe to the opinion that we shall be rather troubled in this country in that connection, and I was impressed by the great height of all the American stacks given in the paper. The reason for this is undoubtedly to overcome the very real troubles which we in this country are beginning to experience. At the present time, by reason of both grits and dust, I cannot help thinking that to install powdered fuel with boilers of any magnitude and with the 100 ft. stacks so familiar in Britain would be to court trouble. In conclusion, I should like to ask the author as a specialist just two questions: (1) In his opinion, is it necessary, in all cases, to use driers? (2) To what degree of fineness is it desirable to prepare powdered fuel? Upon the answers to those questions depends very largely the cost of preparing powdered fuel.

[**Mr. E. H. Hutchinson** also took part in the discussion at Leeds. The substance of his remarks was practically the same as in the discussion at Manchester (see page 445)].

Author's Reply to the Discussion.

Mr. D. Brownlie (*in reply*): In the first place I should like to state that it is hopeless for me to attempt to reply in detail to all the points raised. Not only are there 68 speakers, excluding the discussions at Bristol, Sheffield and Dublin of which reports are not available, but many of the contributions are of great length and I estimate that at least 60 different points have been raised. However, I have done the best that I can in the space available—much in excess of that usually allowed—to answer the more important questions, but to deal fully with every point would more than double the length of my reply.

In the first place I would point out that not one single performance figure has been given me by the Lopulco people. The data are primarily those of Mr. John Anderson of Milwaukee and Mr. R. B. Mitchell of Glasgow, together with those of Mr. Henry Kreisinger and Mr. C. W. E. Clarke, who surely may be regarded as independent. I have omitted a description of the unit system because it is not yet available for large power-station boilers and so far does not seem to be a proved success for steam generation, whilst, above all, to my knowledge no detailed continuous-performance figures are available. If such figures exist, then the obvious thing for the advocates of the unit pulverizer to do is not to criticize my paper but to submit a paper on the unit pulverizer, giving the facts and figures, which everyone would welcome. The same remark applies to other "central" systems, which have apparently not had so extensive an experience of steam-generation work as the "Lopulco." Also, I have not advocated the use of pulverized-fuel firing, but have simply presented the facts in what I have tried to make a readable yet condensed form, so that British engineers may consider this question seriously. Obviously, pulverized-fuel firing has objections, like everything else.

The Comparison between Lakeside and Dalmarnock.

Many speakers are very emphatic, from many points of view, that the comparison between Lakeside and Dalmarnock is not fair. In fact every possible reason seems to have been adduced to explain the elementary fact that Lakeside is running all the year round at 85–86 per cent efficiency and Dalmarnock at 76 per cent efficiency, except the true and obvious one, that pulverized-fuel firing is superior to mechanical stoking. In making the comparison I took one of the largest, most modern, and best-equipped stations in Great Britain, and certainly one which from the steam-generation point of view is not

only controlled on the most scientific lines, probably equalled in this respect by no other in Europe, but is broad-minded enough to allow the results to be published (in this connection also see the remarks of Mr. Blaikie on page 424). Further, as explained at length in the paper the comparison is probably as fair as can ever be obtained, the only real difference being the load factor, for which allowance has been made, and obviously we can never find two stations in the world absolutely identical.

Dealing with several of the points raised, as regards the difference in the quality of the coal, Lakeside is 11 488–12 321 B.Th.U. and 2·25–5·61 per cent moisture, whilst Dalmarnock is 9 802–10 130 B.Th.U. and 12·9–14·8 per cent moisture. Mr. Wimshurst is not correct in taking (page 452) 12 000–13 000 B.Th.U. as against 9 900 B.Th.U., nor is Mr. Pochobradsky in assuming (page 419) as a comparison 3·5 per cent and 14·8 per cent moisture respectively, whilst an equal CO_2 means very little in the sense which he mentions, because other factors are the CO and unburnt gases and the radiant-heat emission. Different moisture-content in fuel is not allowed for in the calculations according to any existing boiler-test code, and this argument can be used both ways in comparing two methods of firing in general. Any difference in heating surface, as raised by Mr. Wimshurst (page 452), is simply that of standard American and British practice, and pulverized fuel in America gives better results than mechanical stoking when both are under the most favourable conditions. Thus at Colfax 1 kW is being obtained for 19 000 B.Th.U. with stokers, and for pulverized fuel the guarantee is 16 000 B.Th.U.

Another complaint, brought forward particularly by Mr. Pochobradsky (page 419) and Mr. Dransfield (page 459) is that the exit flue-gas temperature at Lakeside is only 205° F. against 414° F. at Dalmarnock. The obvious reason is that pulverized fuel is a more efficient method of combustion, the furnace temperature being higher, so that the transmission to the boiler is more effective. It is not the "boiler design" but the method of firing, and it is mainly for the same reason, in answer to Mr. Eccles (page 444), that the chimney-gas temperature at Lakeside is much lower than that at Dalmarnock.

Finally, Mr. Pochobradsky, taking 83·56 per cent efficiency for a day trial at Dalmarnock of 3 hours only, which is of no comparative value on this account alone, and 87 per cent for Lakeside, in spite of the fact that the day figures at Lakeside are 87–91 per cent, coupled with the debiting of Lakeside with calculated figures because the combustion is so efficient that the exit flue-gas temperature is reduced to a minimum, and other equally irrelevant deductions, apparently arrives at the conclusion that Lakeside running all the year round at 85–86 per cent is really inferior to Dalmarnock at 75 per cent. One can hardly be expected to take criticism of this nature seriously. Obviously, the only fair comparison is the actual monthly figures, or at any rate a long series of day trials under equal conditions, especially as regards duration, whilst Mr. Pochobradsky is equally confused over the question of the running and auxiliary costs.

The general idea of most of the speakers in this connection seems to be, although they do not in all cases say so directly, that if the Lakeside plant, exactly as it stands and is controlled, were deprived of the pulverized-fuel equipment and fitted with mechanical stokers instead, then 85–86 per cent efficiency would continue to be obtained and the efficient results are not due to pulverized fuel at all. Mr. Eccles, however, not only states this outright (page 444), but even goes further, as follows: "If Lakeside had been fitted with the Dalmarnock stokers and burning Dalmarnock coal a higher efficiency would have been obtained than was actually done with the pulverized fuel used." He then actually goes on to state that Lakeside requires 100 b.h.p. extra power, although it is clearly shown in the paper that the total auxiliary power, apart from drying, is less than at Dalmarnock.

Finally, as distinct from vague statements without any explanation that the comparison between the two stations is not of any value, such as for example those of Mr. Jockel (page 427) and Dr. Lulofs (page 455), some speakers, such as Mr. Holkunls (page 433), give it as their considered opinion that no useful comparison at all can ever be made between American and European stations!

Naturally, of course, all this trouble would not have arisen if mechanical stoking had been proved to be superior to pulverized fuel, and we should also have been spared such remarkable statements advanced against the use of pulverized fuel as that the moisture of the air of the United States is different from that of Great Britain, the Vitry plant is only to run 900 hours a year, American coals are quite different from British, and there is no useful object in comparing the performance of two electricity stations on different sides of the Atlantic.

Of course, if the Dalmarnock coal were transported to Lakeside and burnt in the pulverized condition there would be no difference at all in efficiency, and most of the speakers mentioned have forgotten that the most efficient and specially designed mechanical-stoker stations in the world do not at present give 80 per cent on continuous performance. To assume, therefore, that mechanical stokers installed at Lakeside would suddenly give 85–86 per cent efficiency is absurd.

Difficulties due to the Lack of a Proper Boiler-test Code.

The increasing confusion and general difficulties due to the lack of a proper international boiler-test code are emphasized very strongly by the discussion, and the remarks of Mr. Baker (page 423) and of Mr. Hendry (page 459) are much to the point. Various speakers such as Mr. Pochobradsky (page 419) have, owing to the present unsatisfactory state of affairs, confused the issue between Lakeside and Dalmarnock, and now that 84–89 per cent boiler efficiencies are being obtained it is becoming imperative that this matter of a boiler-test code be cleared up.

Difference between British and American Fuel.

A number of speakers have stated, or inferred, that there is such a difference between American and British coals that it does not follow that we should obtain equally efficient results with pulverized fuel in Great Britain as are at present being shown in America.

Mr. Partridge (page 419), for example, is much worried that the average calorific value of American coals on the tests shown was over 12 000 B.Th.U. and that engineers in the London area "have hundreds of different classes of fuels at their disposal." I must confess that I cannot grasp this point, since, in answer also to Mr. Hamilton (page 431), for the first time pulverized fuel has given us a method of burning at high efficiency any fuel, irrespective of its heating value, moisture, volatile matter, resinous content, coking properties, mechanical condition, ash, and melting point of the ash.

Further, Sir James Kemnal (page 418) states that American coals are as a rule much more friable than European coals as is shown by the fact that in England we cannot use a mechanical stoker more than 9 ft. wide, whereas in America stokers 24 ft. wide are used. Incidentally, stokers 11 ft. wide are now in operation in Great Britain and units 16 ft. wide are under construction, also installations of over 20 ft. width can be built at any time and are at present being quoted. Further, the friability of coal has nothing to do with the width of stokers, another direction in which British engineering has hitherto lagged behind American. The reason is that we have only just begun to use the modern suspended arch and it is not possible with the out-of-date sprung arch to exceed about 9 ft.

Variety of Fuels that can be Used.

In view of this perfectly well-known and remarkable flexibility of pulverized fuel as regards the quality of the fuel, it is ludicrous that a number of speakers should attempt to show that mechanical stoking is superior in this respect.

Sir James Kemnal (page 418), for example, is emphatic on this point, and Mr. McLaren (page 436) not only says mechanical stoking will burn a wider range of fuels than the Lopulco system, but makes the still more amazing statement that "any amount of ash" in a fuel makes no difference to mechanical stoking. Apart from the fact that even in the discussion itself Mr. Jackson (page 448) gives an example of his own experience of burning successfully in a well-known Newcastle station a quality of fuel by pulverizing methods which is quite impossible with chain-grate stokers, statements of this character will enable the experienced power-station engineer to draw his own conclusions as to the calibre of some of the arguments advanced against pulverized fuel.

Capital Cost.

Another alleged objection to pulverized fuel on the Lopulco system is the capital cost of the installation as compared with the unit pulverizer and mechanical stoking, and some extraordinary statements have been made in this connection.

Sir James Kemnal (page 418) first of all says "no mention is made in the paper" of this vital matter of capital cost; whereas the matter is discussed on pages 415 and 416. He then goes on to assume that "the cost is very high, probably five or six times as much as that of mechanical stokers of the best kind."

Mr. Pochobradsky states (page 421) that the cost of a pulverized-fuel plant to deal with 50 tons a day is £11 562, taken from the paper (page 391), the period being that of the abnormal high prices of 1918, whilst a unit pulverizer for the same duty would cost £800. Mr. Hollands (page 433) says that "the difference in cost is enormous," and the same point is raised by Mr. Forrest (page 454).

It will be agreed that the engineers and managerial staffs who control, for example, the Detroit Edison Co., the Ford Motor Co., the Cleveland Electricity Co., the Cahokia station at St. Louis, the Colfax installation at Pittsburg, the Union d'Électricité in France, and the Willesden and St. Pancras stations in Great Britain know what they are doing, which would not be the case if a number of the arguments advanced on this point are worth anything. That is to say, we should have to admit that many of the most prominent industrial concerns of the world who have placed orders for pulverized-fuel plant to the extent of a consumption of nearly 4 million tons of coal per annum incurred huge and unnecessary capital costs.

It is very difficult, in fact almost impossible, to give a real comparison in capital cost between modern pulverized fuel and mechanical stoking, because so much depends on the conditions. The unit pulverizer is hardly worth considering on present knowledge, as it is not applicable to large boilers and sustained high efficiency, apart also from the fact that it requires, like any other method, auxiliaries in the way of coal-crushers, conveyers and overhead bunkers, together with ash conveyers.

Taking, however, first of all the case of entirely new plant, we have to consider two factors, the size of the plant and the increased output due to pulverized fuel. On one large boiler only, say 50 000–100 000 lb. per hour, the comparative capital cost of the equipment was in a recent instance approximately $1 \cdot 5 : 1 \cdot 0$ (pulverized coal of course being dearer), taking everything on the latest lines—economizers, superheaters, air heaters, fans, overhead coal-bunkers, ash-handling plant, chimney, and the correct combustion chamber in each case. This, however, is not a fair comparison because the output of the pulverized-fuel plant is much greater. Thus at Willesden a 50 000 lb. boiler with 62 500 lb. peak load on mechanical stokers will give 60 000 lb. normal load, 72 000 lb. continuous overload, and 80 000 lb. peak load with pulverized fuel, and when the basis of equal steam output is taken there is little difference in capital cost. For a large plant of, say, six 50 000 lb. boilers, pulverized fuel is no more expensive or even cheaper, as is well known from the extensive American experience, and all the remarks about greatly increased capital outlay can be disregarded. As applied to existing mechanical-stoker plant the matter is different, and in many cases the opinion of Mr. Pearce (page 442), that in these circumstances the capital cost will outweigh the savings, is correct, chiefly because the boilers have to be reset to obtain a proper combustion-chamber volume.

High Efficiency with Mechanical Stoking.

In reply to Mr. Rowe (page 435) and also in connection with the remarks of Mr. Cauthery (page 453) and Mr. Partridge (page 419), very high efficiencies for short tests have certainly been obtained with mechanical stoking, and I am aware that 88 per cent is claimed with

marine boilers and forced-draught, air-heater equipment, and also 85–89 per cent with ordinary water-tube boiler installations of stokers, superheaters, economizers and air heaters. Apart from the great confusion that exists in the method of calculating and expressing boiler-plant tests, the point is, however, that these figures only apply to short tests and not to continuous running.

The Difference between Continuous Running and Test Conditions.

In connection with this question of high efficiency obtained by mechanical stokers the discussion shows that it is almost impossible to get many engineers to understand the difference between a short test of a few hours under special conditions and the actual running results from month to month. The Lopulco figures at Lakeside, 85–86 per cent efficiency, are based on the water evaporated and the coal burnt each month, including all light load, starting-up and shutting-down losses, whereas the short tests vary from 87 to 91 per cent efficiency. In spite of very high figures on short tests, the most efficient stoker plants in the world are only giving about 75–78 per cent efficiency, as, for example, in the case of Colfax and Dalmarnock.

Mr. Hendry (page 459) gives an excellent illustration of this, a typical mechanical-stoker plant running at 76·6 per cent efficiency all the year round but on which as high as 86 per cent has been obtained on a 10-hour test. Yet many speakers persist in claiming 80–85 per cent short-test efficiency for mechanical stokers against the 85–86 per cent continuous figures for Lakeside and not the test figures of 87–90 per cent. For example, Mr. D. Wilson (page 421) assumes that my figure of 75 per cent for the performance of mechanical stoking is a misprint and speaks about 80 per cent and over as if this applied to continous performance. It was for this reason, in trying to emphasize the importance of month-to-month figures, that I mentioned the 400 tests. Again, Mr. Townley (page 458) takes 81·5 per cent as the performance of his mechanical-stoker plant, admits that this is only for 10-hour test figures, and then proceeds to compare this with the continuous figures of 85–86 per cent efficiency at Lakeside. His assumption of only 4 per cent saving is of course quite wrong and should be 6–9½ per cent in comparison with Lakeside day tests of 87–91 per cent.

Steam-generation Efficiency and Cost of Power Production.

Quite a number of speakers also have assumed that I have devoted nearly all my attention to the increase of steam-generation efficiency and said nothing about the total cost of the production of power, which it is insinuated in some cases is really higher with pulverized fuel. Thus Sir James Kemnal (page 418) says that steam-generation efficiency, whether 80 or 85 per cent, does not matter so long as the total cost per unit generated is less, whilst Mr. Partridge (page 419) is of the opinion that we ought to include such items as labour, repairs and maintenance, and interest on capital.

Mr. Wilmshurst says (page 452) that he would prefer to hear less of the overall efficiency of the boiler and more of the total commercial costs of running per unit generated—such figures to include all capital charges and the cost of running auxiliaries.

Again, Mr. Blaikie states (page 424) that "the paper is mainly concerned with the thermal efficiency of steam generation." Mr. Stubbs (page 447) says that "the really important features are lost sight of because of his [the author's] anxiety to stress the question of efficiency." Mr. Troup (page 430) thinks that I have not done myself justice by emphasizing thermal efficiency to such an extent. Further, Mr. Petford (page 457) speaks of "straining after higher efficiencies," Mr. Forrest (page 454) suggests that what matters is the lowest cost of steam generation and not efficiency, whilst Mr. Devey in his remarks (page 434) seems to be under the impression that I have dealt only with efficiency.

These speakers do not appear to have read the paper thoroughly. I have not devoted undue attention to efficiency at all, but have dealt in the fullest detail with every one of the advantages and disadvantages of pulverized fuel, and in this section out of a total of 20 pages (396–416) only 8 pages (396–404) deal with efficiency. I stated also in the clearest possible fashion that the most valuable portion of the paper related to the costs of running at Lakeside.

In reply to the platitudes about generation costs, obviously if the net cost of generating steam is reduced, as shown in the paper, then also the overall power costs will be lowered accordingly, and I have not given these latter because the paper deals with steam generation and is already 40 000 words in length. I can only say again, as already stated in the case of capital cost, that those in charge of many of the most prominent firms in the world know what they are doing and would not have adopted pulverized fuel if the net generation costs were thereby increased.

Objections to the Water Screen.

Another common contention in the discussion is that the water screen for the prevention of the slagging is an objection. In the first place it is stated to be dangerous to work. Thus Mr. Cauthery (page 453) thinks that it may give trouble by overheating, contraction and expansion, and we know from Mr. Pearce (page 443) that one water-tube boiler firm are not only strongly opposed to the water screen but actually have stated that they did not think a boiler insurance company would insure a boiler with such an attachment. Again, it is supposed to require abnormally pure water. Mr. Allwood (page 453) regards it as a weak point unless particular attention is given to the water, and Mr. Train (page 437) is of the opinion that it "is barred on account of the quality of the feed water" and we ought to concentrate on designing a furnace without water screens. Finally, the water screen is stated to be unnecessary, and a number of speakers such as Mr. Hutchinson (page 444), Mr. Hollands (page 433), Sir James Kemnal (page 418) and Mr. McLaren (page 436) are of the opinion that slagging is or can be eliminated without a water screen and merely by proper furnace design.

The facts are, in answer also to Mr. West (page 430) and Mr. Hamilton (page 431), that the water screen does not give trouble and the installations at Lakeside and

Oneida-street have been running for several years without any difficulty, whilst 60 000 kW at Cahokia has been in operation for 6 months. Also it is a misstatement to say that insurance companies have raised any objection, either in America or France, to the water screen, as must be obvious from the number of plants at work.

The best methods of preventing slagging are a matter of opinion, but the water screen is mainly responsible for the fact that several million tons of coal in the pulverized condition are now being burnt per annum for steam generation. When unit-pulverizer firms or any of the speakers can show us actual results of long running with varying qualities of coal on power stations without a water screen, then we can consider their statements seriously. It may be mentioned also that the chief reason why pulverized fuel makes such slow progress for general furnace work, as in the iron and steel industries, is because unit pulverizers cannot entirely stop slagging, and, as Mr. Clements points out (page 425), any satisfactory system must guarantee to prevent this trouble. Finally, from a theoretical point of view the objections to the water screen have no point at all, and on what grounds Sir James Kemnal (page 418) says that it is "a somewhat crude arrangement" is not clear. The apparatus is a 4 in. steel tube, the same as the tubes of the boiler, and it is less liable to burn out or give trouble, and no more requires specially pure water than the boiler tubes. It would be much more logical to apply the above objections to the bottom two or three rows of tubes of the boiler nearest the furnace which have to do 70 per cent of the whole evaporation, an inherent defect in most water-tube boiler design.

Size of the Combustion Chamber.

Arising out of the comparison between Lakeside and Dalmarnock, several speakers seem to regard the size of the combustion chamber as a disadvantage. The fact is, however, that a large combustion space is essential to efficient combustion, and mechanical-stoker practice is suffering heavily because this fact is not recognized in Great Britain as it is in America. The extra capital cost of a large combustion chamber is wiped out in a month or two by the extra efficiency. In this connection the point raised by Mr. Hutchinson (page 444) that the large combustion chamber cannot tend to efficiency obviously has no value since it is at present giving the highest boiler-plant efficiency in the world, whether on continuous running or short tests. Some speakers such as Mr. Nicholls (page 453) complain that a part of the high efficiency of Lakeside is due to proper dimensions in this connection, which is quite correct, but in making the comparison I cannot help it, and all along I have given mechanical stoking the advantage in case of doubt (see page 400).

Mr. Rutland (page 452) seems to regard with pride the fact that marine boilers are crowded into a small space. This is one of the chief reasons why the efficiency of marine steam-generation is so low, averaging probably less than 55 per cent, whereas pulverized fuel in a large water-tube boiler with sufficient combustion-chamber space will give 86 per cent, that is, about 36 per cent reduction in the coal bill. An interesting example from marine practice is given by Mr. W. J. Muller, the chief engineer of the Dutch steamship company, the Koninklyke Paketvaart Maatschappij of Amsterdam, in a paper read in 1923 before the Institution of Naval Architects. He shows that a marine water-tube boiler with mechanical stoking gave 65 per cent efficiency with the usual combustion space, but by merely raising the boiler 2 ft. the efficiency went up to 75 per cent, that is a saving of over 13 per cent in the coal bill. In spite, however, of the triumphant competition of the Diesel engine, marine steam-generation practice continues to blunder along in the same inefficient manner, of which small combustion space is only one of many illustrations.

In reply to Mr. Blaikie (page 424), the main reasons why a Lancashire boiler plant will give 82·5 per cent efficiency with cramped combustion space is the use of a high-grade fuel of low ash-content, often with a low volatile content, adequate draught, tight settings, good firing and an extensive equipment of superheaters and, particularly, economizers.

Fine Ash Discharged from the Chimneys.

Very many of the speakers have raised the point—on purely theoretical grounds—that one of the most serious objections to the Lopulco system of pulverized-fuel firing is a huge amount of fine ash discharged from the chimney. It has been stated also, apart from the present discussion, that 70–80 per cent of the ash is discharged from the chimney, oblivious of the other objections that about 50 per cent of the ash is deposited in the furnace and would cause slagging in the absence of the water screen, whilst 25–30 per cent causes trouble in the boiler tubes and flues. Thus, as an example, Mr. Partridge says (page 419) that "every engineer whom we consulted" told him this and he is of the opinion that "the London area is a very different proposition" from a station by a lake, especially because of "the stringent rules and regulations of the County Council."

Whilst Mr. Petford (page 457) talks about the medical authorities not looking on pulverized fuel with favour, Mr. Mallinson (page 440) is nervous about the deleterious effect on the air of Manchester, and Dr. Lessing states (page 421) that if only 12 per cent of the ash escapes from the chimney this would mean that our vanishing smoke problem would be replaced by a dust problem and that for a successful solution of the powdered-fuel problem the ash must be eliminated. Also Mr. Moxon (page 434) and Mr. Rutland (page 452) express unfavourable opinions upon pulverized fuel on this account, whilst Prof. Bulleid (page 454) wants to know if there is any danger of the ash choking up rain-water spouting, and Alderman Walker (page 447) has apparently misunderstood the figures given in the paper and on the lantern slides.

The facts are, as already stated, that the ash discharged at Lakeside is $17\frac{1}{2}$–25 per cent of the total ash, about 3 per cent of the coal fired, which is approximately the same as that discharged from chimneys to-day with mechanical stoking except that in the latter case much nuisance is caused because of the large particles. The best information on the ash question is contained in a recent paper by Mr. H. D. Savage before the American

Society of Mechanical Engineers. There are only two places in the world, Lakeside and Oneida-street, where the exact amount of the ash discharged has ever been determined, and the ideas often expressed that 40–80 per cent of the ash is discharged are mere guesswork. There has, in practice, never been any trouble with ash, either at Lakeside, as pointed out by Mr. Evans (page 422), or anywhere else. Mr. Savage also mentions that with a super-station of 10 boilers of 15 000 sq. ft. heating surface burning 1 176 tons of coal per day, at 10 per cent ash this is 117·6 tons of ash per day. Even if 30 per cent were discharged from the chimney, that is 35 tons of ash per 24 hours, and if this came down within a radius of 1½ miles, that is 7 square miles, obviously impossible, the ash deposit would be 0·00031 lb. per square foot per 24 hours, or 1·8 ounces per annum. The particles are so extraordinarily small, being the ash skeleton of pure mineral matter from coal of which 65 per cent passes through a 200 mesh, that they are comparable in size, as Mr. W. Wilson (page 456) expresses it, with the motes floating in every sunbeam. In practice they remain suspended in the air until washed down by the rain.

The Height of the Chimney required for Pulverized Fuel.

A number of speakers have assumed that because the Ford steel chimneys are 327 ft. high therefore one of the objections to pulverized fuel is that an enormous and costly chimney is necessary. Thus, for example, Mr. Wadeson (page 458) says that the height of the chimney in the pulverized-fuel station is about 2¾ times that of a mechanical-stoker station, and Mr. Hutchinson (page 444) also mentions this point. They seem to have forgotten that the Ford chimneys deal normally with 70 per cent blast-furnace gas and 30 per cent pulverized coal, so that they might as well have pursued this argument to the end and claimed that pulverized coal emits so much dust from the chimney that even for only 30 per cent of pulverized-fuel chimneys over 300 ft. high are essential. The reason for the great height is that the Ford Company prefer natural draught to mechanical draught, and the above statements are obviously of no value because the Lakeside chimney is 220 ft. high and a very large number of mechanically-fired plants in Great Britain have chimneys as high as this. The lowest practical height for a chimney is a matter of opinion, as we find in connection with the general propositions of high chimney versus medium-height chimney and mechanical draught. Also, as Major Bell points out (page 460), the 100 ft. chimney is already giving much trouble with mechanical stoking.

The Lopulco Vertical Drier.

Mr. McLaren (page 436) says that this "apparently has not yet been thoroughly tried." The answer is that it has been running experimentally for 2 years past at Oneida-street and has also been in operation at the Cahokia plant, St. Louis (60 000 kW), for 6 months.

The Degree of Drying Necessary for the Coal.

With regard to the statement made by Mr. Hollands page 433), it is quite true that I said in the *Iron and Coal Trades Review* drying down to 1 per cent moisture in large revolving driers is a formidable operation, an opinion which I still hold, although we have always got to look at the final net results. But to-day it is not necessary to dry down to 1 per cent or use complicated driers as explained in the paper (for example, page 395), and in reply particularly to Mr. Malpas (page 434), it is now found necessary for the most efficient results in the pulverizer only to drive off the free or surface moisture. The efficiency of the pulverizer is not affected by what is vaguely termed the hygroscopic moisture which is a part of the coal substance. The new vertical Lopulco gravity drier, as described in the paper, is a small and compact apparatus with no moving parts, occupying little room and requiring practically no attention, circulating a mixture of air and exit flue gases at 215° F., which absorbs 3 kW per ton of coal dried. Further, in reply to Mr. Malpas (page 434) the temperature is regulated by means of a damper by altering the amount of cold air supplied. Nearly all the objections raised to drying the coal, such as those of Mr. Hollands (page 433), have no point in reference to this improved type of drier.

Unburnt Ash in Coal.

Just as many power station engineers imagine their boiler plant is running at 75–80 per cent efficiency all the year round, remarkable ideas still exist as to the loss by unburnt fuel in the ash. As an example of this Mr. D. Wilson (page 421) states that "in a well-operated station the carbon in the ash does not exceed 10 per cent" and that "there should be no difficulty in keeping the loss down to 0·5 per cent," meaning presumably by this the figure for the actual coal loss, and then goes on to say that my figures of 3–5 per cent for mechanical stoking are "inaccurate and liable to mislead." The true state of affairs is, however, illustrated by a number of speakers in the discussion. Mr. Maxted (page 432) gives the details of a boiler plant of 6 Babcock and Wilcox boilers under his control fitted with chain-grate stokers and operated on the most scientific lines at 75 per cent boiler-plant efficiency. There is on the plant a loss in the ash and clinker of 5 per cent of the coal fired, that is 1 300 tons of coal per annum, whilst Dr. Lulofs (page 455) of the Amsterdam electricity station gives it as his opinion that 5 per cent of coal lost as unburnt fuel in the ash is a low figure.

Mr. Jackson (page 449) confirms in his experience 1–2 per cent coal loss in the ash, whilst the riddlings on chain-grate stokers are 35 per cent, and Mr. Evans (page 422) gives another example of 20 per cent. The estimate of 3–5 per cent in the paper is an understatement.

Large Size of Boiler with Pulverized Fuel.

In this connection, confirming the remarks made by Mr. Evans (page 422), Mr. Swindin (page 428), Mr. Troup (page 430) and Mr. Platt (page 454), modern pulverized-fuel firing has rendered possible the huge boiler which cannot be operated with mechanical stokers or unit pulverizers. I am glad that Mr. Erith reminds me (page 426) that the largest mechanically-fired boiler has about 170 000 lb. evaporation per hour, but pulverized fuel has been the sole means of making possible the unit

of 30 000 sq. ft. heating surface or over, with a normal evaporation of 300 000 lb. and an overload of 400 000 lb. per hour. It is now proposed, because of the perfection of pulverized fuel, to construct 40 000 sq. ft. heating-surface boilers so that one unit only will supply a 35 000 kW turbine, thus simplifying power-station design.

Temperature in Combustion Chamber.

Several speakers such as Mr. Hutchinson (page 444) and Mr. Dransfield (page 459) have quite misread the temperature of 2 100° F. mentioned on page 405 of the paper in connection with the Ford plant. This relates to 70 per cent blast-furnace gas and 30 per cent pulverized fuel, and not to pulverized fuel only, the temperature of which is certainly well over 2 500° F.

Vibrations of the Boiler.

Mr. Rutland (page 452) raises the interesting point of "organ pipe effects," which is a peculiar vibration of the whole boiler due to pulsations in the combustion chamber. I have not heard of any case of this actually happening with pulverized coal, although presumably it might take place. The cause is rather mysterious and I have known several very troublesome and almost alarming cases of this with chain-grate stokers, in one of which a change in the quality of the coal caused an instant cessation of the effect. The same result can be given to a lesser degree in Lancashire boilers if the superheater is not provided with a mid-feather.

Troubles due to Liquid Condition of Pulverized Fuel.

Mr. Phillips (page 452) raises the very interesting point of the pulverized fuel becoming "liquid," due to particularly good drying and grinding, and running right through the feeders like water. Mr. Phillips is quite correct that the variable pitch of the cast-iron screw feeder described in the paper is designed to reduce this trouble to a minimum. This variable pitch tightens up the coal at the end of the feeder, giving a "plug" of coal, which has the double function of preventing the 10 per cent air at 12 in. water gauge, added at the discharge, from passing back into the pulverized-coal bunker and also acting as a barrier in the case of the "liquid" condition mentioned.

Wear and Tear on Burners.

Mr. Rutland (page 452) asks if there is any mechanical wear and tear on the burner tips with pulverized fuel, following upon his experiences in this respect with unfiltered oil in oil burners. There is no trouble in this respect and the two cases are not parallel, since there is ample clearance space through the burners and the pulverized fuel-air mixture behaves practically as a gas. A more suitable comparison would be with the gas-firing of boilers and not oil burners with an excessively small aperture.

Combined Mechanical Stoker and Pulverized-fuel Firing.

Dr. Lulofs (page 455) deals with a new development which he has undertaken at Amsterdam electricity station, that is the combination of a unit pulverizer and a chain-grate mechanical stoker. The idea briefly is to install a unit pulverizer using much less than the normal amount of air at the back end of the stoker, the jets being parallel with the chain grate and at a slight angle inwards. In this way the obvious and perfectly well-known defect of chain-grate stokers, the admission of excess air at the back as the fires burn thin, giving about 5 per cent CO_2, is remedied by using this air to complete the combustion of the pulverized coal. This is stated to have given excellent results, at least 20 per cent increase in evaporation, and the method is certainly interesting in spite of the defects of the unit pulverizer (to be discussed later).

Radiation Loss.

In reply to Mr. Blaikie (page 424) the radiation loss from a pulverized-fuel plant is not excessive in spite of the large combustion chamber, and the figures for Lakeside of $1\frac{1}{2}$ per cent and of $2\frac{1}{2}$ per cent for Dalmarnock are probably both on the generous side. The old ideas of 5 per cent radiation loss in the case of a boiler plant are quite erroneous.

Cast-iron versus Steel-tube Economizers.

I can assure Sir James Kemnal, in reply to his remarks on page 418, that I am quite aware that in a number of cases cast-iron economizers have been replaced by steel. I am, however, also acquainted with the fact that in various instances the steel-tube economizer has proved to be most unsatisfactory. In this connection the statements made by Mr. Rushworth (page 453) are somewhat significant, not only as regards failures of steel-tube economizers, but also because cast-iron coverings are now being adopted to try to protect the steel.

In reply to Mr. Jockel (page 427) the trouble with the steel-tube economizer is both external and internal corrosion, as pointed out also by Mr. Dransfield (page 459).

In answer to Mr. McLaren (page 436), I do not think that the steel-tube economizer will outlast the water screen, and the proper comparison for the latter is the lower boiler tubes and not the economizer tubes.

Marine and Cylindrical Boiler Practice.

In reply to Mr. Hall (page 434) and Mr. Rutland (page 452), so far as I know, pulverized-fuel firing has made no headway at all with marine boilers, or in fact with any type of cylindrical boiler, a matter obviously of the greatest importance since by far the greater amount of coal burnt in Great Britain for steam generation is consumed in Lancashire boilers. This also is in answer to Prof. Bulleid (page 453) and Mr. Wordley (page 459).

The Unit Pulverizer.

Most attention of all has been given in the discussion to the question of the so-called unit pulverizer, and accordingly I will deal with the matter at some length. The reason why I omitted unit pulverizers from the paper has already been explained (pages 385 and 460).

In the first place, it may be stated that the distinction to-day between the so-called "central" system and the

so-called "unit" system of pulverizing no longer holds good, since the latest Lopulco application appears to combine the advantages of both. In the central system it is usually understood that the crushing, drying and pulverizing of the coal are carried out in a separate pulverizer building and the pulverized coal sent to all the different boilers or furnaces in the boiler house, as at Lakeside, whereas in the unit system a single combined pulverizer, separator, and air-supply fan are used in one unit in front of each boiler, in place of the mechanical stoker.

In the modern Lopulco system, of course, as at Vitry, Cahokia, etc., no separate building is required, each boiler having its own independent vertical drier, pulverizer, separator, pulverized-fuel storage bunker, feeder, water screen and hollow brickwork, all of which are worked separately and independently of one another at practically continuous, maximum efficiency, whilst the space occupied is little more than with unit pulverizers or mechanical stokers and ash conveyers. The fact is also that the unit system has had little or no success for large-scale steam generation, and because of this the central system had to be devised so as to eliminate the obvious defects of the former method. To-day in the United States practically all the boiler plants of any importance fired with pulverized fuel do not use the unit system. My paper is concerned with steam boilers only, not furnaces in general, and Mr. Mallinson's statement (page 440) that unit pulverizers are being developed in the United States is really beside the point, just as are Mr. Hutchinson's remarks (page 444) that one system of unit pulverizers burns $1\frac{1}{2}$ million tons of coal per annum. About 30 million tons are burnt every year for all purposes and I can assure Mr. Atkinson (page 422) that I am not in the least surprised to hear that over 400 turbo-pulverizers are installed, but what concerns this paper is steam generation.

Alderman Walker (page 447) states that he finds on inquiry there are quite a number of unit plants at work, but he does not enlighten us any further as to the result of his investigations. However, Mr. Hollands (page 433) states that 160 unit pulverizers of one make are operating on boiler plants, and Mr. Hutchinson says that 60 plants are at work in France, but no details are given.

As we have already had in the discussion a fairly comprehensive account of the advantages of the unit pulverizer from various speakers, including Mr. Maxted (page 432), Mr. Clemitson (page 451) and Mr. Hutchinson (page 444), it will not be without interest to give the objections to the unit pulverizer, which would seem to be on present knowledge as follows :—

(*a*) Since no magnetic separator is used there is always danger from a serious breakdown due to stray metal particles in the coal, such as nails, bolts, cartridge cases, washers, canister lids, and similar material.

(*b*) A minor accident shuts down the whole boiler, whereas this does not happen on the central system in general, with reserves of pulverized coal and a number of separate burners and feeders.

(*c*) The absence of drying, and the assumption (which is not admitted) that any coal up to 12 per cent moisture can be used direct, mean that the coal varies in moisture content and therefore in physical properties. This results in uneven grinding; that is, a 5 per cent moisture coal does not give the same result as a 10 per cent coal, whereas on the central system there is always one moisture content.

(*d*) The presence of moisture in the coal means excessive power required for the pulverizer. Mr. Train (page 436) realizes this point and suggests the addition of a vertical drier to the unit pulverizer.

(*e*) The presence of moisture in the coal means a lower boiler-plant efficiency, since the moisture has to be evaporated into steam in the furnace, which escapes in the exit gases and carries away a large amount of (latent) heat.

(*f*) A unit pulverizer will work only whilst the boiler is in actual operation, and at a corresponding rate, whereas on a central system, such as the Lopulco, 24 hours' coal supply can be pulverized in 16–17 hours irrespective of the boiler output. Consequently, the pulverizing is done largely at night when the station is on light load and the cost of power practically nil.

(*g*) What may be termed the essential defect of the unit pulverizer is that it is not possible to carry out at one and the same time at maximum efficiency in a single machine the entirely different operations of pulverizing coal, separating the particles, conveying, mixing with air, and supplying to the furnace at the various rates of operation which depend upon the fluctuations in the steam demand. Each one of these operations is only working at a maximum efficiency at one speed, and needless to say these speeds do not coincide. At any given rate of burning, therefore, the net efficiency of the pulverizer unit is the average of all the different operations, and this efficiency is nearly always low because the given speed can only be approximately correct for one or two of the different functions. Thus as the steam demand rises to a maximum the efficiency of the grinding falls heavily, the power required rises, the wear and tear increase, and vibration generally results. Again, a very serious point, there is no real control over the air supply and little flexibility, since the speed of the pulverizer, which governs the air, has to be adjusted, depending on the other factors. It was these reasons that caused the central type of system to be devised, in which the pulverizer works continuously on dried coal at one speed only, that of maximum efficiency, since between it and the burners is a large storage bunker. The coal is intimately mixed with air in an entirely separate feeder under easy control, and is burnt in a number of independent burners working only within a range of high efficiency, individual burners being shut down or started up as required for very light or heavy loads. This will answer particularly Mr. Clemitson's remark (page 451) as to why it is necessary to "go to the trouble" of separators, feeders, etc.

(*h*) The power required by the unit pulverizer is extremely high, averaging 2–4 per cent of the output of the boiler, but at high speeds and peak loads the figure may easily be 5 per cent or over, especially when the pulverizer is a little worn. On the Lopulco system with the new vertical drier the total figure is only about 1 per cent. Mr. Carr-Hill (page 425) gives it as his opinion that a unit pulverizer takes about 3 times the power of

a modern pulverizer, viz. 40–50 b.h.p. per ton as against 13–14 b.h.p., based on 70–75 per cent through a 200 mesh. In reply to Mr. Townley (page 458) it is not generally agreed that "pulverizing takes 20–25 kW per ton." As stated in the paper the Lopulco guarantee is 19½ kW; and with regard to Mr. Pochobradsky's remark (page 420) that the power consumption of the unit system is less than what he calls the central system, I take the strongest exception to his statement, without any figures to support it, that the unit pulverizer takes 25 kW per ton.

(*i*) The wear and tear on unit pulverizers is apt to be very severe on continuous running because of the variations in speed necessary, the construction also often giving heavy vibration at top speed. The beaters wear out very quickly, giving still more inferior grinding and increased power consumption.

(*j*) The mixing of the pulverized fuel and the air is not sufficiently intimate to ensure best results and gives "stratification" in the combustion chamber, as mentioned by Mr. Carr-Hill (page 425). That is to say, since the mixing of the air and the coal is imperfect and the grinding very uneven, in the combustion chamber the heavier particles at once fall to the bottom before they have time to be burnt, so that there is almost a series of different strata, the top being composed of the finest particles and the heaviest being at the bottom, the combustion therefore not being complete. Further, these large particles vary in ash content.

(*k*) On long running a unit pulverizer will not work with only 20–25 per cent excess air owing to the defective grinding and mixing.

(*l*) The unit system sooner or later gives trouble due to slagging, depending on the quality of the coal, especially as the size of the plant increases. This trouble is aggravated by the heavy partially-unburnt particles of coal falling to the bottom of the chamber, and eventually reduces considerably the efficiency of the plant.

(*m*) Another result of imperfect combustion is that the ash in the average unit plant is not completely burnt and cannot approach the Lopulco figure of 0·5 per cent unburnt-fuel loss. In one example of unit pulverizers the ash in the bottom of the furnace contained 8 per cent combustible, whereas in the last pass of the boiler the figure was 38 per cent.

(*n*) A unit pulverizer required a considerable amount of labour and attention, with constant skilled supervision of each separate pulverizer, which would be a troublesome matter in the case of a large station.

(*o*) A unit pulverizer cannot be applied to very large boilers.

(*p*) A point of the highest importance is that on the Lopulco system boilers can be operated entirely from a distant panel switchboard, the coal and air being manipulated by means of small levers as at the Ford plant. This has long been an ideal, leading to the highest efficiency, and is impossible both with unit pulverizers and with mechanical stokers.

(*q*) The net result is that a unit pulverizer will not give 85–86 per cent continuous efficiency on a boiler plant, even with small or medium-sized boilers, and, as already stated, no figures to the contrary are available. There are plenty of vague statements. Thus, Mr. Hollands (page 433) says "the unit system is giving results quite as good as those obtained on any other system," whilst Mr. Pochobradsky (page 420) states that "the performance of a unit pulverizer is in every respect equal to that of a central pulverizing plant and the efficiency of firing is exactly the same in the two systems." Mr. Atkinson (page 422) says "we have had a large number of boiler tests made, many of which show a total efficiency of 85 per cent and over," and Alderman Walker (page 447) thinks that I could have got the same information, that is long detailed performance figures of 85–86 per cent boiler-plant efficiency from both users and makers of unit and other systems. Also, Mr. Dennis (page 432) says that the Buell unit pulverizer will give "all the Americans claim to do." Most of these speakers do not give any figures and I suggest the reason is that such data do not exist.

It is very obvious, therefore, that many of the advantages of the unit pulverizer, such as low first cost, convenience, small space and no drying of the coal, are completely offset, although of course the unit pulverizer is very useful for many cases, such as the adaptation of Dr. Lulofs (page 455), but it does not at its present stage of development compete seriously with the Lopulco or other central system on boilers of the largest size at 85–89 per cent continuous efficiency.

General Remarks.

As regards Alderman Walker's observations (page 447), the answers to the points which he raises will be found in the paper.

In answer to Mr. Phillips (page 452), I have no information at all with regard to Hammersmith and we are all waiting for the results. In this connection I should like to know why Mr. Hutchinson did not quote the Hammersmith figures.

Sir James Kemnal (page 418) makes, in addition to those already discussed, a number of general statements that are quite unwarranted. The statistics issued by the Electricity Commissioners do not show the figures relating to steam production, and the number of private firms who keep such figures is very small. I suggest that the amount of apparatus required is much more a defect of mechanical stoking than of pulverized fuel, especially because of the ash and clinker problem. Also I will challenge Sir James Kemnal to quote a single instance where mechanical stoking is giving an increase in boiler output equal to pulverized fuel. Further, with regard to his remark that "the author states also that British power station practice is far behind that in America," this is quite unwarranted. I have said nothing of the kind, and the only reference in the whole of the paper to a comparison between British and American engineers is on page 400, where I state we are behind America in regard to furnace volume, which is quite correct. Several other speakers have raised, without any justification, the point that I have been antagonistic to British engineers.

Finally, I did not mention that the ash varies with the nature of the coal, because this is obvious to everyone.

In reply to Mr. Devey (page 433), I have not suggested the installation of pulverized-fuel plants and I did not

mention the matter in any part of the paper, nor have I proposed that any existing plant should be scrapped. I quite agree that what we require is more scientific control of boiler plant, and I have advocated this continually for over 12 years past.

It is futile for several speakers such as Mr. McLaren (page 436) to emphasize that the Vitry guarantee is "only 84 per cent efficiency" and therefore to cast doubts on the Lakeside figure of 85–86 per cent and on pulverized fuel in general attaining these figures. The obvious answer is that the Lopulco guarantees are in many cases much higher than Lakeside, as, for example, 88¼ per cent at Trenton Channel, and 89 per cent at Willesden, and presumably the Lopulco people conduct their own business, including the extent of the guarantee, to suit themselves.

With regard to Mr. Atkinson's point (page 422) concerning an article of mine in February 1922, we all change our opinions as experience accumulates. It is not very long ago that Mr. Atkinson himself was an enthusiastic advocate of the central system, which he now condemns in favour of the unit system.

It is extremely interesting, as mentioned (page 425) by Mr. Clements, that the Park Gate Iron and Steel Co. should have put in the first pulverized-fuel blast-furnace-gas plant, as I certainly was not aware of this, whilst the Calumet figures given (page 426) by Mr. Duncan are of much value, although of course most British power stations have not yet installed very wide stokers.

In reply to Mr. Jockel (page 427), I have referred to Mr. Harvey's report in various parts of the paper, as on page 391 for example, and with regard to the point raised by Mr. Hamilton (page 431), so far as I know, carborundum bricks have not been tried and do not seem necessary in view of the efficiency of the air-cooled walls.

PROCEEDINGS OF THE INSTITUTION.

711TH ORDINARY MEETING, 14 FEBRUARY, 1924.

(JOINT MEETING WITH THE PHYSICAL SOCIETY OF LONDON.)

Mr. C. C. Paterson, O.B.E., Vice-President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting of the 31st January, 1924, were taken as read and were confirmed and signed.

Messrs. J. W. Fraser and W. H. Nottage were appointed scrutineers of the ballot for the election and transfer of members and, at the end of the meeting, the result of the ballot was declared as follows:—

ELECTIONS.

Member.

Mather, John.

Associate Members.

Ayengar, Tanjore Krishnasami R., B.A.
Clements, Fred.
Cooper, Harold Cyril, B.A.
Holman, Cecil Leonard.
Inouye, Ikutaro.
Linskill, Harry.
Nicholls, Frank.
O'Connor, Timothy Patrick, B.E.
Orchard, Harold.
Palmer, Lionel Stanley, M.Sc., Ph.D.

Swinney, John.

The discussion on "Loud-Speakers for Wireless and other Purposes" (see pages 265 and 373) was continued, and the meeting terminated at 7.55 p.m.

A VECTOR TREATMENT OF LONG TRANSMISSION LINES.*

By S. HOLMES, Associate Member.

(*Paper first received* 13*th October, and in final form* 22*nd December*, 1923.)

TABLE OF CONTENTS.

1. INTRODUCTION.

In teaching the elementary principles of transmission, the author has found that students understand better what is happening in the transmission lines if a vector method is employed, rather than the method involving the use of complex quantities. It is thought that perhaps this method may be useful to others who are studying the subject for the first time, especially as there is little to choose between the accuracy of the two methods, since each has the equations of the transmission line as its starting-point.

All the currents are separated into their active and idle components respectively in phase and in quadrature with the voltage at the load or receiver end of the lines. Also, the impedance of the line is separated into its resistance and reactance components, so that when each is multiplied by a current the resulting voltage-drops in the line are respectively in phase and in quadrature with that current (see Fig. 1).

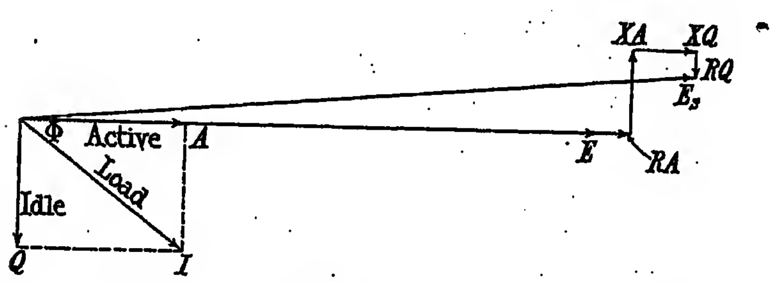

FIG. 1.—Diagram showing the load current separated into its active and idle components, with their corresponding resistance and reactance pressure-drops.

2. SYMBOLS.

E_s = voltage at the supply end of the line.
I_s = current at the supply end of the line.
E = voltage at the receiver end of the line.
I = current at the receiver end of the line.
I_N = minimum idle current supplied by the synchronous condenser for constant-voltage transmission.
I_c = line charging current, and is obtained from the product of B and E, where
B = shunted line susceptance, and is equal to the product of 2π, the frequency and the capacity of one line to earth.*
Z = impedance of one line, and is equal to $\sqrt{(R^2 + X^2)}$, where
R = resistance of one line, and
X = reactance of one line, and is equal to the product of 2π, the frequency and the inductance of one line.
s = spacing of the conductors.
r = radius of the conductors.

3. THE EQUATIONS OF THE TRANSMISSION LINE.

Owing to the distributed nature of the resistance, the inductance and the capacity of the lines, the current and the voltage equations form a converging series.

Neglecting line leakage, the voltage equation is expressed by

$$E_s = E(1 + \tfrac{1}{2}BZ + \frac{1}{2\,.\,3\,.\,4}B^2Z^2 + \ldots)$$
$$+ ZI(1 + \frac{1}{2\,.\,3}BZ + \frac{1}{2\,.\,3\,.\,4\,.\,5}B^2Z^2 + \ldots)$$

and, by omitting all terms beyond $B^2Z^2/(2\,.\,3\,.\,4)$ as negligible in practice, we get

$$\begin{aligned} E_s &= E(1 + \tfrac{1}{2}BZ + \tfrac{1}{24}B^2Z^2) + ZI(1 + \tfrac{1}{6}BZ) \\ &= E + \tfrac{1}{2}EBZ + (\tfrac{1}{4}EBZ)\tfrac{1}{6}BZ + ZI + ZI\tfrac{1}{6}BZ \\ &= E + ZI + Z(\tfrac{1}{2}EB) + Z\{Z(I + \tfrac{1}{4}EB)\tfrac{1}{6}B\} \\ &= E + ZI + Z\tfrac{1}{2}I_c + Z\{Z(I + \tfrac{1}{4}I_c)\tfrac{1}{6}B\} \\ &= E + Z\{(I + \tfrac{1}{2}I_c) + Z(I + \tfrac{1}{4}I_c)\tfrac{1}{6}B\} \end{aligned}$$

The voltage at the supply end of the line is equal to the vector sum of :—

(i) E, the voltage at the receiver end of the line.

(ii) ZI, the line impedance-drop due to the load current I.

(iii) $Z\tfrac{1}{2}I_c$, the line impedance-drop due to the average line charging current, $\tfrac{1}{2}I_c$. This current is of such a value as would be obtained by concentrating one-half of the line capacity at the receiver end of the line in parallel with the load, and is a quarter-cycle ahead of the receiver voltage E.

(iv) $Z\{Z(I + \tfrac{1}{4}I_c)\tfrac{1}{6}B\}$, the line impedance-drop due to the increase in the charging current, $Z(I + \tfrac{1}{4}I_c)\tfrac{1}{6}B$, caused by the rise in voltage, $Z(I + \tfrac{1}{4}I_c)$, from the receiver end to the supply end of the line.

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

* Wkenever a vector is multiplied by B, it is advanced through a quarter cycle.

Similarly the current equation

$$I_s = I(1 + \tfrac{1}{2}BZ + \frac{1}{2.3.4}B^2Z^2) + BE(1 + \frac{1}{2.3}BZ)$$

can be expressed as

$$I_s = I + I_c + Z(I + \tfrac{1}{3}I_c + ZI\tfrac{1}{12}B)\tfrac{1}{2}B$$

The current at the supply end of the line is equal to the vector sum of :—

(v) I, the load current.

(vi) I_c, the total line charging current, which is of such a value as would be obtained by concentrating the whole of the line capacity at the receiver end of the line in parallel with the load, and is a quarter-cycle ahead of the receiver voltage E.

(vii) $Z(I + \frac{1}{3}I_c + ZI\frac{1}{12}B)\frac{1}{2}B$, the increase in the charging current due to the rise in voltage from the receiver end to the supply end of the line.

4. Calculation for a 250-mile, 110 000-volt Transmission Line.

A three-phase transmission line 250 miles long delivers 15 200 kW at 110 000 volts, at 80 per cent power factor and at 50 cycles per second, along overhead lines of 37/0·083 copper cable, equilaterally spaced 144 inches apart.

Resistance of one line.

Diameter of cable = 0·584 inch; cross-sectional area = 0·2 sq. inch.

Resistance per mile at 50 cycles = 0·212 ohm.

Resistance of one line, $R = 0{\cdot}212 \times 250 = 53$ ohms.

Reactance of one line.

Inductance per mile $= 0{\cdot}0805 + 0{\cdot}741 \log (s/r) = 2{\cdot}076$ mH.

Reactance per mile $= 2\pi \times 50 \times 2{\cdot}076 \times 10^{-3} = 0{\cdot}652$ ohm.

Reactance of one line, $X = 0{\cdot}652 \times 250 = 163$ ohms.

Capacity susceptance of one line.

Capacity per mile $= 0{\cdot}0388/(\log s/r) = 0{\cdot}01442\ \mu$F.

Capacity per line $= 0{\cdot}01442 \times 250 = 3{\cdot}6\ \mu$F.

Capacity susceptance of one line, $B = 2\pi \times 50 \times 3{\cdot}6 = 1\,132$ micromhos.

Star voltage at receiver end of line.

$E = 110\,000/\sqrt{3} = 63\,520$ V.

Average line charging current.

Line charging current, $BE = 1\,132 \times 10^{-6} \times 63\,520 = 72$ A.

Average charging current, $\frac{1}{2}BE = \frac{1}{2}72 = 36$ A, a quarter-cycle ahead of E.

Load current.

Power per line = 15 200/3 = 5 067 kW.

$$\text{Current per line at 0·8 power factor} = \frac{5\,067 \times 1\,000}{63\,520 \times 0{\cdot}8}$$

= 100 A.

Active component in phase with $E = 0{\cdot}8 \times 100 = 80$ A.

Idle component a quarter-cycle behind $E = 0{\cdot}6 \times 100 = 60$ A.

Increase in the charging current, $Z(I + \frac{1}{4}I_c)\frac{1}{3}B$.

Active current in phase with $E = 80$ A.

Idle current a quarter-cycle behind $E = 60 - \frac{1}{4}72 = 42$ A lagging (see Table 1).

Multiplying each of these by $\frac{1}{3}B$ or $188{\cdot}7 \times 10^{-6}$ gives the corresponding currents a quarter-cycle in advance of their respective voltage-drops.

$11\,086 \times 188{\cdot}7 \times 10^{-6} = 2{\cdot}1$ A, a quarter-cycle ahead of E.

$10\,814 \times 188{\cdot}7 \times 10^{-6} = 2{\cdot}0$ A, in opposition to E.

Line current, $I + \frac{1}{2}I_c + Z(I + \frac{1}{4}I_c)\frac{1}{3}B$.

Active current = 80 − 2 = 78 A in phase with E.

Idle current = 60 − 36 − 2·1 = 21·9 A, a quarter-cycle behind E (see Table 2).

Total voltage-drop.—7 704 V in phase with E; 11 553 V a quarter-cycle ahead of E.

Supply voltage at full load.

$$E_s = \sqrt{\{(63\,520 + 7\,704)^2 + (11\,553)^2\}} = \sqrt{(71\,224^2 + 11\,553^2)}.$$

= 72 150 V (star).

$= 72\,150\sqrt{3} = 124\,900$ V (delta).

Current at the supply end of the line,

$$I + I_c + Z(I + \tfrac{1}{3}I_c + ZI\tfrac{1}{12}B)\tfrac{1}{2}B.$$

Load current.—80 A in phase with E; 60 A a quarter-cycle behind E.

Total charging current.—72 A a quarter-cycle ahead of E.

Increase in charging, etc., currents,

$$Z(I + \tfrac{1}{3}I_c + ZI\tfrac{1}{12}B)\tfrac{1}{2}B \text{ (see Table 3).}$$

Multiplying by $\frac{1}{12}B = 0{\cdot}00009433$ gives the corresponding currents :—

$14\,020 \times 0{\cdot}00009433 = 1{\cdot}32$ A a quarter-cycle ahead of E.

$9\,860 \times 0{\cdot}00009433 = 0{\cdot}93$ A in opposition to E.

Active current in phase with $E = 80 - 0{\cdot}93 = 79{\cdot}07$ A.

Idle current a quarter-cycle behind $E = 60 - \frac{1}{3}72 - 1{\cdot}32 = 34{\cdot}68$ A (see Table 4).

Multiplying by $\frac{1}{2}B = 0{\cdot}000566$ gives the corresponding currents :—

$9\,843 \times 0{\cdot}000566 = 5{\cdot}6$ A a quarter-cycle ahead of E.

$11\,051 \times 0{\cdot}000566 = 6{\cdot}3$ A in opposition to E.

Current at the supply end of line.

Active component in phase with $E = 80 - 6{\cdot}3 = 73{\cdot}7$ A.

Idle component a quarter-cycle ahead of $E = 72 + 5{\cdot}6 - 60 = 17{\cdot}6$ A.

Total current at supply end $= \sqrt{(73{\cdot}7^2 + 17{\cdot}6^2)} = 75{\cdot}8$ A leading by 4·2 degrees on the supply voltage E_s, since the supply voltage and the supply current are ahead of the receiver voltage by the angles whose respective tangents are 11 553/71 224 and 17·6/73·7.

5. Calculation for Constant-voltage Transmission.

For a constant receiver pressure of 110 000 volts, the supply voltage is 125 000 at full load and 100 000 at no load. In order to keep the voltage constant at

Active, 80 A	Reactance, 80 × 163 = 13 040 V $\frac{1}{4}$-cycle ahead of E
Idle, 60 A (lagging)	Resistance, 60 × 53 = 3 180 V $\frac{1}{4}$-cycle behind E
	Total 9 860 V $\frac{1}{4}$-cycle ahead of E

TABLE 4.

Component of current	Voltage-drop
Active, 79·07 A	Resistance, 79·07 × 53 = 4 190 V in phase with E
Idle, 34·68 A (lagging)	Reactance, 34·68 × 163 = 5 653 V in phase with E
	Total 9 843 V in phase with E
Active, 79·07 A	Reactance, 79·07 × 163 = 12 890 V $\frac{1}{4}$-cycle ahead of E
Idle, 34·68 A (lagging)	Resistance, 34·68 × 53 = 1 839 V $\frac{1}{4}$-cycle behind E
	Total 11 051 V $\frac{1}{4}$-cycle ahead of E

both ends of the line under all conditions of load, synchronous condensers are placed in parallel with the load at the receiver end of the line. The capacity of the synchronous plant is a minimum when it supplies the same current (I_N) both at no load and at full load. The current (I_N) is a quarter-cycle behind the receiver voltage at no load and a quarter-cycle ahead of it at full load.

(*a*) *At no load.*

Idle current $= I_N - 36$, a quarter-cycle behind E.

Increase in the charging current, $Z(I_N + \frac{1}{4}I_c)\frac{1}{8}B$.

Idle current $= I_N - \frac{1}{4}72 = I_N - 18$, a quarter-cycle behind E.

Resistance drop $= 53I_N - 954$, a quarter-cycle behind E.

Reactance drop $= 163I_N - 2\,934$, in phase with E.

Multiplying by $\frac{1}{8}B = 0{\cdot}0001887$ gives the corresponding currents :—

$(53I_N - 954) \times 0{\cdot}0001887 = (0{\cdot}01I_N - 0{\cdot}18)$ A in phase with E.

$(163I_N - 2\,934) \times 0{\cdot}0001887 = (0{\cdot}03I_N - 0{\cdot}55)$ A, a quarter-cycle ahead of E.

Line currents :—

Active current in phase with $E = (0{\cdot}01I_N - 0{\cdot}18)$.

Idle current a quarter-cycle behind E

$$= I_N - 36 - (0{\cdot}03I_N - 0{\cdot}55) = 0{\cdot}97I_N - 35{\cdot}45$$
(see Table 5)

$$E_s^2 = (63\,520 + 158{\cdot}5I_N - 5\,790)^2 + (49{\cdot}8I_N - 1\,850)^2$$
$$= (57\,730 + 158{\cdot}5I_N)^2 + (49{\cdot}8I_N - 1\,850)^2$$

(*b*) *At full load.*

Active current in phase with $E = 80$ A.

Idle current a quarter-cycle ahead of E

$$= (I_N + \tfrac{1}{2}72 - 60) = (I_N - 24)$$

Decrease in the charging current,

$$Z(I + I_N + \tfrac{1}{4}I_c)\tfrac{1}{8}B.$$

Active current in phase with $E = 80$ A.

Idle current a quarter-cycle ahead of E

$$= I_N + \tfrac{1}{4}72 - 60 = (I_N - 42) \text{ (see Table 6)}$$

Multiplying by $\frac{1}{8}B = 0{\cdot}0001887$ gives the corresponding currents :—

$(163I_N - 11\,086) \times 0{\cdot}0001887 = (0{\cdot}03I_N - 2{\cdot}1)$ A a quarter-cycle behind E.

$(53I_N + 10\,814) \times 0{\cdot}0001887 = (0{\cdot}01I_N + 2)$ A in opposition to E.

Line currents at full load,

$$I + I_N + \tfrac{1}{2}I_c + Z(I + I_N + \tfrac{1}{4}I_c)\tfrac{1}{8}B.$$

Active $= 80 - (0{\cdot}01I_N + 2) = (78 - 0{\cdot}01I_N)$ in phase with E.

Idle $= I_N - 24 - (0{\cdot}03I_N - 2{\cdot}1) = (0{\cdot}97I_N - 21{\cdot}9)$ a quarter-cycle ahead of E (see Table 7).

$$E_s^2 = \{63\,520 - (158{\cdot}5I_N - 7\,704)\}^2 + (49{\cdot}8I_N + 11\,553)^2$$
$$= (71\,224 - 158{\cdot}5I_N)^2 + (49{\cdot}8I_N + 11\,553)^2$$

Since the supply voltage is the same both at no load and at full load, by equating the two equations we get :—

$$(71\,224 - 158{\cdot}5I_N)^2 + (49{\cdot}8I_N + 11\,553)^2$$
$$= (57\,730 + 158{\cdot}5I_N)^2 + (49I_N - 1\,850)^2$$

and, on re-arranging,

$$(49{\cdot}8I_N + 11\,553)^2 - (49{\cdot}8I_N - 1\,850)^2$$
$$= (57\,730 + 158{\cdot}5I_N)^2 - (71\,224 - 158{\cdot}5I_N)^2$$

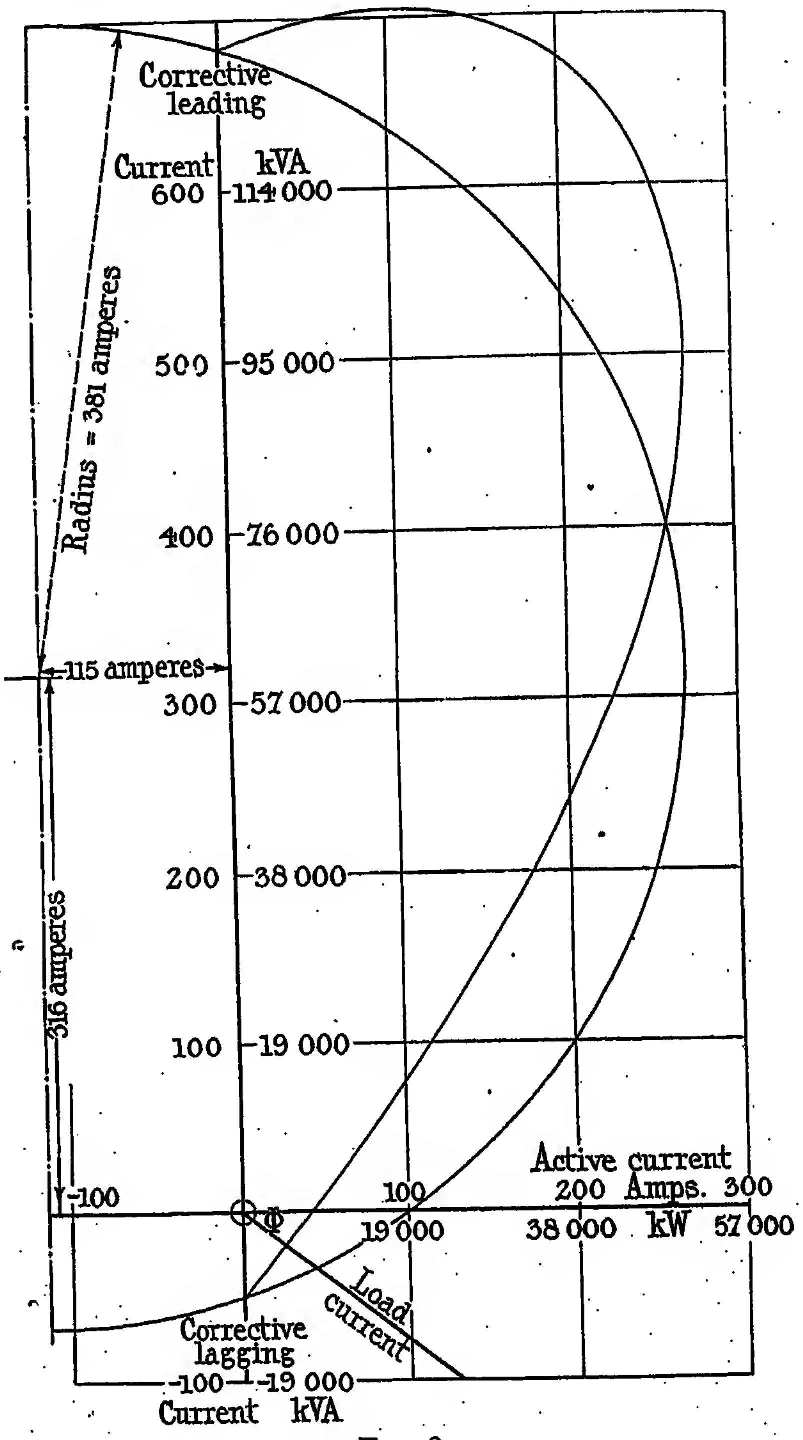

Fig. 2.

Since the difference of two squares is the product of the sum and of the difference of the two numbers forming the squares, we get :—

$$13\,403(99{\cdot}6I_N + 9\,703) = 128\,954(317I_N - 13\,494)$$
$$1{\cdot}33 \times 10^6 I_N + 13 \times 10^7 = 41 \times 10^6 I_N - 174 \times 10^7$$
$$39{\cdot}67I_N = 1\,870$$
$$I_N = 47 \text{ A}$$

The line corrective kVA $= 3 \times 47 \times 63\,520/1\,000 = 8\,960$, a quarter-cycle behind E at no load, and a quarter-cycle ahead of E at full load.

Voltage at supply end of line, $E_s = 65\,250$ V (star) $= 113\,000$ V (delta).

6. Calculation of the Circle Diagram (see Fig. 2).

$E_s = 65\,250$; $E = 63\,520$.

Active component of charging current at no load in phase with $E = 0{\cdot}01 I_N - 0{\cdot}18 = 0{\cdot}29$ A.

Idle component of charging current at no load a quarter-cycle behind E

$= 36 + (0{\cdot}03 I_N - 0{\cdot}55) = 36{\cdot}9$ A (from Section 5).

Solving, we get:—

$$29\,380 A^2 + 67\,520 \times 10^3 A + 29\,380 Q^2 - 185\,500 \times 10^2 Q = 94\,600 \times 10^4$$

$$\therefore\ A^2 + 230A + Q^2 - 632Q = 32\,270$$

$$(A + 115)^2 + (Q - 316)^2 = 32\,270 + 115^2 + 316^2 = (381)^2$$

TABLE 5.

Component of current	Voltage-drop		
Active, $(0{\cdot}01 I_N - 0{\cdot}18)$ A	Resistance,	$0{\cdot}53 I_N -$ 10 V	in phase with E

Idle (lagging), $(0{\cdot}97 I_N - 35{\cdot}45)$ A ..	Resistance,	$51{\cdot}4 I_N -$ 1 879 V	$\frac{1}{4}$-cycle behind E
	Total	$49{\cdot}8 I_N -$ 1 850 V	$\frac{1}{4}$-cycle behind E

TABLE 6.

Component of current	Voltage-drop			
Active, 80 A	Resistance,	80×53 =	4 240 V	in phase with E
Idle (leading), $(I_N - 42)$ A	Reactance,	$163(I_N - 42) = 163 I_N -$	6 846 V	in opposition to E
		Total	$163 I_N -$ 11 086 V	in opposition to E
Active, 80 A	Reactance,	80×163	13 040 V	$\frac{1}{4}$-cycle ahead of E
Idle (leading), $(I_N - 42)$ A	Resistance,	$53(I_N - 42) = 53 I_N -$	2 226 V	$\frac{1}{4}$-cycle ahead of E
		Total	$53 I_N +$ 10 814 V	$\frac{1}{4}$-cycle ahead of E

TABLE 7.

Component of current	Voltage-drop		
Active, $(78 - 0{\cdot}01 I_N)$ A	Resistance,	$4\,134 - 0{\cdot}53 I_N$ V	in phase with E
Idle (leading), $(0{\cdot}97 I_N - 21{\cdot}9)$ A ..	Reactance,	$158 I_N -$ 3 570 V	in opposition to E
	Total	$158{\cdot}5 I_N -$ 7 704 V	in opposition to E
Active, $(78 - 0{\cdot}01 I_N)$ A	Reactance,	$12\,714 - 1{\cdot}63 I_N$ V	$\frac{1}{4}$-cycle ahead of E
Idle (leading), $(0{\cdot}97 I_N - 21{\cdot}9)$ A ..	Resistance,	$51{\cdot}4 I_N -$ 1 161 V	$\frac{1}{4}$-cycle ahead of E
	Total	$11\,553 + 49{\cdot}8 I_N$ V	$\frac{1}{4}$-cycle ahead of E

Let A be the active current in the line at the receiver end in phase with E, and

Q be the idle current in the line at the receiver end a $\frac{1}{4}$-cycle ahead of E.

$$65\,250^2 = \{63\,520 + 53(A + 0{\cdot}29) - 163(Q + 36{\cdot}9)\}^2 + \{163(A + 0{\cdot}29) + 53(Q + 36{\cdot}9)\}^2$$

$$= (57\,520 + 53A - 163Q)^2 + (163A + 53Q + 2\,000)^2$$

This is the equation to a circle whose centre is at a point the ordinates of which are − 115 and 316 amperes and whose radius is 381 amperes.

Multiplying each by $(3 \times 63\,520)/1\,000$ gives the circle showing the relation between the kilowatts and the corrective idle kilovolt-amperes required by the line for constant-voltage transmission.

The synchronous plant at the receiver end of the

line has to supply corrective idle kilovolt-amperes to the load as well as to the line. By drawing in the load-current line at its correct angle of lag, the curve connecting the load in kilowatts and the idle kilovolt-amperes of the synchronous plant is obtained, and is found to be an ellipse.

DISCUSSION ON
"AN INVESTIGATION OF THE FRICTION BETWEEN SLIDING SURFACES." *

Mr. O. R. Randall (*communicated*): On page 151, while dealing with the resistance of a system containing a semi-conductor, the author states: "As far as we are aware no attempt has been made to distinguish between body and contact resistance." Experiments carried out at Birmingham University have been successful in separating contact resistance from the other factors involved in the problem. It was found during the course of the work that, in order to determine the part played by the contact, it was necessary to consider all the following quantities: (*a*) The resistance of the stone up to a plane very near the contact; (*b*) the resistance of the thin layer of stone near the contact; (*c*) the capacity across the contact; and (*d*) the resistance of the leak across the capacity. It will be seen that the resistance of the contact can mean either the true resistance across the interface between the conducting surfaces, or the resistance of this region added to the resistance of the adjacent layer of stone. The separation of these two resistances without introducing capacity was very difficult, as it was found that they varied together, and under most test conditions none of the quantities mentioned in (*a*), (*b*), (*c*) and (*d*) above is constant. The method used to separate the resistance of the body of the stone, not including the layer very near the contact, from the resistances (*b*) and (*d*) added together, was as follows: A group of similar contacts was placed at each end of a large slab of stone, and while a unit contact was left connected to one pole of the supply, at the other end the contacts in parallel were gradually increased, the current meanwhile being kept constant until, on further increasing the area, there was no change in the current. When this condition was reached the total voltage decrement needed to maintain constant current measured the initial resistance-drop across the unit contact, which the process had eliminated. A great many tests were carried out with various modifications of this general plan, and the results clearly showed that the resistance of the body of the stone, together with any back E.M.F., was in general only 2 or 3 per cent of the whole resistance of the system. An interesting result of these tests was that it was shown that the total contact drop [including (*b*) and (*d*) above] was not the same for the two ends of the system, the contact connected to the negative end of the supply always showing a larger voltage drop than the contact connected to the positive end. Representative figures are given below showing the values found in two tests:—

Test A.

Current = 0·27 micro-amperes.
Voltage across positive contact and adjacent layer of stone = 9·7 volts.
Voltage across negative contact and adjacent layer of stone = 15·2 volts.
Back E.M.F. plus the resistance in the body of the stone = 1·5 volts.

Test B.

Current = 0·18 micro-amperes.
Voltage, positive, as above = 6·9 volts.
Voltage, negative, as above = 11·0 volts.
Voltage in body of stone and back E.M.F. = 1·1 volts.

In the above experiments, as in all those dealt with in this contribution, the contacts were formed by tinfoil on lithographic stone. The results of these tests were important in connection with the experiments carried out to separate the quantities mentioned in (*a*), (*b*), (*c*) and (*d*) above, since they showed that by making one contact large compared with the other, its effect would be correspondingly small. Using this principle a circuit was arranged in which one of the contacts was so much larger than the other that all the voltage of the system could be assumed to be distributed over the region of the smaller contact. This small contact was treated as a condenser in series with a high resistance (the layer of stone near the contact) and shunted by another high resistance (the true resistance across the interface). These tests were more difficult to analyse than the last, because it was necessary to introduce time as another variable, and there were progressive changes in the value of the quantities being measured. Consistent results were obtained, however, and the results of a representative test are as follows:—

Resistance of layer of stone near contact = 195 megohms.
Resistance across contact = 98 megohms.
Capacity = 1·4 microfarads.
Area of contact = 2 cm².

In connection with the resistance of the stone itself, experiments have been carried out using a prism of lithographic stone machined to a uniform section and long compared with its width and depth. At the ends large contacts were placed, and bands of tinfoil were fixed round the middle part, separated by a known distance; these test-contacts were connected to a standard condenser, which was charged over a length of time found by experiment to be long enough to eliminate the effect of the contact resistance at the test or charging contacts. The condenser could be discharged through a ballistic galvanometer, and so the potential difference between the test-contacts could be determined. A knowledge of the current in the circuit then gave the value of the resistance between the test-contacts. This apparatus gave very consistent results, and by its means the effects of temperature and moisture were investigated. The result of temperature-changes was very interesting: the tests showed that the specimen had a resistance/temperature rate of change equal to 2 megohms per degree C. between the limits of temperature reached in the tests. This was about 6 per cent of the average initial resistance, and indicates that the material would have quite a low resistance if the temperature were raised through a range easily realized in a laboratory (the tests are not yet completed). It should be noted

* Paper by Dr. H. M. Barlow (see page 133).

that this does not mean that the resistance of the set as a whole is reduced to this extent, since the contact resistance gives the character to the whole set.

The author states on page 151: "By testing various thicknesses of a particular sample of semi-conductor, the body and contact resistance are easily separated." My experience makes me doubt the reliability of the method proposed, as it has been found that small variations in contact conditions are sufficient to mask the changes in resistance which it is intended to estimate. The method was tried during the preliminary tests, and it was given up because of the objection stated. In several places the author mentions the effect of wetting the contact, and yet he washed the samples of lithographic stone before using them. During the course of the experiments described above it has been found that the effect of wetting a stone, or even of making the air in the room very wet, was gradually to alter the resistance of the stone, and that the change sometimes took place over several days. In view of these observations, it seems doubtful if one hour's drying after washing would result in uniform initial conditions.

Dr. H. M. Barlow (*in reply*): The experiments carried out by Mr. Randall are very interesting and, although I cannot agree with him in the procedure he has adopted, it is satisfactory to observe that he has arrived at the same general result as I did, namely, that the effective body resistance of lithographic stone is only a small part of the total resistance between the electrodes. In the first place it seems to me that to treat the thin layer of stone near the contact as a separate entity is simply to introduce unnecessary complications. There is no reason to suppose that the surface layer of the stone differs in constitution from the internal layers, or that there is any discontinuity between these layers. It is true that the bounding surface will be pitted and thus have an irregular contour, but it is largely in virtue of these irregularities that the contact acts as a condenser. It would appear, therefore, that the true contact resistance is simply in parallel with the interface capacity, and the hypothetical series resistance is really a part of the body resistance of the stone. The description of the experiments with the unit contacts is rather difficult to follow, but, as I understand it, the number of parallel contacts at one pole is gradually increased until the resistance of this connection is relatively negligible. Then the total amount by which the applied potential difference has been reduced to maintain a constant current is equal to the product of this current and the resistance of the unit contact. In my view the accuracy of this deduction depends entirely on the unit contacts having the same resistance. Mr. Randall points out that my experiments with various thicknesses of semi-conductor are inclined to give misleading results on account of variations in the contact conditions. He states that he abandoned this method on account of these difficulties, but it appears to me that his tests with the unit contacts suffer from precisely the same objection, which would be specially marked with the tinfoil electrodes employed. Moreover, apparently no allowance is made for the necessary variations in the distance between the two poles, the influence of the capacity of the contacts, and the gradually increasing back E.M.F. due to absorption. My experiments in this direction show that a long time is required to establish steady conditions even with a small contact.

The method employed for determining the internal resistance of the stone is distinctly ingenious and is independent of the nature of the contact. I cannot, however, agree with Mr. Randall that the surface layer of stone is not included in these measurements. Since the current only flows longitudinally when the steady state is reached, it must distribute itself over the whole cross-section of the prism. Theoretically, an infinite time is required to reach the final condition when the P.D. across the standard condenser should be measured, but I have no doubt that reasonable accuracy can be obtained in practice after a few hours' charging. It appears difficult to calculate the specific resistance of the material from the data obtained. The back E.M.F. due to absorption and surface leakage must also be involved in these measurements. When further details of Mr. Randall's work are available, I shall welcome an opportunity of a more detailed discussion.

INSTITUTION NOTES.

Mascart Medal.

The Société Française des Electriciens have founded a Medal of Honour to be called the Mascart Medal, in memory of that eminent French scientist, the Medal to be awarded triennially to scientists or engineers of any nationality distinguished for their work in pure and applied electricity. The first (1924) award of the Medal has been made to Monsieur A. Blondel, an Honorary Member of the Institution.

War Thanksgiving Education and Research Fund (No. 1).

The grant for 1924 in connection with the above Fund has been made by the Council to Mr. Alexander Ramsay, of Glasgow University.

Portrait of the late Mr. Willoughby Smith.

Mr. W. O. Smith and Mr. W. S. Smith, Members, have presented to the Institution an oil painting of the late Mr. Willoughby Smith, who was President of the Institution in 1883.

Associate Membership Examination Results: February, 1924.

OFFICERS OF THE ROYAL CORPS OF SIGNALS.

Passed.

Anthony, Lieut. H. H. (17th Pack Battery, R.G.A.).
Childs, Lieut. C. (R.F.A.).

Informal Meetings.

The following Informal Meetings have been held :—

48TH INFORMAL MEETING (7TH JANUARY, 1924).

Chairman : Dr. H. M. Barlow.

Subject of Discussion : "Troubles experienced with Domestic Electrical Appliances" (introduced by Mr. J. W. Beauchamp).

Speakers : Messrs. A. F. Harmer, M. Pulvermacher, A. W. Blake, W. P. Fanghanel, F. Selley, M. Napier Prentice, E. E. Sharp, W. L. Wreford, E. W. Lovell, W. Betts, R. Grierson, F. J. E. Nesbitt, and C. E. Charman.

49TH INFORMAL MEETING (21ST JANUARY, 1924).

Chairman : Mr. R. Grierson.

Subject of Discussion : "Broadcasting" (introduced by Mr. E. H. Shaughnessy, O.B.E.).

Speakers : Messrs. G. F. Bedford, C. F. Phillips, W. H. Lawes, H. J. Neill, P. Voigt, J. Coxon, W. E. Warrilow, W. Day, E. G. Bedford, J. R. Bedford, E. S. Ritter, and R. Grierson.

50TH INFORMAL MEETING (4TH FEBRUARY, 1924).

Chairman : Mr. A. F. Harmer.

Subject of Discussion : "Storage Battery Troubles" (introduced by Mr. F. W. Crawter).

Speakers : Messrs. W. R. Rawlings, J. W. Beck, J. R. Bedford, F. C. Raphael, A. G. Hilling, K. L. Wood, R. V. Hook, F. A. Sclater, W. A. Ritchie, W. R. Cooper, and A. F. Harmer.

51ST INFORMAL MEETING (18TH FEBRUARY, 1924).

Chairman : Mr. F. Gill.

Subject of Discussion : "Electrical Development in France" (introduced by Mr. E. M. Malek).

Speakers : Colonel T. Rich, Messrs. G. L. Addenbrooke, W. E. Rogers, A. C. Sparks, W. J. Minton, A. G. Hilling, J. Coxon, A. W. Berry, S. W. Melsom, R. A. MacMahon, R. V. Hook, R. Grierson, and A. R. Rendall.

52ND INFORMAL MEETING (3RD MARCH, 1924).

Chairman : Mr. E. F. Hetherington.

Subject of Discussion : "The Selection and Location of Converting Plant for Supplying D.C. Networks" (introduced by Mr. R. D. Spurr).

Speakers : Messrs. W. E. Rogers, H. Craske, A. F. Harmer, C. M. Mayson, E. F. Hetherington, A. G. Hilling, R. V. Hook, A. H. E. Tomkinson, and R. Grierson.

53RD INFORMAL MEETING (10TH MARCH, 1924).

Chairman : Mr. A. G. Hilling.

Subject of Discussion : "The Work of the International Conference on E.H.T. Lines held in Paris, November 1923" (introduced by Mr. J. Tribot Laspière).

Speakers : Messrs. R. Borlase Matthews, W. E. Rogers, P. V. Hunter, C.B.E., A. Jacob, E. H. Rayner, J. Coxon, Prof. C. L. Fortescue, Messrs. K. Edgcumbe, P. Dunsheath, O.B.E., and P. Good.

54TH INFORMAL MEETING (17TH MARCH, 1924).

Chairman : Mr. A. F. Harmer.

Subject of Discussion : "Illuminating Engineering, its Application and Value to the Electrical Industry" (introduced by Messrs. L. Gaster and J. S. Dow).

Speakers : Messrs. J. Eck, P. Good, W. E. Bush, W. Day, A. Cunnington, W. P. Fanghanel, J. Coxon, P. Dunsheath, O.B.E., J. R. Bedford, and E. W. H. Wilson.

55TH INFORMAL MEETING (31ST MARCH, 1924).

Chairman : Mr. F. Pooley.

Subject of Discussion : "Economics in Engineering" (introduced by Mr. F. Gill).

Speakers : Messrs. D. J. Bolton, W. E. Rogers, W. Day, B. O. Anson, S. W. Pook, P. Dunsheath, O.B.E., L. M. Jockel, P. Good, H. M. Sayers, E. S. Byng, F. Tremain, and H. Brown.

56TH INFORMAL MEETING (14TH APRIL, 1924).

Chairman : Mr. W. E. Warrilow.

Subject of Discussion : "Some Idiosyncrasies of Electrical Manufacturers" (introduced by Mr. J. R. Bedford).

Speakers : Messrs. J. Coxon, W. Day, P. Rosling, W. E. Rogers, J. F. Avila, D. Dixon, A. Kirk, W. L. Wreford, H. Brown, F. P. Sexton, W. E. Twells, F. Pooley, J. T. Bedford, C. F. Mounsdon, W. Riggs, A. F. Harmer, A. G. Hilling, M. Whitgift, R. V. Hook, V. N. Halliday, and W. E. Warrilow.

The Benevolent Fund.

The following Donations and Annual Subscriptions were received during the period 26 March–25 April, 1924 :—

	£	s.	d.
Allan, P. F. (Newcastle-on-Tyne)		12	6
Bailie, J. D. (Leeds)	1	2	6

SOME RESEARCHES ON THE SAFE USE OF ELECTRICITY IN COAL MINES.

By Professor W. M. THORNTON, O.B.E., D.Sc., D.Eng., Member.

(*Paper first received* 18*th September, and in final form* 22*nd November,* 1923; *read before* THE INSTITUTION 31*st January, before the* MERSEY AND NORTH WALES (LIVERPOOL) CENTRE 14*th January, before the* NORTH-EASTERN CENTRE 28*th January, before the* NORTH-WESTERN CENTRE 19*th February, before the* SOUTH MIDLAND CENTRE 12*th March, before the* NORTH MIDLAND CENTRE 18*th March, before the* SCOTTISH CENTRE 9*th April, and before the* WESTERN CENTRE 3*rd May,* 1924.)

SUMMARY.

The limiting electrical conditions under which ignition of coal dust and firedamp may occur have been worked at in the author's laboratory for the past 14 years, as part of a general investigation of the mechanism of ignition of gases. The paper contains an account of some results of practical interest, and deals with the electrical ignition of coal dust alone, coal dust with gas present, of methane and associated gases by disruptive sparks, steady or impulsive, transient arcs, direct or alternating, with varied voltage and frequency, in all percentages of mixture with air. Examples are given of the application of the results to promote safety in mines, notably the influence of currents of higher frequency than usual, of safety bells, safety lamps which give an alarm signal when dangerous mixtures of gas occur, and an improved earthing plate.

TABLE OF CONTENTS.

(1) INTRODUCTION.

Electricity is the perfect medium for conveying energy underground. Its advantages are clear to all, but, like other systems, it has limits. There is the possibility of leakage, from which in the old days shocks were not uncommon, and there is the electric spark. It used to be held that every visible spark would fire an explosive gaseous mixture. One of the objects of the paper is to show how far this is from the truth and to define the limits within which the safe use of electricity is possible for the various purposes of mining. The researches of which a brief account is now given were started after the West Stanley, Hulton and Senghenydd Colliery explosions, to find an answer to the many questions more or less directly raised as to the risk of ignition from electrical causes. At that time a vague unrest was felt about the working conditions of electricity in mines, but little or nothing was known of the influence of the various factors in the problem, of voltage, frequency, metal of poles, gas pressure, capacity, inductance, and frequency. Considering the immense importance of the issues involved and the necessity for precise knowledge, it seemed worth while to enter on the laborious task of determining the critical limits in each of the above cases. Every engineer knows that only by accurate measurement of the breakdown values of the materials that he uses can safety be ensured. In the present work the breaking point is the current or voltage which just causes ignition, other factors being systematically varied or kept constant. The alternative to such investigation is to wait for the event, hold an Inquiry and act upon the finding. The cost in life and material of such a method is high and, so far as electricity is concerned, need never be paid if the human element of carelessness could be for ever removed, for to each possibility of electrical risk there is a simple and effective preventive.

The inflammable part of pit gas in this country is methane (CH_4), the lowest and most inert of the paraffin series of compounds. It is to this inertness that coal-mining owes the greater part of its immunity from explosions. Most of the accidents in mines are mechanical in origin, and are due to the poor illumination on haulages, or to the difficulty of keeping earth movements under continual observation. Safety in coal mines, now and in the future, depends on efficient ventilation (already excellent), the elimination of all sources of flame or open sparking, the improvement of underground illumination, not so much at the face as along the roads, and on the training into habits of constant observation and carefulness of those upon whom the getting of coal depends.

The growth of the use of electricity in mining followed closely that in other forms of industry, but, when it is considered that only 11 per cent of the coal raised in England and Wales is cut by electrical machines, there is room for expansion. Scotland alone cuts 36 per cent mechanically; but it is in electrical haulage that development is likely to be greatest. The electrical age in mining began in the early eighties, and it may be noted that in the Report of the Prussian Firedamp Commission * of 1881, made in 1887, there were no cases on record of accident from the use of electricity. Of the total number of explosions, 56·8 per cent were due to naked lights, and 14·6 to shot-firing. This Report is noteworthy for the section, 56, on Ignition by Electric Sparks, by Professors Wüllner and Lehmann,

* Translated by Professor P. Phillips Bedson.

of Aachen, which was really an inquiry preliminary to using electricity on a large scale underground. Their experiments did not go very far but established several interesting facts. Long sparks from an electrophorus would not fire pit gas, nor would bright condenser discharges. Certain least igniting currents are given, 18 amperes in one case, but voltage is not mentioned. Mallard and Le Chatelier had previously investigated ignition by hot wires, and had given many instances of the failure of ignition by wires at temperatures approaching the melting point of silver, which were confirmed and extended by Wüllner and Lehmann. In 1904 a British Departmental Committee was appointed by the Home Office and special rules * were formulated as a result of the evidence, but the rapid introduction of electricity into coal mines from 1895 onward, and the not altogether satisfactory manner of its installation, gave rise to a further committee in 1910 to investigate the working of the special rules. The Report † (3) of this latter committee and the rules as modified by it may be regarded as the Reform Bill of electricity in mining so far as British practice is concerned. Open sparking of any kind is prohibited, flame-proof gear specified, and armouring and its earthing insisted upon. In effect, electricity was put on a level with naked lights and was not to be used when more than 1¼ per cent of gas was present. Everything was considered but signalling bells, whose sparks were not regarded as being dangerous. They soon after received attention.

Three great colliery disasters occurring at short intervals, i.e. West Stanley (Durham) in 1909, Hulton (Lancashire) in 1910, and Senghenydd (South Wales) in 1913, the last with a death-roll of 439 (the greatest on record), each directed attention during the Inquiry to possible weaknesses in the electrical equipment of collieries, which have now been rectified. The specification of flame-proof apparatus with wide metal-to-metal flanges and bushes, covers the first two cases, and the provision of signalling bells the spark of which is made inert in various ways is enforced by the third, of which a sparking bell was the suspected cause.‡

(2) Inflammable Gas and Dust.

All but a few colliery explosions have begun by ignition of gas. With modern ventilation, gas cannot collect in mixtures rich enough to transmit a continuous explosion throughout the workings. Local ignitions may result in nothing more than a burst of flame, burning those in contact with it. In an enclosed space the pressure may rise to about eight atmospheres, but if the place opens into a road with larger volume not full of gas the pressure-rise is not so great; there must be constraint for pressure to develop. If, however, there is coal dust thrown down from the roof and ledges by the sound or pressure wave of such a local explosion, quickly enough to be caught in the first rush of flame, there is probability of transition to the much more dangerous form of explosion of coal dust alone. This dust is present everywhere through the workings and all the great disasters have been dust explosions, ignited in most cases by a small gas explosion. First proved by Professor W. Galloway * in 1884, it is only within the past 20 years that this has received full recognition, and even now large-scale coal-dust explosions are arranged at Eskmeals from time to time by the Mines Department to convince possible doubters.

Methane is inflammable between 5·6 and 14·8 per cent in air.† In mixtures both weaker and richer than these there may be burning around the source of ignition, but there is no sustained explosion wave or marked rise of pressure. In the case of coal dust there is a wide variation in the mass of dust required to transmit an explosion, but the cloud must always be dense. It depends in the first place on the fineness of the dust and on the ratio of the combustible to the non-combustible components. If 50 per cent of stone

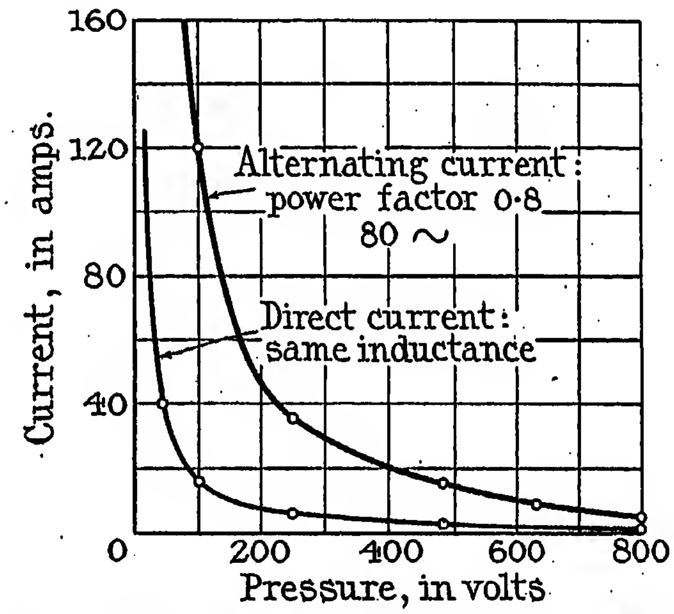

Fig. 1.—Least currents for ignition of coal dust by transient arcs.

dust is added it usually, though not with every kind of coal dust, prevents the transmission of flame. With any dense cloud of dust the presence of 2 per cent of gas makes a coal-dust explosion inevitable.‡ This is the real danger in coal mining; dust with a little gas forms a most dangerous mixture and for this reason haulage is not permitted in return air-ways where the combination is likely to occur. The rise of inflammability is regular from zero to the maximum, as shown in Table 1.

Coal dust can be ignited without the presence of gas by blown-out shots and by electric flashes, provided that there is a dense cloud formed before the arc is struck. Heise and Theim stated § that single electric arcs could not fire coal dust, but this is not the case.

The limits* given in Fig. 1 are quite clearly marked and show that such an ignition is well within possibility, though the risk is remote in modern practice. It will be observed that ignition by alternating-current arcs is

TABLE 1.

Direct-current Non-inductive Circuit: 480 *volts,* 3·5 *amperes.*

Percentage of methane in air, by volume	Percentage of full dust explosions
0·0	7·0

0·50	17·0
0·75	31·0
1·0	53·0
1·25	75·0
1·50	97·0

more difficult than by direct-current arcs. At 1 000 volts they are much the same on account of the longer arcs at break.

(3) Ignition by Electrostatic Discharge and Friction.

Ignition of coal dust by single condenser discharge sparks has not so far been obtained; nor does it appear probable, for the progress of dust ignition is by a process of disintegration and combustion under the influence of heat and for this a longer time is necessary than the duration of a condenser discharge. It becomes, then, a question of how firedamp can be ignited by such a spark, for there are many conditions of mining which give rise to static discharge in dry atmospheres. Belts, especially those of rubber composition, when rapidly strained and released are subject to this form of electrification, but I have never succeeded in lighting a stream of gas by the long, thin sparks from such a belt. Another very active source of electrification is the formation of dust clouds. Rudge † has shown the potential induced by this to reach thousands of volts, but the surfaces electrified by friction and separation are too small for united discharge to occur in the dust, and only on the colossal scale of dust storms in nature is there sufficient electrification of neighbouring conductors such as clouds to permit spark discharge. Rudge has not succeeded in causing ignition of gas in this way, but it is conceivable that the intense electrification always present in a sudden dust cloud may help the transmission of flame, though experiments that I have made show that an external electric field has no measurable influence on a gas explosion.

A phenomenon of regular occurrence which I was once asked to investigate is the production of long, powerful, sparks at the nozzle of an hydraulic jet filling cement grout into stone packing. This is an example of electrification produced by splashing similar to that of waterfalls and waves, and can be observed by directing a powerful jet of water alone against a surface at short range in the dark. A luminous blue disc will be seen where the jet strikes.

A common instance is the luminous patch where the condenser circulating water outflow of a ship strikes the sea. In the mining case the electrification produced is conducted back through the liquid to the nozzle and the spiral wire support of the rubber feeding tube, and, although gloves are provided, sparks of several inches in length have been known to pass to the body of the worker, with very unpleasant though not dangerous shock. The remedy is to earth the wiring of the supply pipe. In this case also it is unlikely that ignition of firedamp would occur. The activity *per unit length* of the spark is insufficient to start self-ignition of the gas.

The so-called sparks given off at a grindstone are particles of incandescent iron and silica. In spite of their fiery appearance they are singularly inert, but they can ignite pit gas, as also can the sparks from a stone block rubbing on stone. On the merely thermal view of ignition this depends only upon the temperature of the particles; on the ionic view there is the well-known electronic discharge from heated silica to be considered.

Occasional reports are received from coal-cutter operators that a blue flame has been seen to flash around the back of the cut. This may possibly be ignition of minute blowers of gas by hot particles or spots on the cutter tools. It has nothing to do with the electricity supplied to the machine.

A possible source of ignition is electrification by crushing or shear of rock faces, a well-known phenomenon in splitting crystals, which has been observed on a large scale underground when masses of stone are brought down.* This was at one time a favourite explanation of pit explosions, but it is extremely difficult to fire pit gas in this way experimentally. Trials on a larger scale than are possible in a laboratory are necessary to prove electrification by splitting to be a possible source of ignition.

So far the electrical sparks discussed have nothing to do with the use of electricity in mines, except that they illustrate electrical ignition, but sparks occasionally pass between the rotor and stator of induction motors in belt-driven haulages. By their appearance they are static discharges and are caused either by surges on the high-tension system, in which case a spark would be followed by a "power current" and this is never observed, or by electrostatic charge from the belt passing by the shaft to the rotor and escaping by discharge across the narrow air-gap rather than by breaking down the oil film of the bearings. To prevent this the rotor, as well as the stator frame, must be earthed. It is not very likely that these sparks would fire gas if present in the right proportions, but such machines are not now placed where 6 per cent of gas can accumulate, and would be totally enclosed and flame-proof for use inbye.

I have shown elsewhere † that a short spark having an energy of 0·03 joule will just ignite pit gas.

* See Report of the Prussian Firedamp Commission of 1881, par. 97.

† "The Ignition of Gases by Condenser Discharge Sparks," *Proceedings of the Royal Society,* 1914, ser. A, vol. 91, p. 17.

This corresponds to the discharge of a condenser having two plates about 40 cm^2 area at a distance apart of 3 mm and charged to 10 000 volts. Areas as small as this can certainly be discharged without ignition, and this indicates that it is not the total energy which is important but the energy per unit length of the spark, in so far as it is a question of energy as distinct from "activation" of the gas by the voltage gradient.

(4) Signalling Bells.

The sparks previously considered are disruptive, that is, they are formed by the process of ionization by collision under the influence of a high voltage gradient across an air-gap. Those now to be examined are break sparks or transient arcs formed at the point where a current-carrying circuit is broken. There are three such circuits to be considered, each with special characteristics, i.e. for signalling, lighting and power. The first is highly inductive, the second usually non-inductive, the third much higher in voltage and with some inductance. The definition of a non-inductive circuit taken here is one the time-constant of which is about 1/1 000th of a second, corresponding, on an alternating current at a frequency of 50, to a power factor of 0·95.

The direct-current signalling bell used in mines is an improved form of the ordinary trembler bell with magnetically operated make and break. Sparking occurs both at the point from which the signal is made (either by means of a push switch or by bringing together bare galvanized-iron wires running along the timbers of a road), and at the trembler contact. Before the signalling bell received special attention both of these could cause ignition. In my earlier work an electric bell was regularly used as the source of ignition when illustrating the effect of broad flanges extinguishing flame. It was this, in fact, that directed attention to the possibility of such an effect occurring in coal mines, and led to the introduction of the first safety bell.* Experiments on break sparks had shown that the essential feature in ignition is some form of ionization. The formation of an arc, as distinct from intense glow discharge or a spark, is only possible when there is a free discharge of electrons from that pole which is for the instant the cathode under the influence of heat. True thermionic discharge precedes an arc and is started by the heat set up in the high-resistance film of gas or metal vapour at the point of separation. There may be heating at a bad contact, but an arc cannot be drawn out unless there is a free thermionic discharge of electrons. The ionization in the arc is maintained by the collision of electrons with molecules and by the collision of charged with uncharged molecules under the intense voltage gradient. The voltage across the break is therefore the most important feature of an arc as a source of activation of the gas in which it is formed. On this view it was only necessary to suppress the inductance voltage at a break in order to minimize the risk of ignition from a bell, and the direct way to do this is to connect across the ends of the magnet winding a non-inductive resistance of value sufficiently low to act as an efficient shunt, but as high as possible to lessen the demand on the signalling battery while the bell is in action. The magnitude of this depends on the inductance of the windings, but resistances as high as 20 times that of the coils were on occasion effective. Between 10 and 20 times is usual.

So long as the pressure across the trembler contact does not exceed about 25 volts, a bell can be made to ring freely in the most explosive mixture of illuminating gas and air—much more sensitive to ignition than firedamp—without igniting it. Pressures of 150 volts across the trembler break are not unusual in an ordinary 2-volt bell. Unless the inductance voltage is suppressed, a bell becomes a miniature magneto so far as regards its power of ignition. The oscillograms of Fig. 2 show how much the voltage is suppressed in a working bell by shunting the magnet windings.

Other means of checking the rise of voltage at break are the use of a short-circuited parallel winding or by copper sleeves over the magnet core.* These delay the change of magnetism, while the shunt diverts the voltage produced by it. Modern direct-current bells can be specified so that inflammable gas shall not be ignited by the spark at the trembler contact. Bells for alternating-current circuits have usually no make and break, but work with a magnetically operated oscillating armature. They have a highly inductive winding and the spark at the signalling point where the circuit is made and broken is dangerous. It can be suppressed by arranging a high resistance across the wires so that it is brought into action by a double contact when the signal is made. Many bells have now, in addition to the electrical safety devices mentioned, mechanical protection by flame-proof enclosure.

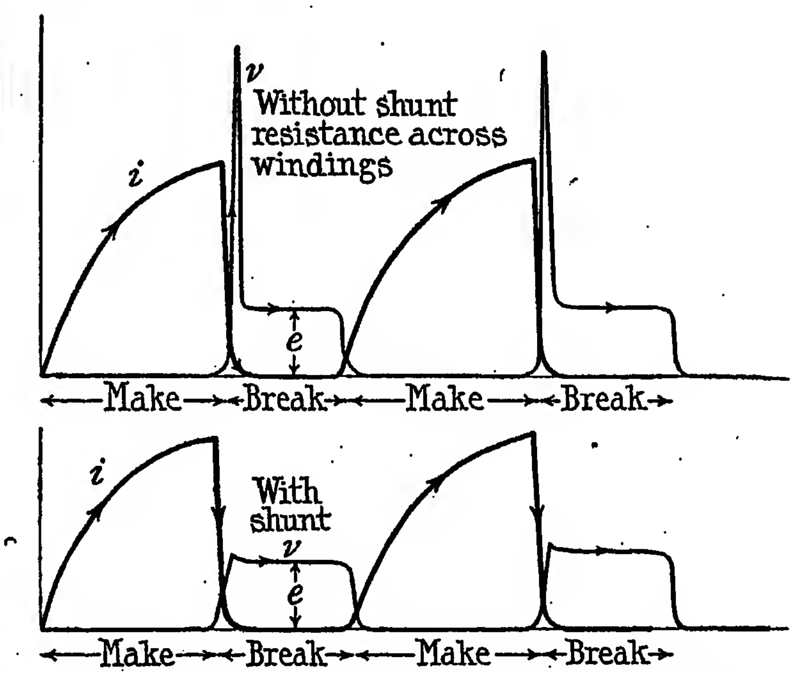

Fig. 2.—Oscillograms of signalling-bell currents, and voltage across trembler contact.

(5) Shot-firing Generators.

The alternating-current hand generators by which detonators for shot-firing are exploded are of two types, high and low tension, giving voltages of 150 and 1·5

* W. M. Thornton: "A New Battery Signalling Bell," *Transactions of the Institution of Mining Engineers*, 1915, vol. 50, pt. 1, p. 19.

* R. V. Wheeler and W. M. Thornton: Home Office Report on "Electric Signalling with Bare Wires so far as regards the Danger of Ignition of Inflammable Gaseous Mixtures by the Break Spark at the Signal Wires" [1916].

on load respectively. The difference between a good and bad generator may depend only upon their voltages. A common method of testing whether a generator is in good working order before a shot is fired is to touch the ends of the leads together and observe the nature of the spark. Since many thousands of shots are fired in a day in the British Isles alone, it is important to know whether there is even the remotest possibility of ignition of firedamp by these testing sparks. Four out of five of such machines will, I find, ignite a 9·5 per cent mixture of methane and air, generally after many trials. Since, however, before a shot is fired the place must be declared free from gas, the risk of testing the circuit by open sparking is less dangerous than the risk of having uncertain shot-firing. Where it is thought necessary, a small closed tube with a flexible make-and-break contact inside is a safe means of examining the spark.

(6) Lamps, and Ignition by Hot Wires.

Electric lighting in coal mines is passing through two phases, the displacement of the portable oil lamp on account of its poor light and possible risk of ignition by breakage, and the improvement of general lighting not only at shaft landings but also along the roads. The economic value of the former change is now recognized, and for the latter there is no reason why the working roads of a mine should not be as well lighted as those above ground if by doing so an economic advantage can be proved in safety and rapidity of handling haulages. Stress is laid here on the economics of the question, for unless it can be shown by trial that immunity from accident and rapidity of transport are obtained, there is no reason to change the present state of affairs.

From the point of view of safety, lighting circuits differ only from power circuits in the vulnerability of the lamp. Thanks to the severe conditions of running, the filaments of such lamps as motor-car headlights are as robust as can be desired. Experiments made by the United States Bureau of Mines have shown that hot-wire lamps with short, thick filaments are relatively more dangerous than those with finer wires,* as previously shown for carbon lamps. The voltage on portable lamps is limited by the weight which can be carried, but the future of fixed road lamps might well be in the direction of running them at the signalling voltage, 25, permitted everywhere inbye, and using standard car lamps, protected from mechanical damage by the usual glass and metal shades. If the voltage is raised much above 25 a new condition enters. There is for all conductors a minimum arcing voltage. The spark at break of a 100-volt, 16 candle-power carbon filament will fire gas if the broken ends remain in fizzling contact. That at 25 volts will not, as the arc cannot persist. There is again a remarkable difference between direct- and alternating-current breaks as a source of ignition which will be considered later. Ignition arising from broken lamps is regarded chiefly from the risk of contact of gas with the hot, unbroken filament. The general problem of ignition by hot wires has been worked out experimentally* and the following conclusions have been reached. Ignition of hydrogen mixtures, taken as the most sensitive, begins with most metals at a temperature well below red heat, at that in fact at which thermionic emission from the wire is first observed, i.e. about 200° C. It always begins by surface combustion, the heat from which may fire the rest of the mixture or may be dissipated by radiation so rapidly that self-ignition does not occur. The least igniting current is a linear function of the diameter of the wire. Methane can only be ignited by any hot wire below a temperature of about 1 800° C. when a current of gas is swept over the wire. With platinum wires 0·01 cm in diameter over 2 amperes are required to reach ignition conditions, and as often as not the wire melts without firing the gas if the circuit voltage is low. With tungsten wires there is no difference between the igniting currents of hydrogen, methane, carbon monoxide or coal gas, and the wire is always red hot before ignition of the mixtures occurs. The igniting current is independent of the proportion of inflammable gas in the mixture in the case of all the paraffins, and is independent of total gas pressure down to one-third of an atmosphere or up to seven atmospheres. Electric or magnetic fields have no influence on hot-wire ignition. Ignition by tungsten wires below 0·2 mm diameter is more difficult than with any other metal—a fact of importance in mining, since no greater safety could be obtained by the use of filaments of other metals than that now commonly employed.

A recent decision of the United States Bureau of Mines makes it necessary to provide some automatic means of cutting off the current in a hot-wire vacuum lamp as soon as the glass is cracked so that an inflammable mixture may enter. One method of doing this consists of a pneumatic collapsible chamber which operates a small switch contact when air is admitted to the lamp. The smallest pressure at which it will operate is about 1/25th of an atmosphere, more usually about 1/10th. Firedamp is not inflammable by hot wires at pressures below one-third of an atmosphere. There is here a very fair margin of safety.

A simpler and safer plan than trusting to safety cut-out devices in lamps when broken, is to provide an indicator on each lamp, either electric or oil-burning, to give a danger signal to the worker when a dangerous proportion of gas is present, so that he may withdraw from the place until the ventilation copes with the inrush of gas.

(7) Ignition by Break of Circuit.

A complete break of cable is very rare in coal mining. A fall of stone may force the conductors into contact with one another or the sheath or armouring. In such a case protective cut-out gear operates. In order to ascertain whether there could be a dangerous flash from an unarmoured lead-sheathed, three-phase cable cut into by a fall, the following trial was arranged with the co-operation of the Newcastle Electric Supply Co., Messrs. Reyrolle & Co., and the Metropolitan-Vickers Co.

A 20-ft. length of 3 000-volt, three-phase, paper-

* H. H. Clark and L. C. Ilsley: "The Ignition of Mine Gases by the Filaments of Incandescent Lamps" (Bureau of Mines, Washington, Technical Paper No. 52).

* W. M. Thornton: "The Ignition of Gase by Hot Wires," *Philosophical Magazine*, 1919, ser. 6 vol. 38, p. 613.

insulated, lead-sheathed cable was sealed at one end and connected at the other through a 50-ampere oil switch to a 200-kVA transformer, and through it to the 5 000-volt busbars of a large substation fed direct from Carville. The cable was placed on a concrete floor beneath a platform some 4 ft. high, and a steel wedge was laid on it in such a way that a stone weighing about 1 cwt. dropped from the platform should strike it fairly. The object of the test was to see whether a flash could be observed to issue from the cable at the point and moment of damage. Two observers were stationed close to the spot, and though the conductors were cut well into by the fall, no external flash was seen. The trip-gear operated quickly enough to prevent any sign of burning at the point of short-circuit.

On two occasions at West Stanley and Auckland Park, where cables had been short-circuited by falls and ignition suspected, no sign of external flame or

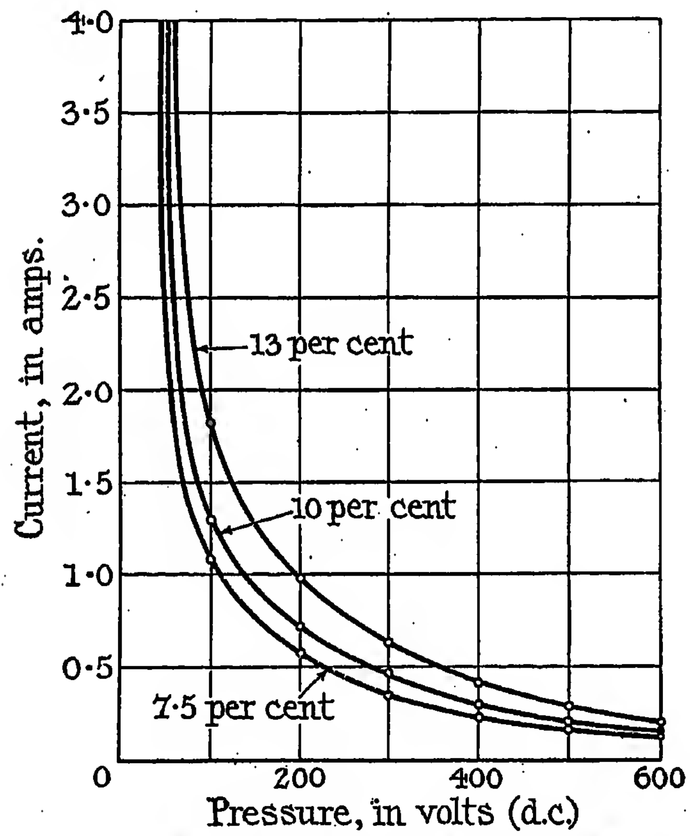

FIG. 3.—Least igniting currents of methane-air mixtures by transient arcs.

even break was found. From these and many other practical tests it may be concluded that with modern armoured cables the risk of open sparking due to the damage of a cable by a fall is slight, and the further condition that there should be at the same moment a mixture of firedamp and air between 5·6 and 14·8 per cent makes the possibility of a local explosion from this cause remote. It is, however, possible that a cable may be drawn out of a junction box by a fall, but the break of circuit will then have taken place within it and the enclosure must be strong enough to deal with the arc until the trip-gear operates. In pulling clear there may be an external break of circuit, and it is therefore necessary to examine the limiting conditions of ignition by break arcs with both direct and alternating current.*

* W. M. THORNTON: "The Electrical Ignition of Gaseous Mixtures," *Proceedings of the Royal Society*, A, 1914, vol. 90, p. 272.

(i) *Direct current.*

(*a*) *Influence of voltage.*—There is for every gaseous mixture a sharply defined current which just causes ignition when broken in it. Fig. 3 gives for pure methane the range of variation of the least igniting current with voltage when iron poles are used to resemble armouring. The curves have a mean equation $(V - 15)/(I - 0\cdot 11) = 10\cdot 5$. Below 15 volts ignition by break of a non-inductive circuit is extremely difficult if not impossible, and at high voltages a current of about 0·1 ampere is sufficient. The lower voltage is below arcing potential; at the higher a transient arc becomes a spark characterized by ionization by collision in the field across the break.

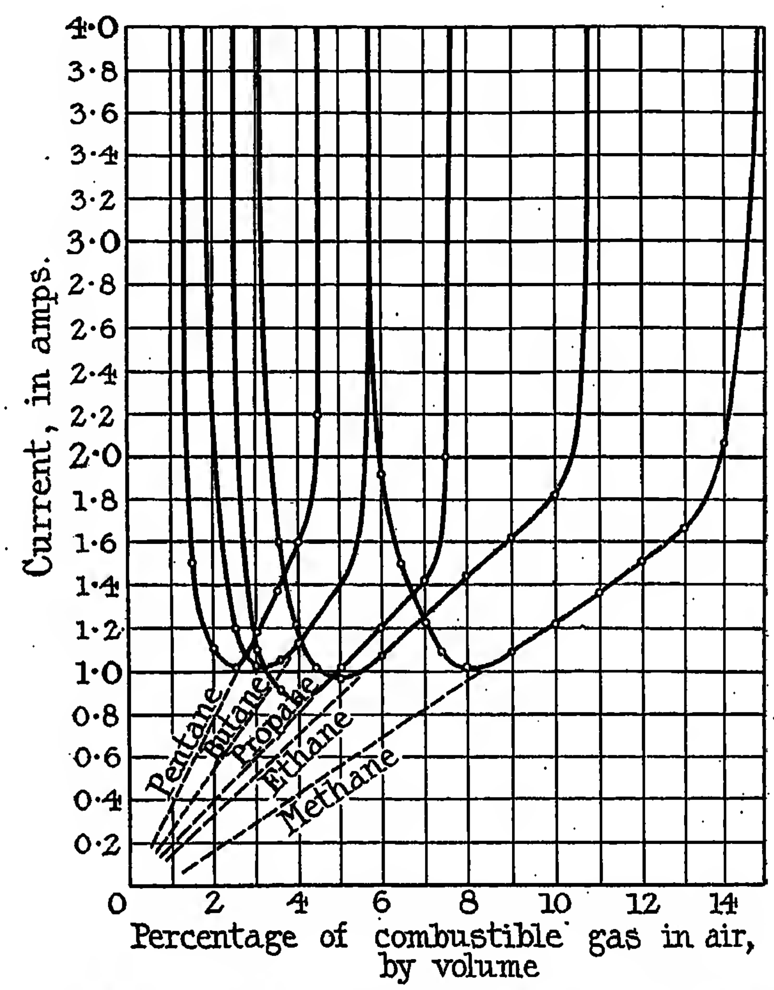

FIG. 4.—Influence of proportion of gas in air on least igniting direct currents.

(*b*) *Influence of proportion of gas in mixture.*—The characteristic phenomena of ignition by direct currents are well illustrated by the curves given in Fig. 4.

Mixtures of firedamp and air are most easily ignited at 8 per cent and, though this is a point of less practical importance in this country, all the paraffins have the same least igniting current in their most sensitive mixtures. The physical and chemical meaning of this has been discussed elsewhere.

(ii) *Alternating current.*

(*a*) *Influence of voltage.*—The essential feature of ignition by alternating-current break sparks is the remarkable influence of frequency at different voltages. The curves of Fig. 5 illustrate this. Thus at 500 volts a direct current of 0·2 ampere will cause ignition, quite possible in a badly earthed armouring with a fault developing, but at the same voltage and a frequency of

100, 11 amperes are necessary, other things being the same, a ratio of 55 to 1 in favour of high-frequency alternating current. At 50 periods it is about half this—quite worth having.

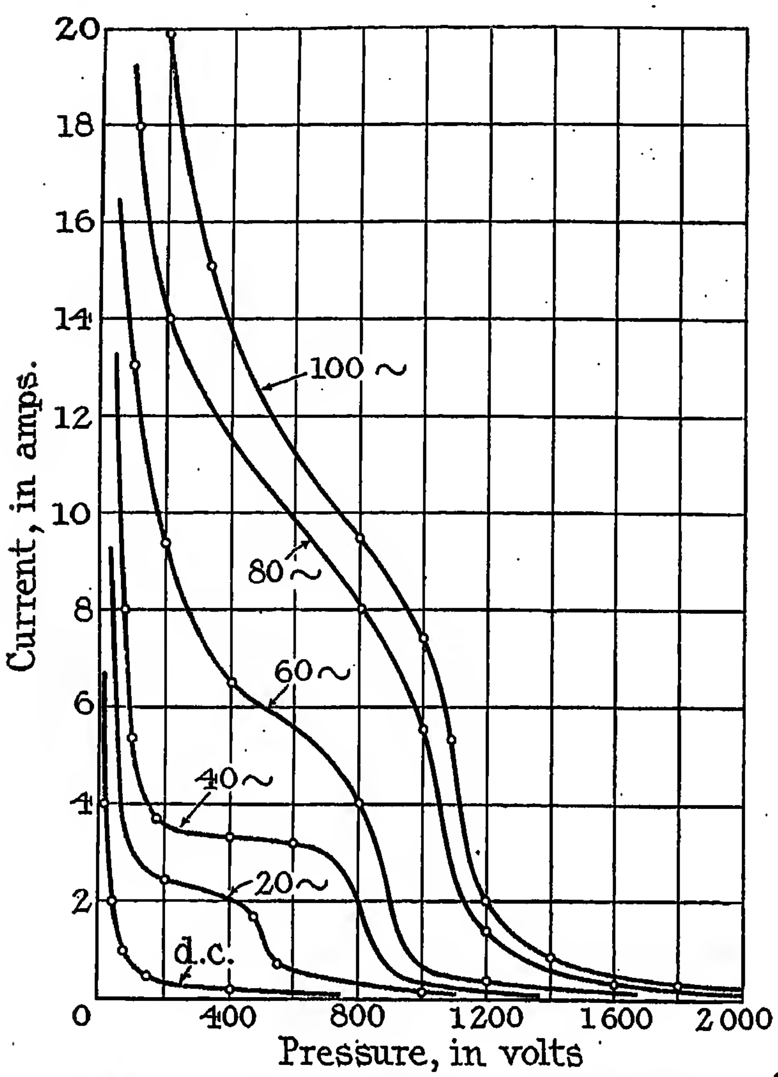

FIG. 5.—Influence of frequency on the ignition of methane by transient arcs, at various voltages.

(*b*) *Influence of proportion of gas.*—Remarkable as the above curves are, they are perhaps less striking than those of Fig. 6. The curves are a set of parabolas symmetrical between the limits of inflammability, so that the most easily ignited mixture is midway between them (see Table 2).

value are most difficult to ignite; a fact that calls for explanation by those who support the thermal theory of ignition.

(*c*) *Influence of frequency, the voltage being constant.*—A recent examination of the influence of frequency up to 500 periods shows the complex nature of the physical changes in the act of ignition. Fig. 7 is for pure methane in a 9·5 per cent mixture ignited by the break of a non-inductive circuit maintained at 200 volts.

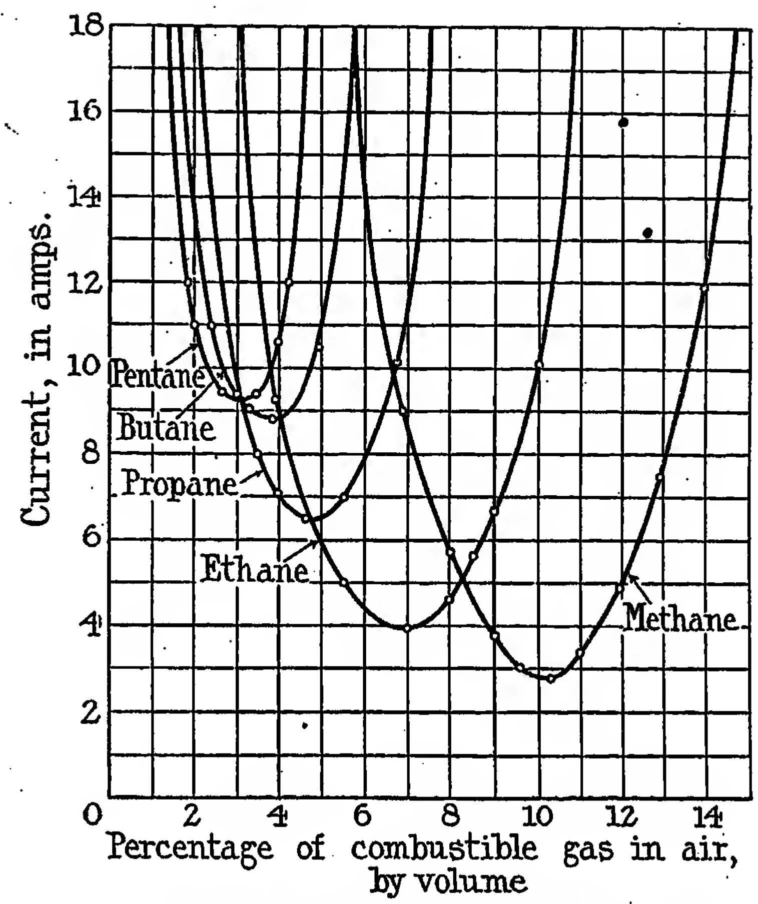

FIG. 6.—Influence of proportion of gas on least igniting alternating currents.

The first point to be observed is the high values of the currents necessary. After an initial delay the curve begins to rise as if logarithmic. There is an apparent time-constant, the meaning of which gives the reason for the curve. Writing the equation for the latter in the form $i = I(1 - \epsilon^{-f/c})$ the critical constant is clearly a frequency, and by the usual method of determining time-constants this is found to be about 110. What is there about an arc that can have such a critical time-relation? A transient alternating-current arc differs only from a direct-current arc in the fact that

TABLE 2.

Gas	Limits of inflammability		Mean	Observed minimum	Combustion to CO_2 at	Combustion to CO at	Mean of these
	Per cent	Per cent	Per cent	Per cent	Per cent	Per cent	Per cent
Methane ..	5·6	14·8	10·2	10·2	9·4	12·0	10·7
Ethane ..	3·1	10·7	6·90	6·90	5·5	7·7	6·6
Propane ..	2·17	7·35	4·76	4·80	3·96	6·0	4·98
Butane ..	1·65	5·7	3·67	3·75	3·07	4·38	3·72
Pentane ..	1·35	4·5	2·92	3·05	2·51	3·61	3·06

The practical bearing of this is that when alternating currents are used there is much less risk of ignition of the weaker mixtures. The most sensitive point is 2 per cent higher than in Fig. 4.

One notable feature is that gases of greatest calorific

each pole is alternately anode and cathode and is heated and cooled as the current rises and falls. Since the maintenance of an arc depends in the first place upon the stream of electrons from the cathode,* such a relation must mean that when the frequency reaches a critical value the poles remain hot enough to give a continuous thermionic discharge while the current falls to zero, facilitating the activation of the gas in contact with the poles and improving ignition. For it is clear that ignition is relatively easier at high frequencies in the sense that the rate of rise is then less. If the early rate had been maintained it would have been impossible to ignite firedamp at frequencies of 500 except by the break of circuit of a machine of some 250 kW working at full load on unity power factor. There is at a frequency of 165 p.p.s. in the case of methane, but rather higher in coal gas, a most singular increase in ease of ignition. This is not maintained, for at a frequency approaching 400 the curve reverts to its earlier type.

The heating of the cathode or negative pole is greatest

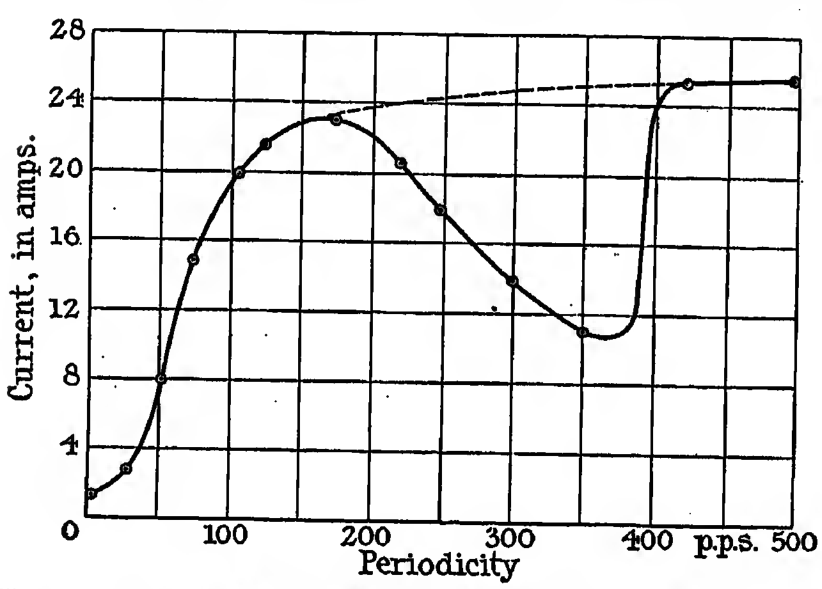

FIG. 7.—Influence of higher frequencies on ignition of methane. Transient arcs at 200 volts.

when the current is unidirectional, and the smallest igniting currents are therefore found in that case. As the frequency is raised, the difficulty of striking an arc increases on account of the delay in making a hot spot from which thermionic emission can take place. Now it is found that at the 200 volts used, and with the relatively small currents, there is never any "overshoot." Wherever in a half cycle the current is broken, it falls to zero and stops. During this fall the fresh gas mixture rushes into the space occupied by the arc, and ignition can occur if it is long enough in contact with arc and hot metal to be activated. The higher the frequency the shorter the duration of contact and therefore the higher the current necessary to obtain the result in the time. It will be clear that at some frequency the pole will continue to glow and give off electrons after the arc is extinguished for so long that ignition can occur even though the arc itself does not last long enough for that purpose. In addition, if ignition is ionic rather than thermal—as everything indicates—the more rapid removal of the arc may make ignition easier by bringing the gas more quickly into contact with a hot surface still emitting electrons. There can be no doubt that the rate of liberation of electrons from the cathode in air is much greater than that from the surface of the arc itself, for if the latter were greater the arc in air would expand in volume, like an explosion, by continually enlarging its conducting path. At still higher frequencies the heat given to the pole while the arc lasts is insufficient to raise more than a minute part of the surface to emission temperature. Heat is conducted from this so quickly that hot-spot ignition can no longer occur. There are few phenomena more striking than the suddenness with which thermionic emission ceases when there is a small drop of temperature from a critical value,* and the reversion of the curve of Fig. 7 to the original type at a frequency of about 380 is, I take it, an illustration of this.

Other gases have been examined, but the dip in the curve is most marked in the case of methane. Fig. 8 shows the variation in illuminating gas both when the poles are of iron and of nickel. The presence of hydrogen raises the depression and makes it a straight line.

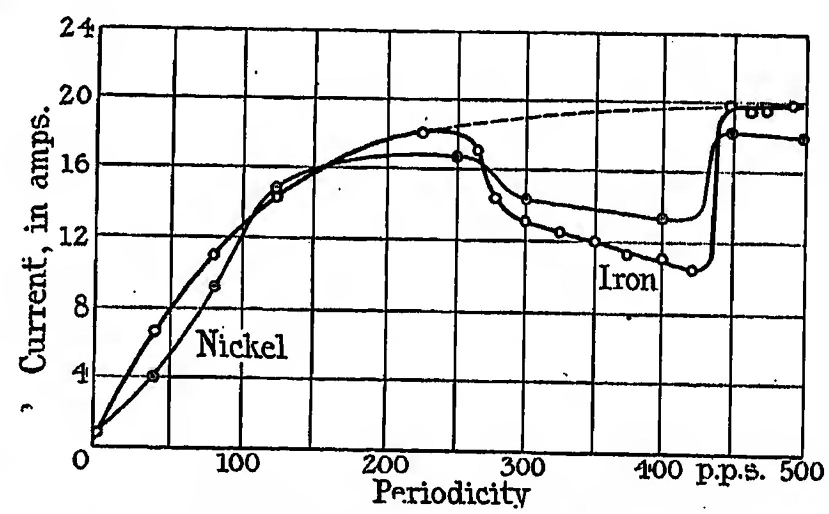

FIG. 8.—Ignition of illuminating gas at various frequencies and 200 volts.

The statement has been made here that ignition is electrical rather than thermal. As a test of this in the case of break sparks the following experiment was made. The least igniting current of a 35 per cent hydrogen-in-air mixture was found by trial at 200 volts, 250 p.p.s. to be 0·4 ampere. The same poles were than sparked in pure hydrogen to remove oxide or occluded oxygen, and it was then found that the explosive mixture could not be ignited with less than 6 amperes broken. The sparks were large and bright but were electrically inert though their thermal value was many times greater than before. The first step in ignition is the formation of active oxygen ions. There is direct evidence for this in the phenomena of ignition by condenser discharge. There is no difference between hydrogen and other gases except in sensitiveness to spark ignition.

The conclusion to be drawn from these determinations of the safety limits is that alternating current is always safer than direct current when there is little inductance, but that with the voltages and currents in use there is no

* MAURICE LEBLANC (fils): "L'arc Électrique," p. 22, par. 14.

* O. W. RICHARDSON: "The Emission of Electricity from Hot Bodies," p. 52, Fig. 8.

real security for power circuits of either kind, except by complete enclosure. The currents in lighting and signalling circuits can, however, be kept well within the limits of safety so far as a break is concerned, and ignition by the hot filament of a lamp, always so difficult in methane, can also be prevented by some device which breaks the circuit when the lamp is cracked.

(8) Improved Lighting in Coal Mines.

(*a*) *Main roads.*—The results just described provide a means of improving the lighting of coal mines and at the same time increasing the safety of working. At a frequency of 150 p.p.s. the least current for ignition from a lighting circuit is 23·5 amperes at 200 volts. The least direct current at this voltage is 0·4 ampere. The ratio of these is 60 to 1, which should commend alter-

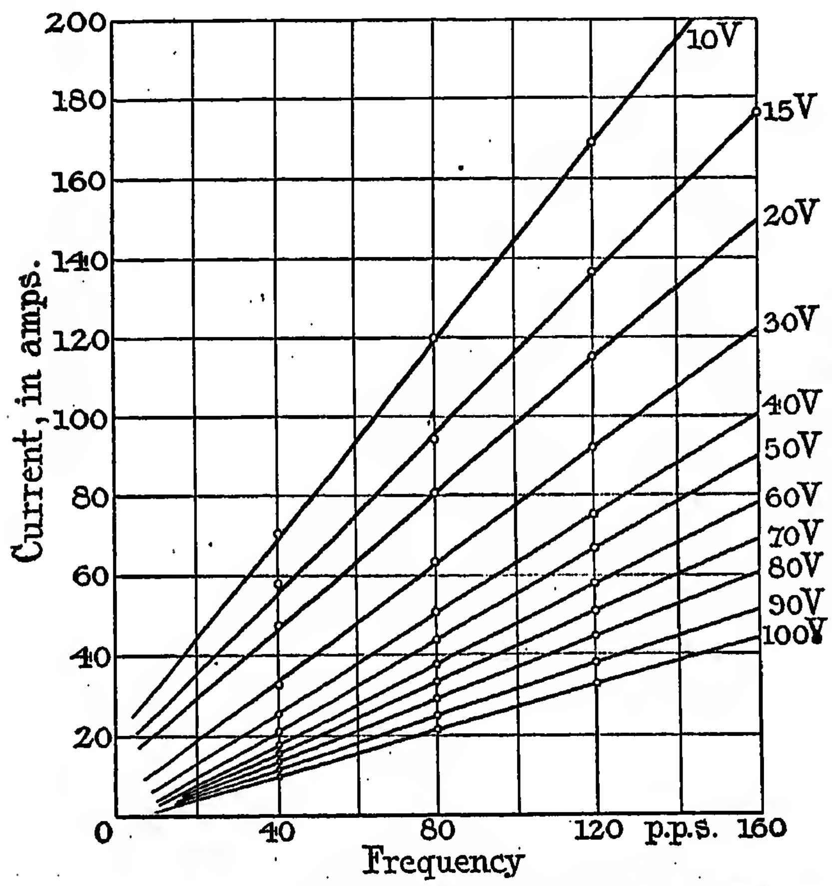

Fig. 9.—Ignition of methane by low-voltage transient arcs at various frequencies.

nating current to those who desire "safety first" in lighting. But there is no necessity to run lighting leads at this voltage, a voltage of 25 being, as previously stated, permitted everywhere. When we come to examine the currents necessary to ignite firedamp from such low-voltage circuits, the results of Fig. 9 are obtained. At 160 periods and 15 volts not less than 175 amperes would fire the most explosive mixture (10 per cent of firedamp) when broken in it. Lighting and signalling might be operated from the same circuit if desired, and, with the requisite protective gear to keep the maximum current in the case of a combined short-circuit and break to less than 175 amperes, immunity as complete as possible, apart from the human element, is obtained. The inclusion of a resistance of 0·16 ohm, or of a choking coil of similar reactance, would secure this, though the less inductance the better, so far as ignition is concerned. Since there is no risk of shock at this voltage there is no reason why enclosed replaceable fuses should not be used in each lamp fitting and feeder.

(*b*) *At the coal face.*—In order to improve lighting at the working face it is necessary to devise a flexible and safe means of making contact. The following arrangement was devised for this purpose. Each portable lamp is fitted with a plug in its base so that it can be connected in the usual way to a socket of special design attached by flexible "cabtyre" leads to the 25-volt supply or to the power circuit through a transformer. The battery of the portable lamp of this type is smaller than in present lamps, for it has only to supply energy sufficient to give light when travelling to and from the working place. The double-filament lamp is pressed into the socket in which there is a safety interlock, and the contact is then switched over from the 2-volt to the 15- or 25-volt filament. The increase in illumination obtained by this will be evident, but it is doubtful whether so great an increase is desirable, or desired by the miner himself. If it is an economic proposition to increase the lighting at the coal face to ten times its present amount, then here is a means of doing it with a factor of safety greater than that of present practice. The current taken by each lamp would be about 1 ampere, and this at 15 volts is only 0·6 per cent of the clean break igniting current. By the use of these higher-frequency currents and lamps with both internal and external cut-outs it is possible to do for the miner what the Davy lamp did in the old oil lamp and candle days—to give better illumination with greater safety than is even now possible.

(9) Electrical Oscillations on Cables Sheaths and Conductors.

The experiments recently made at Ashington on wireless communication with places underground is a revival of those made by Mr. A. W. Heaviside many years ago in the same district, and brings forward again the possibility of risk from oscillations on cable sheaths, and sparking to earth at points of high potential. I examined this some years ago and found that electrical oscillations on the conductors within an insulated lead sheath due to switching or surges did not give rise to high-voltage oscillations on the sheath, nor any sparking at the ends where the potential-rise might be expected to be greatest. In the case of cable armouring it may be possible to obtain minute sparks, for the surge impedance of such a conductor is higher than that of a plain tube, on account of the twist of the wires. The passage of electrical oscillations along a corrugated surface such as the longitudinal section of a cable has not been investigated mathematically. The impedance of such a path might be great. There is, however, a real danger in the case of an unenclosed circuit in which there is heavy inductance, a voltage transformer for example. A surge on such a system reaching a coil has been known to give rise to a spark to adjacent conductors by which gas might be fired, and in one case such a surge has been suspected of causing an explosion in the cubicle of an oil switch underground. The gases given off by heavy switching are a mixture of hydrogen and methane, the products of dissociation of the oil by the arc. The presence of hydrogen extends the range of inflammability

of "switch gas" and air, for it alone is inflammable in mixtures from 6 to 72 per cent. For the safety of coal mining two things are necessary: (i) The space above the oil must be thoroughly ventilated so that the gas is conveyed clear of the cubicle, and the switch so constructed that even if the enclosed gas is ignited no flame can emerge; and (ii) all live conductors should be enclosed so that there is a continuous bond between the armouring and the switch-box metal. To prevent the possibility of a surge spark through air the space must be filled with compound.

(10) Electrical Endosmose and Faults.

For everything except haulages in which fine speed-control is necessary, alternating current is preferred to direct current. From the point of view of incidental safety the advantage is with alternating current, not only on account of the lower risks of ignition previously discussed but also on account of the relative freedom from faults. It is impossible in a mine to avoid having cables in contact with moisture in some place or another. Direct-current systems are often subject to trouble in damp places. There is a mechanical pressure of electrical endosmose by which an incipient fault is always augmented. "Electricity only moves electricity," and the motion is clearly ionic. Water is carried down an electric field from positive to negative pole. Mr. Evershed demonstrated this excellently in his paper * read in 1913. If an alternating field is applied, the amplitude of the movement can be observed under the microscope. At a frequency of 80 p.p.s. it is about $0 \cdot 0003$ cm in a thin film of water. An approximate estimate of the pressure may be made as follows. Assume the whole action to be electrical and consider a single molecule to be carrying a unit ionic charge e. The value of this is $1 \cdot 57 \times 10^{-20}$ electromagnetic units. The force on such an ion in a field of 5 000 V/cm (a not unlikely value in the dielectric) is He dynes, where H is the field in absolute electromagnetic units, here $5\,000 \times 10^8$. Thus $He = 5\,000 \times 10^8 \times 1 \cdot 57 \times 10^{-20} = 7 \cdot 85 \times 10^{-9}$. The diameter of a water molecule is about 4×10^{-8} cm and its cross-sectional area $12 \cdot 56 \times 10^{-16}$ cm^2. The force on this area alone is $(7 \cdot 85 \times 10^{-9})/(12 \cdot 56 \times 10^{-16}) = 6 \cdot 25 \times 10^6$ dynes/cm^2, i.e. 14 lb./cm^2 or 90 lb./sq. in., a quite considerable pressure forcing moisture into the fault. It is less than this on account of the space factor of molecules in a liquid, but not much. The number of molecules, N, in a gramme molecule of gas is about 7×10^{23}. The molecular weight of water being 18 there are 4×10^{22} molecules in a gramme of gas or liquid. Taking each molecule of water as $3 \cdot 5 \times 10^{-8}$ cm diameter (its lowest estimate), its volume, v, is $2 \cdot 25 \times 10^{-23}$. The product Nv is $0 \cdot 9$ cm^3, and, since a gramme of water at 15° C. has a volume of 1 cm^3, the space factor is $0 \cdot 9$.

The well-known Hebburn case, in which the number of small cable faults was reduced from 164 to 1 in 6 years by changing over from direct to alternating current, is the most remarkable example of the above effect, and of the further valuable fact that a faulty cable dries itself out when the supply is alternating.

* "The Characteristics of Insulation Resistance," *Journal I.E.E.*, 1914, vol. 52, p. 51.

(11) Earthing.

One of the difficulties in mining is the provision of an efficient earth underground in order to avoid electric shock, and, since coal is not a conductor but a very good insulator, a leakage to earth on an underground network cannot as a rule return to the earth plate at the surface without the risk of a large potential gradient somewhere underground. This is one reason why a continuous bonding of armouring to bank is specified in the special rules, in order to avoid shock by leakage. It is not too much to say that on the provision of an efficient earth the whole safety of electricity in mining depends. There are two types of earth plate in general use, viz. a tube driven vertically into the ground, and a flat plate also vertical. The essential feature of a good earth is to get the lines of leakage flow to diverge as quickly as possible from as large an area as possible, in order that the resistance may be small where the area of flow is small. In the case of a vertical tube the lines of flow

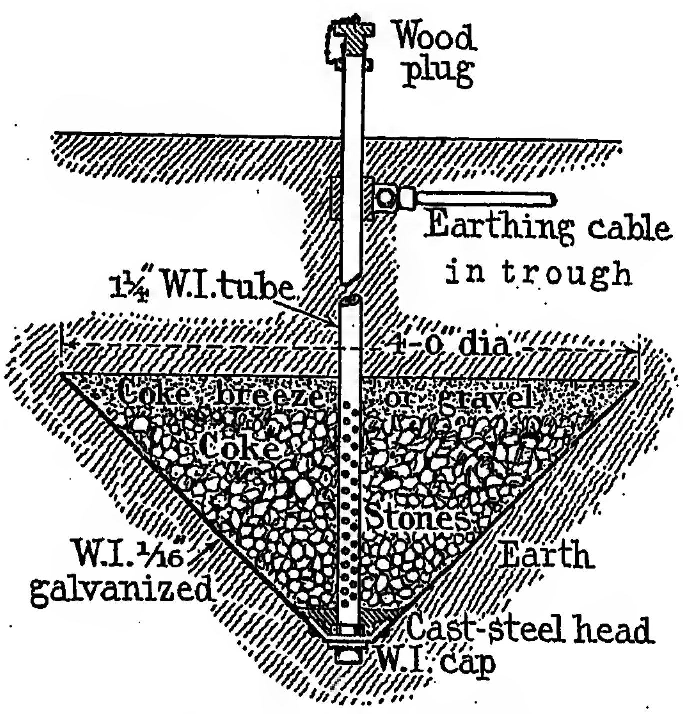

Fig. 10.—Earthing plate.

to another similar earth of opposite polarity at a great distance are at first radial. The voltage gradient is then inversely proportional to the distance from the tube, for if I is the total leakage current per unit length the current density at a distance r is $I/(2\pi r)$, and if the resistivity of the ground is everywhere the same the gradient is $\rho I/(2\pi r)$, a maximum when $r = a$, the radius of the tube.

In the case of a plate the lines diverge to a circle and the gradient near the plate then remains nearly constant for a distance comparable with about half of the width perpendicular to it. The lines of flow from a long, flat, earth plate are hyperbolas and the equipotential lines confocal ellipses becoming, in effect, circles at a radius of about $1\frac{1}{2}$ times the width of the plate. The resistance-drop from such a plate therefore remains high and nearly constant for a much greater distance than that of a tube of the same periphery. For example, take a plate π ft. wide, and the corresponding tube 1 ft. in diameter. At a distance of 3 ft. from the centre of the

plate perpendicular to it, the current density has fallen to rather more than one-half its value at the plate. In the latter at the same distance from the surface it is one-quarter of the surface density, but, since the plate has two surfaces and the tube one, there is practically no difference between them as regards their value as an earth.

With a hemispherical earth plate the lines spreading radially give a gradient inversely proportional to the square of the distance, reaching a maximum of $I/(2\pi a^2)$ at the surface, neglecting any current flowing from the inner side. If this is also active the maximum density is $I/(4\pi a^2)$. Comparing this with a square plate of side b they will have the same current density if $I/(4\pi a^2) = I/(2b^2)$, or $a = b/2\cdot5$. Taking $b = \pi$ ft. square, a is nearly 15 in., and at a distance of 3 ft. from the surface the current density is one-ninth of the maximum value. By keeping the earth moist (and therefore of low resistivity) around the plate the voltage gradient is lowered in the place where it is necessary that it should be low.

Vertical surfaces are difficult to maintain in good contact with surrounding earth. The earth plate shown in Fig. 10 was designed to make its own contact without additional stemming, to give a rapidly diverging flow and so to have low resistance close to the surface, and to provide an underground pool of water from which by diffusion the ground around the plate might be kept moist.

A conical dish of $\frac{1}{16}$-in. galvanized iron is riveted to a cast-steel boss into which is screwed a wrought-iron pipe about 8 ft. long. Holes $\frac{3}{16}$ in. diameter are drilled in the lower part of the pipe, and the bottom of the dish is filled with a pitch cement to avoid leakage. The plate is sunk into the previously moistened ground and filled with broken half-bricks or small stones, covered with gravel and the earth is then returned. Sufficient water is admitted to fill the dish to overflowing, and a fresh supply can be given if the resistance rises in dry weather.

(12) Conclusion.

The researches mentioned in the paper, though they are a small part of the whole ground, will have served to show the variety of the phenomena and the need for an attempt to cover so wide a field. From shock there is now little risk of accident; in signalling circuits there is need for further control in the use of alternating-current bells, but there are many advantages in its use, especially in connection with improved electric lighting below ground. By keeping the leakage trips set low, transient arcs due to break of circuit and armouring may be kept below the limits found here to be dangerous. No other mode of obtaining safety is reliable. Oscillations due to wireless or other surges are not regarded as a serious risk. Alternating current is preferred to direct current on account of its freedom from water faults or endosmose.

Discussion before The Institution, 31 January, 1924.

Mr. C. P. Sparks: I consider that the industry, as a whole, will have good cause to thank the author for his very exhaustive and persistent work over the past 12 or 14 years spent in investigating this subject. On page 481 it is pointed out that safety in coal mines depends on (*a*) efficient ventilation; (*b*) elimination of flame or open sparking; (*c*) improved illumination; and (*d*) training in habits of observation and carefulness —in other words, "safety first." As far as electricity is concerned we have to do with items (*b*) and (*c*) only. In view of the responsibility thrown on the management by the use of electricity, the paper is of a reassuring character, as it enables a considered opinion to be formed as to which class of open sparking is safe and which is dangerous. The use of electricity in mines depends directly on the judgment of the management, the mine manager being held responsible by Act of Parliament and by the Home Office Regulations as to where, when and how he may use electricity. We can only advise the mine owners as to the merits and possible methods of using electricity, but the responsibility for its use rests upon the mine manager, and it is a very serious responsibility. For instance, the Government Regulations contain this definition: "'Open sparking' means sparking which owing to the lack of adequate provisions for preventing the ignition of inflammable gas external to the apparatus would ignite such inflammable gas." The manager and his staff have to decide if there is danger from "open sparking"; if there is, he must not use electricity underground. Regulation 132 commences: "In any part of a mine in which inflammable gas, although not normally present, is likely to occur in quantity sufficient to be indicative of danger, the following additional requirements shall be observed." Then it details the requirements, always with the expression "so that in the normal working thereof there shall be no risk of open sparking." The manager has, therefore, to have a considered idea as to what "open sparking" is and what is safe. Here the present paper is of a reassuring character: it is most helpful to the management to be able to see that, under certain conditions, sparking that appears dangerous (as one spark may look exactly the same as any other) may under the defined conditions of working be safe. The author's investigations show that, far from every visible spark being dangerous, they may be divided into several categories: (1) Those that are safe; (2) those that are risky; and (3) those that are dangerous. The author's investigations show that electric power development in collieries has been fortunate in several respects. While the first development took place with direct current, the advantage of transmission has resulted in the 50-period, three-phase system becoming the general standard. The author shows that direct current is 25 times as dangerous (from the point of view of a spark firing an explosive mixture) as alternating current at 50 periods per second. In this case commercial development has been on the lines of general safety, although the 50-period system was adopted primarily

for other reasons; it was not known in those early days, in fact it has been known only comparatively recently, that it was so much less harmful. The second factor assisting electrical development is the inertness of methane. A third factor (see page 485) shows that the peculiar characteristics of tungsten, which is used for lamp filaments and which was not chosen from the point of view of safety, have given a greater margin of safety than could be obtained with any other metal. The author's experiments, while they indicate what may occur under a combination of circumstances, show that ignition results from combinations which rarely happen. This is emphasized by the long period during which electric signalling bells were in use before they were found to possess dangerous characteristics. I believe that the first electric development in mines was the signal bell some 40–50 years ago, but it was not until 1913 that any suspicion arose with regard to the danger of electric signal bells. In 1913, following the Senghenydd disaster, very careful investigations were made by several people, and in 1916 the author and Dr. Wheeler showed how electric signalling bells could be made absolutely safe. The fact that this hidden danger existed unsuspected for so many years, emphasizes the fact that the risk of danger only occurs under a combination of circumstances. The importance of research is emphasized by the fact that directly research was applied to the characteristics of electric signalling bells they were found to possess an element of danger. Safety in mines has been increased in the past due to improved illumination, and the further improvement in illumination will still further reduce the daily roll of accidents. Again, electric power lightens the burden of work, and the range of seams that can be worked is increased by better illumination and the use of power, thus reducing the cost of winning coal (benefiting both the worker and the public), whilst the use of electric power will result in a great reduction in the number of horses at present employed underground. The author's investigations of the effect of frequency on ignition are of special value as opening up definite possibilities of increasing the standard of illumination not only on the roads but at the face. I see no special difficulty in increasing the frequency of a small proportion of the power from 50 to 150 periods, or even higher, if this gives complete immunity of risk from lighting. While not desiring to throw any doubt on the author's experiments, I feel that, before we can ask the Home Office to modify the existing Regulations to allow the use of a periodicity of 150 for lighting at the face, a further exhaustive series of tests are essential.

Mr. R. Nelson: In that section of the paper headed "Conclusion" the author states (1) that the risk of shock has practically been eliminated, and (2) that by keeping the leakage trips set low there is no risk from transient arcs due to the accidental breaking of an armoured cable. I entirely agree with those two statements. The position in both respects is well established, and from the point of view of safety a great deal of ground has been cleared thereby. It might indeed be asked: What remains? The three things upon which safety in mines chiefly depends are mentioned by the author, viz. efficient ventilation, the elimination of all sources of flame or open sparking, and the improvement of underground illumination. The last alone of the three has not yet been attained, but, as the author justly remarks, it is doubtful whether an increase is really desired (in the sense of being demanded) by the miner himself. Fig. 9 indicates that at a frequency of 50 periods and at a pressure of 50 volts, which is a reasonable voltage for local distribution, something of the order of 25 amperes is required to ignite firedamp. That is to say, 8 or 10 lamps could be used in a gate road with a reasonable factor of safety. That is a very remarkable conclusion and opens up a very wide prospect for improved lighting below ground. On the other hand, I hardly follow the author's suggestion that portable lamps and "cabtyre" flexible cable should be provided for lighting the coal face. I think it is not unlikely that the miner, in the effort which we all know he constantly makes to improve the nation's output of coal, would become entangled in festoons of "cabtyre" cable. In my view, improvement will in practice lie in the direction of the better lighting of main and gate roads rather than in the better lighting of the coal face. There is one other aspect of the lighting problem. On page 29 of the last Report of the Secretary for Mines there is a Section dealing with diseases of occupation. Under that head is nystagmus, which is by far the most prevalent occupational disease amongst coal miners. Compensation for total or partial disablement is paid to 0·99 per cent of the workers, and it must cost the nation more than £1 000 000 per annum. The Report proceeds as follows: "The general consensus of medical opinion is that the essential cause is deficient illumination and that the only remedy is better lighting. . . . The problem of illuminating coal mines more effectively is perhaps the most important as it is certainly one of the most difficult of the health and safety problems confronting the coal mining industry." It appears to me that the author provides a remedy at hand. I should like to subscribe fully to all that Mr. Sparks has said, but on one point of fact he is not quite correct. He is not right in thinking that previous to the Senghenydd explosion no risk was thought to attach to electric bells. About six months before that explosion the coal owners of South Wales were circularized by the then Divisional Inspector of Mines for South Wales (Sir William Atkinson) and informed that such bells were dangerous, this as the result of an experience at Bedwas Colliery in Monmouthshire. The author begins the paper by saying that in view of the necessity for precise knowledge it seemed worth while to enter into the laborious task of determining the conditions for safety in working. In my opinion it is proved to have been abundantly worth while.

Mr. J. A. B. Horsley: It is very appropriate that the Institution should take an interest at headquarters in an industry in which electrical motors aggregating more than $1\frac{1}{4}$ million horse-power are used. The author remarks that the daily toll of life, and, may I add, the super-tax on maintenance, need never be paid if it were not for the element of human frailty. I suggest that is the important factor, for though research may prescribe limiting conditions to ensure safety

it must always be borne in mind that the best plans will often miscarry. An experiment is described in the paper which seems to show that there is no danger of open sparking where a cable suffers injury resulting in short-circuiting following a fall of roof, but there are on record instances where timber which had fallen with the roof has been set on fire in consequence of a short-circuit following such injury to an armoured cable. The arc is not always so transient or so controlled as to ensure that the dielectric will not take fire. With another type of cable it is not an uncommon occurrence, as a result of a short-circuit—not necessarily brought about by a falling roof or similar injury—for what are called "bursts" to occur, when the arc between the conductors persists long enough to burn a hole right through the coverings of the cable. I do not want to exaggerate or over-accentuate the possibilities of such accidents, because I feel sure that the risk of danger following a short-circuit can be diminished by a more extensive use of automatic protective principles other than those which are represented by fuses or their mechanical equivalent. I am very interested in the author's design of an earthing plate, but the attachment of the cable to the central rod should be at a point above the surface of the material with which the excavation has been filled in. The proportion which the number of accidents due directly to electricity bears to the total number of accidents which occur in mines in this country is very small, but it is the ambition of all engineers who are concerned with the use of electricity below ground still further to reduce the number of those accidents. To illustrate the influence of the human factor in mining problems I recount an incident which I heard of from the manufacturer concerned. As a coal-cutting machine motor repeatedly broke down, the maker visited the pit with the colliery manager. Upon opening the gate-end fuse box they found, in place of the proper fuse, a piece of substantial 7-strand cable. Explanations were demanded and given by the machineman with candour and vigour, to the effect that he had only been restrained by physical conditions from inserting a piece of the tram rail, such was his objection to automatic interference with his work of cutting coal.

Mr. S. W. Melsom: The author suggests that coal is an insulator, and I agree with him. He goes on, however, to talk of earth as a conductor, whereas dry coal and dry earth are both insulators. It is perhaps as well to realize that efficient earthing depends not only on the moisture in the soil, but also on the extent of the impurities in that moisture. It is only the impurities in ordinary water which in any sense make it a conductor. The question of earthing is becoming of the greatest importance not only in coal mines, and I should be glad if the author would say what he considers to be an efficient earth. In America an earth having a resistance of 100 ohms is quite common, whereas in this country the figure is often 1 to 2 ohms. The author mentions that it is necessary to pour water on his earth plate at intervals, but that is surely relying too much on the human element. The question is not merely an academic one. The Mining Regulations specify the insulation of the system in terms of the leakage current which may flow, the leakage current being expressed as a proportion of the maximum current. If the miner forgets to water the earth plate on any one day and there happens to be a leak on the circuit, the very fact that the earth is of very high resistance would of itself limit the current to a value lower than that required by the Regulations, whereas if the man had performed his duty a leakage current would flow and so indicate a fault. One would expect that in coal mines, where earthing is essential to secure safety to the operator, and where it is easy to make a really good earth connection, there would be a great deal of data on the matter, and it would be helpful if the author could give us a little more detail as to the actual resistance obtained and the methods used for determining the resistance of the connection to earth.

Mr. P. J. Higgs: The author states that it is not too much to say that upon the provision of an efficient earth the whole safety of electricity in mining depends, and I should like to add a few remarks on this part of the paper. In Section (10) he brings to the fore in a rather striking manner the subject of electrical endosmose. This is a subject which, although generally well known, is very apt not to be considered in its proper degree of importance. In a resistivity test on moist soil in a glass container, I found that electrical endosmose was very apparent; on the application of a direct current, in time the soil around the positive electrode gradually and visibly became drier, while that around the negative electrode became wetter. This was a simple though interesting example of the actual transfer of moisture through soil in the direction of the current. The earth plate illustrated in Fig. 10 would appear to be of good design, since it takes care of two important factors in the question of low-resistance value. The wedge-like sides tend to maintain, by the action of gravity, good contact between metal and soil, and provision is made for supplying water to keep the soil moist. The filling material of the earth cone, however, is given as stone and gravel, and I would suggest that coke or coke breeze (free from sulphur) is to be preferred in order to gain the advantage of conductivity along the third and horizontal edge. It may so happen that the earth connection is under a drying influence, in which case it is probable that the horizontal edge would retain its moisture longest, due to the rising evaporation of whatever moisture may still remain inside the cone. In such a case as this the horizontal edge may, if coke be used, serve to give the greatest conductivity to the soil, whereas with stone or gravel—being practically insulators—this advantage would be largely lost. I should be glad if the author would indicate in his reply the order of resistance to be expected from the earth connection shown in Fig. 10, since the results of American experience appear to point to the fact that it is an exception rather than the rule to obtain values of the order of 1 or 2 ohms with an earth electrode of limited extent. Practically the whole of the resistance of an earth connection is that due to the medium within about 5 or 6 ft. of the electrode. The medium underground would be coal, while at the surface it is soil. The resistivity of coal, even in its natural state, is of the order of that of an insulator.

Dry soil is also practically an insulator, but with a moisture content up to about 20 per cent by weight, as is common in its natural state, the resistivity is of the order of that of a poor conductor. Since soil and pure water are of themselves materials of high resistivity, it is evident that soil conductivity is primarily due to the dissolved salts in the moisture. This is substantiated by the effect of only small additions of salt to the soil around an electrode in very appreciably reducing its resistance. It would appear from American practice that about 30 ohms is an average value of the resistance of an earth connection of limited extent, and it is stated to be a rather difficult and expensive matter to obtain resistance values of the order of 5 ohms and less with such electrodes or system of electrodes. The use of the water-pipe system, a common earth wire, or an underground ring main of all available metal within a certain area, bonded together, is therefore advised. If such earth connections of unlimited extent are used, resistance values of the order of a fraction of an ohm can be obtained. The nature of an earth connection is such that with every appearance and impression of satisfaction the condition due to a high resistance may be quite unsatisfactory, and it would therefore appear that further information in regard to the important question of earthing as adapted to the needs of this country is very necessary.

(*Communicated*): The conclusions arrived at in the paper favour the use of alternating current at a fairly high frequency (of the order of 160 periods) and a relatively low voltage (of the order of 25 volts), for maximum safety in coal mines. A frequency of the order of 160 periods would be satisfactory for lighting, but would not be favoured for power purposes, since it brings in the well-known disadvantages of increased losses, lower power factors, and difficulties in design and speed regulation of rotating machinery. Since it is stated that it is in electrical haulage that development is likely to be greatest, this aspect is important. It would therefore appear that two a.c. supplies would be necessary, one of high frequency for lighting and one of low frequency for power. The use of a low-voltage supply would entail large currents for the same energy. The importance of this is shown in the relations between least ignition current and voltage; for 150 periods and 200 volts the least current is given as 23·5 amperes, and at 15 volts the least current is 175 amperes. For the same condition of safety against the breakage of a cable while delivering the same amount of energy, the least ignition current at 15 volts should be 330 amperes. It would therefore appear that the higher value of current for the lower-voltage supply is not of itself a factor of safety. The factor of safety is evident, however, in the case of a fault to earth, where the lower voltage would produce a smaller flash-over current. Generally, however, it is to be expected that an accidental earth in a coal mine would itself be of a high order of resistance such as strictly to limit the earth current; therefore the danger would be limited to that of short-circuit between conductors or an interruption of current due to a sudden break in the circuit. The author deals fully with the effect of current, voltage and frequency, but it appears to me that not sufficient reference is made to the factors of inductance, capacity, time, etc., as bearing directly upon the great importance of transients. American practice tends to recognize that the protection and design of electrical circuits against transients is of greater importance than the design for normal operation and working, since most breakdowns are primarily due to transient conditions. The transient conditions of the circuit would appear to be directly applicable to such a subject as sparking. An electric circuit generally contains two components of stored energy: viz. (i) that due to the capacity C ($\frac{1}{2}e^2C$), and (ii) that due to the inductance L ($\frac{1}{2}Li^2$). The capacity factor of energy is greater for high voltages, while the inductance factor is greater for high currents. In general, low inductance and high capacity factors are to be desired in order to decrease the intensity of sparking when breaking full-load current in a circuit. A change of current in a circuit requires a redistribution of the stored energy and an induced E.M.F., dependent upon the rate of change of current and the inductance of the circuit. In the case of a break of the circuit the current flowing will tend to fall to zero in a short interval of time; the stored energy of the circuit will appear practically entirely in the intensity of the spark at break. The induced voltage across the break would also momentarily reach a value which would primarily depend upon the constants of the circuit and the current, and be practically independent of the normal voltage of the circuit. It may happen, therefore, that the apparatus of an a.c. system may introduce greater inductances than would occur in a d.c. system, so that the transient phenomena in the former may be so great as largely to offset the experimental advantage shown by a.c. systems. The lower distribution voltages would also increase the inductance effect due to larger currents, and this again may partly offset the experimental advantage of immunity to dangerous sparking shown by the use of low voltage. Let us take a particular case of a short-circuit between two conductors protected by an overload circuit breaker. After the instant of short-circuit the circuit breaker will take time to operate; a typical figure is 0·18 sec., which for a 25-period circuit gives about $4\frac{1}{2}$ complete periods for the duration of short-circuit. During this time the current greatly increases and a large amount of energy is poured into the circuit. Now at the instant of break by switch, the intensity of spark will be a measure of the energy in the circuit in the transient state, and this may bear no relationship to the normal current and voltage of the circuit. It would appear, therefore, that possible transients, surges, oscillations, etc., of both voltage and current are very important in connection with the study of the use of electricity in mines.

Mr. W. M. Selvey: The author has had very special experience in investigating unfortunate occurrences. There is a tendency to attribute the cause of these, perhaps too readily, to open sparking, and hence to infer that electricity is a dangerous servant for mining work. I would contend on the contrary that it is, compared with other means, an exceedingly safe servant if properly used. Since a case has in some instances been allowed against electric ignition caused by open sparking, it becomes a duty to investigate thoroughly

all contributory conditions which go to make up a dangerous condition. Prolonged investigation has been made, and the net result is that these conditions can now definitely be arranged on a laboratory scale. A study of these conditions when compared with practice shows, what has always been dimly apprehended, how rarely a perfect parallel can occur. This study also indicates that the regulations as to the cessation of all working when the gas percentage rises to a certain value are both valuable and necessary, and if strictly followed would render almost impossible the combination of circumstances denoting danger. It is because of this perhaps, as Mr. Sparks has pointed out, that open sparking from bells as a danger was unsuspected for 30 or 40 years. That is to say, it took all this time even to suspect that danger was possible, and once attention was directed to the matter the risk was speedily removed without difficulty. Modern developments will, in my opinion, improve the factor of safety. They may be directed to using as high a pressure as possible for power, and as low as possible for lighting. High-pressure apparatus is more mechanical, requires but little current and readily lends itself to protective devices. More and more light should be used at low pressures, e.g. 50 volts and lower, and combined with high-pressure switchgear there is room for development. In an installation in which I am interested, I know of only three interruptions in four years on an extensive high-pressure power and low-pressure lighting system. Two of these were caused by flashing-over inside a closed oil-immersed controller. In each case the pit was cleared. Although some engineers may not think it good practice thus to interrupt work, my experience leads me to place the value of the moral effect higher than the cost of the interruption. I think that too much attention cannot be paid to the earthing system. In the system detailed in the paper, danger occurs due to the fact that the attachment to the earth plate is out of sight. Such an attachment would corrode away. It is better to have a prominent earth plate bricked around on the surface, with at least two visible attachments of the copper to the iron. It is better to have solid copper strip of substantial section bolted to the iron than to depend on any other form of attachment. For a certain distance from the earth plate it is well to reinforce the conductivity of the cable armouring by a special earth conductor, say as far as any considerable group of apparatus on the surface, in order to prevent any rise of voltage at the pit bottom and inbye. The author is here making a bold suggestion. Having definitely decided the dangerous conditions, by avoiding them it is now possible to use electricity freely at a place where (sooner or later) gas will occur, i.e. at the face. The paper contains the germ of a system of apparatus which would allow unlimited lighting at the face (at a frequency of, say, 150), and which could be destroyed by a fall without the slightest risk of ignition. Such a system would of course have to undergo extremely rigorous tests before it could be adopted and before the regulations could be modified to allow of it. I should be glad if the author would give in his reply some further indication of the type of apparatus that he has in mind for providing and controlling the supply of current.

Mr. F. O. Hunt (*communicated*): The paper is of great interest, not only for the immediate light thrown upon an involved subject but by reason of its promise of greater things to come. Coal and its economical winning are among the primary considerations in maintaining the commercial position of this country, for it was the application of the energy of coal to manufacturing which originally made this country the workshop of the world. That impetus has expended itself, and already the exhaustion of the more easily worked seams tends to make the cost of our coal increase. Consequently it is of the utmost importance that we should find better means of utilizing our coal. I suggest that this paper really represents part of the spade work which, by bringing to light the mechanism by which gases combine, may enable us to obtain electrical energy direct from coal gas or producer gas. It would seem that an understanding of the electrical conditions which promote combination might well be the stepping stone to the production of electrical effects by means of such combination. The effects of frequency seem to be very extraordinary, especially as the "presence of hydrogen raises the depression [in the curve of ignition]." The paragraph which follows (on page 488) is the most striking evidence I have yet seen with regard to the ionization theory of the initial stage of combination. I should be glad if the author would say whether the condenser to which he refers on page 484 is one having an air dielectric.

[The author's reply to this discussion will be found on page 509.]

MERSEY AND NORTH WALES (LIVERPOOL) CENTRE, AT LIVERPOOL, 14 JANUARY, 1924.

Mr. T. B. Morgan: I should like to ask the author if, in the course of his experiments on the general question of underground signalling, he has ever included the problem of telephones. The maximum voltage allowed by the Home Office rules for signalling apparatus is 25, whereas a magneto telephone (of which there are hundreds installed below ground) can easily generate from 100 to 200 volts. It would be interesting, therefore, to learn if experiments showed them to be dangerous or otherwise. I should like to know whether the author would favour one earthing point on the surface for the whole of a colliery undertaking, or whether he would prefer a number of earth plates at different points underground, such as sump holes, etc. Also, would he expect the same results in the earthing system of a colliery having, first, a three-phase system with the neutral point unearthed, and secondly, a three-phase system with the neutral point earthed?

Mr. B. L. Myer: The author states that the ordinary thin spark due to an electrostatic charge is not dangerous and is incapable of causing ignition of coal dust or gas; according to Section (3) of the paper it has not

been found possible to cause ignition of firedamp by this means. It would be interesting to know whether any experiments have been made in the deposition of coal dust from the atmosphere by means of a silent electrostatic discharge. In view of the statement that such discharges are not capable of producing ignition, such a method might possibly be devised to limit the amount of coal dust in the atmosphere.

Mr. H. Midgley: The use of pulverized coal in this country has up to the present been in the nature of an experiment, and amongst the troubles experienced have been explosions of the mixture of air and powdered coal during its passage from the pulverizing plant to the burners. As the powdered coal is practically coal dust it is, perhaps, not outside the scope of the paper to ask the author whether he would suggest that there is any possibility of these explosions having been due to static charges generated by the passage of the powdered coal through the pipes; or, alternatively, whether the heat generated by the friction of the powdered coal against the pipes may have been sufficient to fire the mixture.

Mr. W. Bolton Shaw: The curves of ignition seem rather to point to the conclusion that the only way to make electricity absolutely safe underground is to have a zero voltage and an infinite frequency. In the lantern slides showing curves for ignition by hot wires, I think that the author had in mind the question of the possibility of firing gas by the breaking of the globe of an electric lamp and the explosive mixture coming into contact with the glowing filament. The curves are, I think, given for only one gauge of wire, viz. 0·1 mm diameter, and it would be interesting to know how this diameter compares with that of the filament used in vacuum and gas-filled lamps, and whether, as one would naturally expect, the possibility of ignition increases or decreases with the size of wire. If the author has carried out a series of experiments to determine this relation, perhaps he will refer to them in his reply. I should also like to ask him whether he has made any experiments on the firing of gas or a mixture of gas and coal dust by mechanical sparks such as those produced when rotating metal rubs on metal. It is more or less held by mining electrical engineers that in the event of metallic sparks being given off by the rubbing of the rotor core on the stator of a motor of which the bearings are badly worn, there is a risk of these sparks firing any gas that may be present. This is a point of considerable importance, in view of the fact that open protected-type motors are not definitely prohibited in places where Regulation 132 of the Coal Mines Act applies. The ignition of gas by sparks produced by the rubbing of metal on hard stone is established by the fact that gas-lighters for domestic purposes are constructed on this principle. The earthing plate shown in Fig. 10 would appear to be very effective, in that the surface in contact with earth approximates to a hemispherical form (which is the ideal); the shape and construction are such that the earthing surface of the plate is kept in contact with the earth in such a way that any shrinkage or shifting of the soil will be followed up and the contact maintained; the connection to the plate can be substantial; and it is possible to get moisture to the contact surface in a simple manner. In criticism I would say that for colliery work something more substantial than $\frac{1}{16}$-in. galvanized iron would be necessary for the cone; the pipe should be not less than 2 in. steam piping; and the cable connection to the pipe should be above ground and not under the surface, as shown. Also, this connection would be better if made by screwing a heavy collar nut on to the top of the pipe with a locknut to fix it, the collar having screwed into it a stud of, say, 1 in. round copper, formed at its outer end into a terminal lug to which would be bolted the sweating socket on the end of the cable, or preferably the cable itself, looped and bound to form an eye.

Mr. H. E. Dance: In designing the case of an explosion-proof motor a pressure of 110 lb. per sq. in. is usually taken into account and a large margin of safety allowed. The space inside the average motor, in which gas can accumulate, consists of two distinct volumes of annular shape, one round the commutator and the other round the opposite end of the armature. These spaces are connected by the channels left between the coils of the magnet system. Now, if an explosion were to occur at the commutator end—and it is at this end that one would expect it to commence—the gases at the opposite end would, provided the channels were sufficiently small, be compressed before they exploded, and the resulting pressure would be considerably in excess of 110 lb. per sq. in. This phenomenon is well known, but I have never been able to obtain a figure which would represent within reasonable limits the pressure to be expected in a motor under these conditions. The figure of 110 lb. per sq. in. appears to be fairly reliable in enclosures where the explosion takes place freely. Can the author suggest an approximate maximum figure to be used when the explosion occurs successively in two volumes which are approximately equal and connected by a number of small channels, as in the typical motor?

Mr. H. Pryce-Jones: I believe that the filament temperature of a gas-filled lamp is considerably higher than that of an ordinary vacuum lamp. This being the case, I should like to ask the author whether the danger of explosion due to instantaneous ignition of gas, consequent upon breakage of a lamp in a "fiery" working, is any greater when the more modern type of lamp is employed. Also, if this theory is correct, has its verification been obtained as a result of experimental work or merely as the outcome of the comparison of the number of explosions over a given period in mines adopting the different forms of lamp?

Mr. A. E. Malpas: I have several times been down the pits, but have never really examined the construction of the lamps used. These were always handed out in the usual way after examination in the lamp room at the surface before descending the pit. Looking at the example of lamp now exhibited, one could hardly realize what would happen if the glass broke.

Mr. J. A. Morton: On page 486 an experiment is described in which an unarmoured cable is cut in two without an external flash being observed. In this case the trip gear was near at hand and operated quickly. In actual practice, however, the fault might be on an

inbye cable a considerable distance from the tripping gear, which might not operate so quickly as in the experiment. I should like to know which of two cables the author thinks is the better from the point of view of gas ignition, an inbye cable, bitumen-insulated and double-wire armoured, or an inbye cable, paper-insulated, lead-covered and single-wire armoured. In conclusion, I should like to ask whether the earth plate described has been patented.

[The author's reply to this discussion will be found on page 509.]

North-Eastern Centre, at Newcastle, 28 January, 1924.

Professor Granville Poole: The author's contributions to the subject of electricity in mining are well known and fully appreciated by the mining industry. It would be of considerable interest if he could give us a complete list of his papers, for the work described to-night is only a small part of the whole. The safety lamps which he has demonstrated mark a very considerable advance. An electric safety lamp which will indicate the presence of gas has long been in demand, and if the author can succeed in giving us one that will do this he will confer a great benefit on the mining industry.

Mr. C. Vernier: I am particularly interested in the section on electrical endosmose and the theoretical investigation in regard to the possible pressures produced. This explains clearly why so much trouble is experienced with the single-core leadless type of cable on d.c. networks when an incipient breakdown of the insulation occurs. It is well to point out that the same trouble is absent with lead-sheathed cables as the electrostatic field does not extend outside the cable, and even an incipient fault such as a small hole in the lead sheath is largely screened electrostatically by the adjacent lead sheath, and there is therefore no tendency for negative electrification to force water into the insulation. With positive electrification it is, of course, well known that the leadless type of cable dries out. The Hebburn case referred to in the paper was the outcome of a serious bitumen gas explosion resulting in loss of life, the explosion originating in a breakdown of leadless cables, and being caused by electrical endosmose. As the result of this accident it became urgently necessary to find some method of preventing similar accidents. Experience with a.c. cables indicated the great reliability of such cables, and a few experiments with leadless cables under the two different electrifications (see *Journal I.E.E.*, 1915, vol. 53, p. 360) very soon confirmed this to the satisfaction of all concerned. It was therefore decided to change over the network to alternating current, and the change, as stated by the author, has been altogether remarkable, resulting in a practical cessation of all cable faults and absolute freedom from liability to explosions. The improvement is immediate and certain, and the few faults which occur can clearly be traced to previous damage caused by the d.c. supply. Since that time a number of other networks have been changed over from direct current to alternating current, with equally remarkable results, and this is now becoming a common practice all over the country. The freedom from mains faults, and the great saving in maintenance charges are, it is needless to say, by no means the only advantages secured by such a change, other advantages being the saving of attendance charges by the use of static substations instead of rotary substations on large systems generating alternating current, and the ease with which increasing loads can be met by sectioning old networks and feeding them from additional static substations as required. It is certain that the practice of converting networks from direct current to alternating current will become general within a very short time. This question of endosmose should receive careful consideration in connection with cables for use in mines. Many mine managers favour the leadless type of cable, but it should be borne in mind that this type of cable from this point of view, and also from the point of view of fire risk, leaves very much to be desired.

Mr. H. J. Fisher: I should like to ask the author if he has succeeded in igniting gas by static sparks; it is quite possible to get these conditions when steam is blowing in the shaft or on the surface and has charged the lines or conductors. Extraordinary phenomena sometimes occur in mines. In one case two signal bells were burnt out under peculiar circumstances. They were worked on an incline with a single wire and earth return, and there was no electric power in that portion of the pit. This burn-out occurred at the time of a fault on an overhead 6 000-volt transmission line. The incline ran parallel to the line and was about 120 fathoms from the surface. I have often noticed stray direct current when testing armoured cables, at a time when all plant is shut down. I have been able to get low-pressure current up to 0·8 ampere; this I ascribed to the tramway system. Many years ago I carried out experiments with a view to getting flames to pass between machined joints, and at the same time to try to burst joint boxes with heavy short-circuits. I took a cast-iron box, 12 in. square, 8 in. deep, and $\frac{3}{8}$ in. thick, with $1\frac{1}{4}$ in. machined flanges, and short-circuited a fuse (designed to blow at 500 amperes) with plenty of power behind it. I never succeeded in passing any flame or in bursting the box, nor could I blow a cork, which had been fitted moderately tightly, out of the top. In regard to the experiment with the 3 000-volt cable, the potential danger lies not so much in a sudden penetration of insulation and the resultant short-circuit or earth, but in the fact that the fault may be switched in again and again, the sparking getting worse each time. An earth leakage protection would, I think, increase the safety. I have no doubt that the type of earth plate designed by the author will be very efficacious. I have always advocated the use of heavily galvanized iron plates, particular care being taken in regard to the connection of the earth lead to the plate, and also in regard to the insulation of the earth lead from the surrounding earth. I have always been an advocate of the earthed neutral. Unless the earthing system in the mine is kept perfect,

or earth leakage protection is adapted, one is apt to get sparking at haulage ropes.

Mr. J. Schuil: I should be glad to know if the author has any figures relative to the actual pressure obtained at the moment of explosion in the box which he exhibited. I believe that this was the original box made when I first started experimenting with explosion-proof gear and found difficulty in getting records of the pressure obtained. The origin of the gear was a report published about 30 years ago in the *Elektrotechnische Zeitschrift* describing experiments made in regard to the spreading of explosions through small tubes. It was stated that, providing the tubes are long enough in proportion to the diameter, no explosion can be communicated to the outside. This is now limited to very small tubes. It is also found that the shape of the box has a great influence on the violence of the explosion. The more cubic in form the box and the larger its capacity, the more violent the explosion. A very violent effect is obtained by blowing a very large fuse in a box. All the tests which I carried out were performed with direct current. The strength of the box may be very easily calculated from the formula given in Professor Unwin's book.

Mr. E. E. Grover: In Section (2) the author mentions arcs, and in Section (4) he refers to sparks. Does he consider that an electrical spark can ignite the dust or cause a coal-dust explosion if no gas is present? Table 2 clearly shows that a mixture of methane and dust will explode with a less percentage of methane than is necessary to cause an explosion when the methane is mixed with air alone. I take it that these explosions of dust and gas mixed were obtained by means of a sustained arc, and that a flame or sustained arc is necessary to start a coal-dust explosion. I notice that in these experiments the coal dust was added to gas and that the mixture exploded. I am under the impression that the addition of gas to coal dust does not affect it and that the coal dust cannot be ignited by means of an electric spark. I should be glad if the author would confirm this view.

[The author's reply to this discussion will be found on page 509.]

NORTH-WESTERN CENTRE, AT MANCHESTER, 19 FEBRUARY, 1924.

Mr. W. T. Anderson: In dealing with inflammable gas it may be of interest if I exhibit the sketches issued by the old Home Office Department of Mines to illustrate the detection of gas in quantities of $1\frac{1}{2}$ to 3 per cent by observing the cap in the miners' safety lamp of the oil type, particularly as this has a bearing on the question of ignition by hot wires, or their equivalent hot gauzes, referred to in Clause 1. It was the personal opinion of Mr. John Gerrard, the late Divisional Inspector for the Lancashire area, that at least one great explosion was attributable to this elongation of the cap and consequent heating of the outer gauze to redness. With regard to the reference to the Eskmeals tests, surely these very elaborate experiments by the Mines Department were not made to convince possible doubters, as the author suggests, but to set up conditions for research as to how explosions could be minimized or actually avoided, for instance by stone dusting. In dealing with the small amount of risk attaching to breakdowns from mechanical causes on metal-sheathed cables when these are properly protected, it would have been of assistance if the author had dealt with the risk attaching to unarmoured trailing cables at the face, in connection with which leakage protective devices in the region of the gate end box are in a very undeveloped condition. In my opinion the greatest risk at the moment attaches, not to multicore trailers but to those of the concentric type which are still compulsory, in one form or another, when used with concentric mains—this apart from the obvious setback their continued use must cause to the advance of leakage (as opposed to overload) protection. It is not necessary to enumerate the anomalies which have dogged the development of these trailers. Suffice it to say that at the moment the outer of the type of concentric flexible cable generally used has to have a conductivity of 1·5 times the inner. To attain satisfactorily the requisite degree of flexibility this outer has to be applied in the form of braid or, more correctly, a series of braids. This entails a very short lay and consequent long length of spiral per unit of length of cable, involving such high electrical resistance that a very large number of compensating wires are necessary to attain the required conductivity. Hence a metal-to-metal comparison between outer and inner is actually in the nature of 3 to 1. This means that a concentric trailer becomes so stiff that the term "flexible" is a misnomer, and when one reflects that the life of a trailer primarily depends on its flexibility it will readily be seen that such stiffening as I have described leads to almost unavoidable mechanical breakdown, with undoubted subsequent flashing in that part of the mine where it can least be endured. Samples that I have examined undoubtedly bear this out, and it cannot be argued that such flashing was necessarily momentary. I feel very strongly that the use of a three-core trailer on a concentric system would be no more illogical than is the use of a four-core trailer on a three-phase system. It would undoubtedly be a great deal safer, and I should greatly value the author's views on this subject. In my opinion the ideal form of trailer is multicore with a lightly braided sheath round the insulated cores, to operate in connection with a leakage protection device. Such a sheath would not, of course, contain anything like the weight of metal required in cables of the purely concentric type. The suggestion of 25-volt lighting at the face opens up a most desirable state of affairs, though the transmission difficulties at that pressure are obvious. I have long expected legislation with regard to lower pressures for underground lighting, but at the moment the manufacturer has to face difficulties as they exist. He has to provide fittings which can be used, if necessary, on 500-volt power circuits for the series lighting of, say, haulage houses far inbye,

an extremely undesirable practice. He has to provide arrangements by which similar haulage or pump houses can be lighted, say, from concentric power cables by twin wires which he can only use by putting in a rotary converter between them. He has to provide light at the bottom and in the insets of upcast shafts when these are used for winding, where, in spite of the $1\frac{1}{4}$ per cent gas ruling, no human agency can possibly predict when a mixture of explosive proportions may happen to pass. I have recently been associated with experiments dealing with such contingencies. In this investigation we started on the assumption that although hollow fittings can, under certain conditions, be made flame-tight, no hollow fitting can be rendered gas-tight. Every colliery electrician knows that it is not practicable to fill small lighting fittings with hot compound, and this difficulty was overcome by using in its stead a plastic resilient plug. Incidentally, I should like to hear the author's views on what he considers to be the minimum safe flange for small fittings of the hollow type. Switches were similarly treated except for the infinitesimal spaces required for the make-and-break movement of the switch, which cavities were catered for by a long screwed surface through which the handle of the switch was operated. This only left a real cavity to be dealt with in the cubicles for the double-pole fuses, with which every reduction in cable size must legally be protected, and it was found possible so to construct these that, when blown under gross overload and filled with a mixture of firedamp in the proportions of 8·5 per cent, no flame on explosion was communicated to the surrounding atmosphere although it was charged with methane in the proportion of 8·9 per cent. In connection with the same subject of lighting, an anomaly to which attention might be drawn is that underground low-tension cables (up to 250 volts) need not, under certain conditions, be armoured. This, more than anything else, has been responsible for an appalling amount of bad work, as it is impossible to comply with the regulation demanding that such unarmoured cables shall be "efficiently suspended from insulators" without their coming into frequent contact with pit props and the like. In other words, conditions which are ostensibly allowed could be at once prohibited under the "General Safety" Regulation No. 132. With regard to sparking from metallic sheathings, the value of the paper would have been increased if the author had referred to the dangers involved by the continued use of concentric systems with bare outers. In my opinion the carrying of any heavy current by means of bare conductors in unsuitable places, such as safety lamp pits, should be rigidly prohibited. As a result of such currents, I myself have seen heavy sparking between haulage ropes and jockey pulleys 2 000 yards inbye and have known of an authentic case of a boy relighting his lamp between the armour and the nearest tramrail. In this connection I do not refer to concentric systems with insulated outers, and I see no reason why the Government should not allow systems of this class to be mixed with twin systems, a practice which, according to the strict letter of the law, is at present inadmissible. I disagree strongly with connections to earth plates being made in the ground (as shown in Fig. 10). Many years ago I adopted an arrangement, which has subsequently become to a large extent standardized, of installing nests of cast-iron pipes in such a manner that all connections to the busbars crossing their surfaced flanges were always visible and readily accessible. This is highly desirable, not only on account of dissimilarity of metals but also on account of probable rapid action set up by the coke or breeze, usually containing sulphur, with which earthing gear is generally surrounded. In connection with the same matter I would urge the vital necessity of periodical resistance tests being taken between earth plates on all colliery installations, and the careful logging of results. This not only allows comparisons to be made between the dry and wet months of the year but also goes a long way to ensure protection of the metallic sheathings of the shaft cables which are the most liable to electrolytic attack, particularly on large installations where there is bound to be a considerable amount of surface leakage underground.

Mr. W. Bolton Shaw: The paper adds the weighty argument of greatly increased safety to those practical considerations usually put forward in favour of the use of alternating current in preference to direct current for underground colliery work. The curves shown in Figs. 7 and 9 give the results obtained by varying the voltage and frequency of the current taken to fire methane by transient arcs. Presumably Fig. 9 shows the lower portion of curves similar to those in Fig. 7 but on an extended scale, and if this is so I do not understand why the lower part of the curves in Fig. 7 are curved while those in Fig. 9 are straight. The curves in Fig. 9 give the results for a 9·5 per cent mixture of methane in air. The author's arguments for using 25 volts at a frequency of 150 for safety reasons are apparently based on these curves, but one wonders whether this condition of the air is a more inflammable one, as regards the current necessary to fire it, than a mixture of methane in the presence of coal dust, for which a series of results are given in Table 1. Are the curves in Fig. 9 affected by the presence of coal dust, and, if so, to what extent? With regard to the question of lighting at 25 volts, I do not quite see the force of the remark that 25 volts is permitted everywhere in a mine, because, so far as I am aware, all ordinary lighting voltages are permitted everywhere in a mine, and open sparking where Regulation 132 applies is not permitted even on 25 volts. From the point of view of the Mines Act as at present in force, 25 volts does not therefore stand on any better footing than any other lighting voltage. Perhaps the author's suggestion is, however, that at 150 periods 25 volts is so safe as regards the firing of gas that open sparking might be permitted. Leaving aside the question of producing the necessary frequency, I see no inherent difficulty in lighting at 25 volts, but there will obviously be an extra cost in cables in order to avoid too heavy a voltage-drop for satisfactory illumination. The cost of this system, compared with that of one at 55 volts, which is quite a practical proposition and one which I advocate, would be something like 25 per cent greater, while compared with one at 110 or 220 volts it would be perhaps 30 per cent higher. There is a further practical advantage from the point of view of reliability and

maintenance, viz. the greater sturdiness of cables and lamps at the lower voltage. The author's argument depends, however, largely upon the question of frequency, and here the difficulty is in the frequency-changer. If a satisfactory frequency-changer could be designed of the same nature as a static transformer or preferably a transformer performing the double function of changing both the voltage and the frequency, the electrical industry would be greatly benefited. Coming to the question of lighting the coal face, the practical mining engineer will at once see a difficulty. The number of small flexible cables crossing the face from the lamps to the common cable supplying them would be a nuisance and very liable to damage. A single coal-cutter trailing cable, which is a much more robust affair than these small flexible cables, is always more or less in the way on the coal face and is a sufficient source of anxiety. On the other hand, with the element of danger from shock or burning or of sparks firing gas entirely eliminated, as the author claims, I do not think that there would be any insuperable difficulty in getting the colliers working on the face to accommodate themselves to the use and care of these flexible cables if they found, as they no doubt would find, that the greatly improved lighting was of substantial advantage to them in the getting of coal. A collier, from the very nature of his work, is accustomed to adapting himself to awkward and difficult conditions, and he would no doubt soon become accustomed to using flexible cables just as other workmen have become accustomed to the use of portable lamps in other awkward situations particularly unfavourable to the use of flexible cables. Mr. Anderson has drawn attention to the question of sparking from the earthed outer of concentric cables. Another and similar case of arcing which sometimes occurs is not always appreciated; that is from the armouring of an ordinary three-phase cable when a heavy short-circuit to the frame of the machine or switch or to the armouring of the cable itself occurs at the far end of a long cable (say, 1 000 yards long) and the earth current travels back by the armouring to the neutral point of the alternator. The drop of voltage in the armouring of the cable may be of the order of 100 to 150 volts, and if the armouring happens to be in contact with metal such as the frame of a haulage pulley or the haulage rope itself or the armouring of another cable, severe open sparking may take place at the point of contact.

Mr. S. H. Lee: That part of the paper which deals with the difference between a.c. and d.c. supply gives support to the attitude taken up by engineers over a long period, but one must now add to the conclusions that the a.c. supply is the safer. I should be glad if the author would say whether the adoption of his suggestion in regard to electrical transmission would improve the factor of safety. It is evident that the illumination on the coal face is, in the author's opinion, not what it should be. Are we to conclude that improvement would mean greater working safety, better working conditions for men, and an increased output? If this assumption is correct the most important point is freedom from electrical ignition. Can we rely on the system advocated to give this? It would be of interest if the author were to give particulars of the following apparatus to be used on a face 200 yards long where at present electrical cutters are being employed, with gates every 20 yards: (1) Type of fittings; (2) switch and protective gear; (3) number and candle-power of lamps; and (4) type of cable. In one case when starting into operation a new colliery power station a report came from the boiler attendant that while raking out the ashes he received a shock. I confirmed this fact and shut the plant down, but still the charge was present. On investigation a pipe joint over the boilers was found blowing, so a plate pointed at one end was fixed with the point set $\frac{3}{4}$ in. from the manhole cover handle, the other part in direct contact with the escaping steam. A spark $\frac{3}{4}$ in. long was obtained and photographed. Sparks are also caused by coal-cutter picks. I should like to have the author's opinion in regard to the use of bare wires for signal purposes, contact being effected by putting them together. Does he think that an insulated system would be safer if used on the Fryar Davis system? In this system switches are fixed every 200 yards on the road, and attached to the operating handle is a pull wire. This enables the bells to be rung from any convenient point. In Section (7), particulars of a penetration test on cables are given to ascertain if there was an outside flash. Taking in consideration the fact that all cables in a mine are armoured, why was only a lead-sheathed cable used? Again, why was a pointed wedge used? This in itself would prevent an outside flash. Has the author ever dropped a weight of 6 cwt. for 10 ft., the face of the weight being about 6 in. square (similar to the bottom of a girder)? I have used such a test on all types of cable after sprinkling the outside with petrol, with very interesting results. The earth plate illustrated in Fig. 10 is very practical, but I should like to know why the material used is only $\frac{1}{16}$ in. thick.

Mr. J. H. Buchanan: I take it that the curves in Fig. 9 are intended to show a comparison between the effects produced at different voltages, and there is undoubtedly some advantage in the lower voltage from the point of view of current required to cause ignition. But for a given amount of lighting it is necessary to consider the power which is used rather than the current, and, if the curves are examined from this point of view, I think it will be found that 100 volts appears to be a better pressure to use than 10 volts. Take, for example, the values of current for 10 volts and 100 volts at 140 periods—a convenient point on the scale. At 10 volts the current is roughly 200 amperes, and at 100 volts it is about 40 amperes. Now, 40 amperes at 100 volts is equivalent to 4 kW, while 200 amperes at 10 volts is equivalent to only 2 kW. The disadvantage due to the smaller current permissible at the higher voltage is more than balanced by the increase in available power. That is to say, if a spark occurs due to a break in the circuit, the higher voltage will be the safer for a given amount of power in the circuit. According to Fig. 9, at 140 periods it is safe to break up to 4 kW at 100 volts, but the danger point is reached at 2 kW with a 10-volt circuit. This would not necessarily apply to the case of a short-circuit, although the higher impedance of cables and transformers on the

higher voltage would tend towards making a short-circuit no more dangerous than on the lower voltage, for which the impedances would be extremely small.

Mr. G. S. Corlett (*communicated*): The most interesting part of the paper is perhaps the section dealing with the relation of frequency to the minimum current that will ignite gas. I gather that this is limited to lighting, as the cost of raising the frequency of existing power circuits would be prohibitive. On page 481 the author says: "Most of the accidents in mines are mechanical in origin, and are due to the poor illumination of haulages, or to the difficulty of keeping earth movements under continual observation." By "haulages" I presume he means "haulage roads" and not "haulage houses" and I take it that his second sentence hints, among other things, that it is now difficult to see when a fall of roof is likely to occur. It is common knowledge that many accidents, all too frequently fatal, occur due to falls of roof, and that such accidents would not have arisen if additional supports, provided close by for the purpose, had been fixed. The fixing of these supports is in many cases outside the discretion of the workman; that is to say, it is his duty to fix them at definite spacings. It is also unfortunately true that many other accidents arise due to the neglect to use one form or other of the many safety devices available, probably mainly due to familiarity with the particular danger, in short the same general motive or frame of mind which induces otherwise sensible people to jump off a train before it stops or to run violently after a tramcar. I fail to see how the most perfect illumination, or the most perfect observation of earth movements, would reduce these accidents at all. I do not want to imply that this neglect is only on the part of the workman; the owners at times do not provide the best appliances or maintain them in the best condition. It is also a regrettable fact that far too many of the accidents which do occur are officially classified as "preventable" and would not have occurred had something necessary been done. All possible steps should be taken to reduce these accidents. I should like to ask what is meant by the statement that "accidents are mechanical in origin." In the next sentence the author sets out the principal conditions on which safety in mines depends. It is not clear whether the author suggests that these points, which I agree embrace a wide range, deal with the whole question of safety, or merely with that portion due to electricity. Further, the tone of the paper as a whole is that (subject to the few items mentioned in the concluding paragraph, which will require watching) all the necessary information is available to carry out the work on these safe lines, and, for example, if one wants flame-proof apparatus he takes it out of stores or buys it as a standard in the open market. If that were true and the conditions set out by the author the only ones to be observed, the mining electrical engineer would have no cause to worry. It seems to me that the author is looking at the subject from the wrong perspective. The danger from this open sparking is primarily the ignition of methane with or without coal dust. There are, of course, other inflammable materials, but in an installation on modern lines and with fireproof motor houses, conforming to the regulations, the danger is small. The electric firing of methane is a rare occurrence and there are few cases on record that are conclusive. During the "electrical age," as the author describes the present era, there has been much bad electrical work, and some still remains, although it is a diminishing quantity. Nevertheless, this type of accident is fortunately infrequent. Though it may seldom happen, the precautions against it should not be relaxed in the slightest. In my view where the danger exists the precautions cannot be too drastic, because such an ignition may develop into one of those too-frequent disasters with heavy loss of life. Fortunately, the vast majority of plant underground is located where this danger does not exist and, except on some coal faces, the positions in a mine where electrical plant is required and where gas is likely to occur in dangerous quantities are few and far between. I am not clear whether by the expression "elimination of all sources of flame or open sparking" the author means that totally enclosed apparatus is to be used throughout. The standard ventilated squirrel-cage motor is certainly a potential source of flame, since no insulation is everlasting, and a liquid controller is the most suitable apparatus yet designed for heavy haulage, but it sparks openly. To my mind it is folly to prohibit these, except in the danger zone. As to the danger zone, i.e. where methane is likely to be present, I should like to emphasize that what is really necessary is a combination of apparatus which is jointly, as well as individually, safe. It is useless to have one or more links of such a chain defective. The author says on page 489 that real security for power circuits can only be obtained by complete enclosure, but I should like to know where such enclosed apparatus is obtainable of a safe nature. The simplest possible combination is a motor, switchgear and connecting cables. The author's experiment in a power house with a cable does not seem to me to be very convincing, and I do not think we have evidence to warrant our saying that with a fall of roof open sparking might not occur on a cable. As to motors, the Home Office Regulations apparently contemplate the use of open motors and appear to be based on the assumption that failure of the insulation and open sparking arising therefrom is not likely to occur simultaneously with an influx of gas. It is true that gas frequently comes slowly into a place and so can be detected in the early stages, but it is also true that it frequently comes without warning. For many reasons totally-enclosed motors are undesirable; and there has lately been a great output of certificates in regard to switchgear which is supposed to be safe in mines. I myself attach very little value to these certificates, as all the experiments are based on the ignition of the gas inside the enclosure by means of an induction coil. It should be remembered that in practice there will be no induction coil and the gas inside the enclosure will in all probability be ignited by some defect, probably a short-circuit. So far as I know there has been no research whatever as to the type of enclosure which will withstand the combined effect of a short-circuit and gas ignition when the supply is taken from a large power station. It seems to me

that there is a very real danger of the apparatus being completely smashed or at least of a hole being burnt through the covering, thus producing open flame. Again, these particularly dangerous positions are usually those remote from the shaft and consequently less likely to be visited frequently by the higher officials, and there is unquestionably to-day a very real danger of ineffective maintenance which I am afraid will continue for some time to come. It is most interesting to know that so much more current is required to fire gas at 150 periods than at 50, and this knowledge may at times be of great value. This is no doubt, however, limited to gas ignition, and current at 150 periods will fire cable coverings, wood and other inflammable material as readily as at any other frequency. I do not clearly follow what the author recommends as general practice for lighting collieries underground, but probably he means, in addition to what is usually done now, viz. shaft sidings, engine houses, main junctions, and the like: (*a*) That all lighting should be at 150 periods, 25 volts or thereabouts; (*b*) that haulage roads should be lighted; (*c*) that coal faces should in many cases be lighted; and (*d*) that lighting of other main roads should at least be considered. To illustrate this, I quote below data from an actual colliery on which I am at the moment professionally engaged; it is an old pit getting its relatively small output from two shafts and from various seams: (1) average daily output, 600 tons; (2) length of haulage roads along which this coal passes, 13 910 yards; (3) number of working coal faces, 22; (4) average length of each working face, 125½ yards; (5) total length of coal face, 2 761 yards; (6) average distance from the centre of each coal face to nearest existing substation, 1 132 yards. To adopt in this particular case what I conceive to be the author's recommendations, is no small matter. A good light to work by is of course desirable and as a rule directly promotes safety, but it is impossible commercially or practically to light all the roads of a colliery; it is a peculiarly trying experience to move to and from bright and dark areas, and may be dangerous. I have frequently bumped my head when a man walking in front of me on an underground roadway allowed his lamp to shine in my eyes now and then—the effect is quite blinding even if the illumination is of only 1 candle-power. Coal faces vary in dimension, fairly typical figures being: Height, 2 ft.; length, 300 yards; and inclination, 1 : 6. The machine would cut at night, and coal be loaded up by day probably by a mechanical conveyer; there would be a large number of wooden props supporting the roof and these would, after the machine had passed along, be quite close to the face, which would advance laterally about 1 yard each 24 hours. Assuming also that such a face could be fed at about the middle from one transformer and that there were 12 to 14 lamps, it follows that the wires and lamps must be disconnected each night, threaded back to the centre (because the props cannot be moved) run out again, fixed and connected up. Remember also that many faces are wet, and others very liable to falls. I know of no system of wiring which would last one month under those conditions, even if the law were modified to allow it. The whole tendency of modern legislation and practice is to restrict, and in the case of new collieries to prohibit, the travelling of workmen generally on haulage roads. Again, in the particular colliery that I have quoted, there are 14 000 yards of such roads. To light the whole of those roads the following would be required: Numerous motor-generators to raise the frequency to 150 periods; a double system of wiring throughout; feeders at, say, not less than 200 volts; distributors at, say, 25 volts; numerous step-down transformers and switchgear, as the economical area to be fed at 25 volts is small; and maintenance difficulties such that I do not wish to contemplate.

[The author's reply to this discussion will be found on page 509.]

South Midland Centre, at Birmingham, 12 March, 1924.

Dr. C. C. Garrard: With reference to the phenomenon mentioned by the author, viz. that heated platinum easily ignites gas, I should like to know whether the words "activation" or "ionization" are not other names for the catalytic action which, as is well known, is exercised by platinum in many chemical processes. I should be glad if the author would state what value of earth resistance can be obtained under practical conditions from the earth plate illustrated in Fig. 10. He has shown several ingenious lamps for detecting gas, but are the electrical methods which have been proposed not reliable? As regards the general question of the use of electricity in mines, the author clearly shows that there are certain limits of current and voltage below which there is no danger of gas ignition. I take it that it is not proposed to install any system working below these limits without the usual safeguards which have now become good standard practice in collieries. The Regulations say that open sparking shall not be allowed in the specified zones. Open sparking is defined as a condition of affairs which will allow an internal flame or explosion to be communicated to an external explosive atmosphere. This is, I think, explicit and entails the use of flame-proof enclosures. Research is undoubtedly wanted on the flame-proof enclosure question. Wide differences exist in the practices of the different countries. It would appear from Bulletin No. 68 issued by the Bureau of Mines, Washington, on Electric Switches for Use in Gaseous Mines, that colliery owners in the United States are prepared to regard as explosion-proof, apparatus which does not pass muster here. On the other hand, I understand that in Germany the problem of making, for example, a complete motor flame-proof has been given up as insoluble, and the rules issued by the Verband Deutscher Elektrotechniker for the use of electricity in collieries have been modified, permitting the use of what we should call motors with open-type windings (provided they conform to certain requirements as regards insulation), simply making the slip-rings flame-proof. Dr. Wheeler has given us data from which it would appear that it is a very simple matter to make any enclosure flame-proof. All that is required is to

use a $1\frac{1}{2}$ in. flange with a $\frac{1}{32}$ in. gap. This, I understand, has been shown to prevent any dangerous pressure occurring due to an internal explosion, and at the same time to prevent the egress of a dangerous flame. Personally, I had not thought that the problem was so simple. I think, however, that the fact that these varying practices exist in different countries shows the need for continued research on this question of flame-proof electrical apparatus.

Mr. A. E. Angold: The curves which deal with the ignition temperatures of various mixtures of gases appear to cover all possible variations, but those showing the effects of transient arcs do not take into account possible variations of speed of break and the size, shape and material of the arcing contacts. I understand that the speed of break used was intended to represent ordinary switching speeds. If the author had used the slowest break that is likely to occur in practice, quite different results would have been obtained. I suggest that one of the worst conditions that will be encountered is the case where a cable is pulled out of a terminal but one strand is left in poor contact with the terminal, resulting in overheating and finally in arcing. My experience has been mostly with means for starting and maintaining arcs, but such experience has shown that there is greater difficulty in maintaining low-periodicity arcs and suggests that they would be safer than the high periodicities tried by the author, i.e. they would give just the opposite effect when the particular conditions suggested above occurred. It will most probably be found that no circuit is safe unless it is an a.c. circuit, is protected by a non-inductive resistance and has a voltage below the minimum arcing voltage of the metals used, viz. 25 volts or less. The author's theories as to the conditions of transient arcs which do or do not fire explosive gases seem to be too much influenced by the theories due to investigations into mercury-vapour rectifiers, thermionic valves and the like. In all these the positive pole does not get hot enough to give any character to the phenomenon as a whole, whereas arcs as known to the power engineer are for him so much metal melted and probably evaporated from the positive pole. With a.c. arcs both poles suffer because they are *positive* in turn. The temperatures of the positive pole and of the greater part of the gases are governed by the material of the positive pole. The hot spot (on that pole which is negative for the time being) from which the true arc starts, and the central core of gases which acts as the conductor, will also at times have their temperatures modified by the temperatures of the gases surrounding them and thus more or less delay the restarting of the arc at each half period until the voltage has risen sufficiently to suit the existing temperature. The chief interest that the power engineer has in this characteristic of the arc, namely that it can only start from or shift to a hot negative conductor, is the opposite fact that the other or positive end will transfer itself to a cold positive conductor. It would thus seem preferable to earth the negative pole on d.c. systems and thus prevent arcs in switch boxes, etc., from jumping across to the iron case as they have a habit of doing when the earthed case is positive.

Professor W. Cramp: I propose to deal with the difficulties which arise when one compares the author's results with those of other workers. In attempting such a comparison, the first difficulty which presents itself is that of understanding what is the meaning of the terms used to distinguish the various forms of discharge. The author, for instance, divides his into two categories, one called "disruptive" and the other "break sparks" or "transient arcs." On the other hand, Mr. J. D. Morgan, whose work on this subject is well known, speaks of two types, which he describes as "capacity" and "inductance" sparks respectively. It is important that this question of terminology should be settled, and I hope that it may be taken up by the B.E.S.A. We may distinguish at least four types: (1) The silent discharge or glow which exists between two electrodes when the circuit conditions are such that ionization of the intervening air can only take place in regions near the electrodes. (2) An intermittent discharge of an oscillatory character which takes place when the pressure across the electrodes is increased beyond that under (1). (3) A succession of discharges, each started by a discharge of the form under (2), but hot enough to cause combination between the nitrogen and oxygen of the air, and consequently to set up a flame, which is extinguished as it lengthens. (4) A low-pressure arc formed when the current through type (3) is increased, and which depends chiefly upon the vaporization of the electrodes. Oscillatory effects are present in type (2) and can almost always be traced in (3) and (4). But for a given sparking distance the voltage is higher for types (2) and (3) than for type (4), although by properly adjusting the circuit the discharges may be made to merge one into another. In any case the circuit conditions determine the type of discharge, and it is of the utmost importance, therefore, for such work as the author's, that the circuit conditions should be rigidly stated. The information at our disposal only records the fact that the circuit was "non-inductive"; that is to say, according to the author, on a frequency of 50 its power factor was 0·95. This, however, is insufficient. The time-constant that is unimportant on such a frequency may be of the greatest possible importance on frequencies such as are obtained with oscillating discharges, and there is no doubt that some of the sparks with which the author has been dealing were of this nature. The frequency might easily have been 100 000, and might possibly have been as much as 1 000 000, in which case not only does the above time-constant become of supreme importance but it will be modified by the presence of capacity in the windings and terminals. No information is given with regard to the latter, although it has been repeatedly shown that the size and form of the electrodes modify not only the type of the discharge but also the energy required to fire a mixture. Evidence of this is to be seen in Mr. Morgan's paper in the *Philosophical Magazine* (1923, vol. 45, p. 969). This again introduces the question of the energy required to fire a given mixture, which is stated by the author to be 0·03 joule, although Morgan and others have obtained explosions with as little as 1/10th of this figure. This discrepancy is probably due to the inaccurate method of calculating the energy, which is often based upon the maximum energy in the

capacity in circuit. But this maximum energy has no connection whatever with the energy absorbed by the spark. It is possible to have a circuit containing a spark gap, with suitable circuit conditions, in which a current of 50 amperes is maintained by the charge and discharge of a condenser, and yet the energy expended in the gap may be almost negligible. So long as such methods are adopted, Mr. Morgan's remark, that the results obtained by different investigators can never be comparable unless carried out with identical apparatus, will remain true. The question as to whether the firing of a gas is thermal or electronic has, in the author and Mr. Morgan, two supporters of the rival theories. This matter does not seem to me to be of importance, as the minimum energy required can probably be expressed in terms of either theory. The attempt that Mr. Morgan has made, in the paper quoted above, to show that this is a thermal question is to me not very convincing, since the assumptions made are too rough to be acceptable, and I concur with the present author that many of the phenomena are more easily looked at from the point of view of the discharge of electrons.

Mr. W. Wilson: By giving much definite information as to what is safe, as well as what is dangerous, the author has afforded data upon which important results can be based. I was particularly interested in his reference to the comparative effect of direct and alternating currents upon the insulation of cables. In the case quoted at Hebburn it is to be presumed that all the faults took place upon the negative cable, since the tendency would be to expel the water from the positive one but to drive it into the former. I am particularly interested in the testing of electrical apparatus for safety in a gaseous atmosphere, and I should like to ask the author what in his opinion is a fair method of exploding the test mixture in such an apparatus. Since the exploding agent in practice will in nearly every case be a transient arc, it seems to me that a spark from an induction coil cannot be a thoroughly representative means and may result in a weaker explosion than would be given under actual working conditions. As a preliminary to the routine testing of a range of contactor boxes for mining work, measuring about 3 ft. × 2 ft. × 1 ft., I carried out a number of experiments with various forms of transient arc for exploding the pentane mixture used for testing purposes. The three methods experimented with were, first, a 5-ampere fuse; secondly, a 50-ampere fuse; and thirdly, the actual 100-ampere contactor that was to be fitted in the case. The pressures produced, as recorded in the small pressure-indicator described on page 76 of my paper in this volume of the *Journal*, were 16, 30 and 40 lb./sq. in. for the three species of arc respectively, these being approximately in the ratio of 1 : 2 : 2·5. These were the average of a number of tests which were not carried out consecutively, and gave results which were quite close together for each variety of arc. It will be seen that there is a considerable variation in these, and if the first method had been employed to investigate the safety of the box, or if a spark had been used, it is quite possible that the apparatus would have been actually unsafe although it survived the test. It would appear that the explosive pressure produced has a definite bearing upon the safety of the apparatus, for not only must the disruptive strength of the enclosure be adjusted to resist the maximum pressure, but the transmission of flame through the relief apertures would also vary approximately with the pressure produced. My own opinion is that the igniting means should give at least as high a pressure as that which can occur with the standard apparatus. In connection with these tests it is of interest to record that the explosion pressure produced with the contactor when closing the circuit—the ignition being due to the small arc formed by the usual rebound of the moving contact through about $\frac{1}{32}$ in.—was at least as high as that developed by the breaking of the current, producing an arc originally $\frac{3}{4}$ in. in length, which was stretched out to extinction by the magnetic blow-out. Some observations in connection with the use of relief apertures are perhaps worth describing. One of the most convenient methods employs a large number of small holes drilled in metal between 1 in. and $2\frac{1}{2}$ in. thick. As the result of varying the number of holes and testing each variation, I have found that the explosion pressure is approximately in inverse proportion to the square root of the number of holes. In connection with ironclad oil switches, there is sometimes a diaphragm in the explosion chamber, separating the tank from the box containing the trip mechanism. With the volumes of these chambers approximately in the ratio of 1 : 3, and firing first in the smaller chamber, it was found that the explosion pressure was approximately twice that of a similar explosion in the box without a diaphragm. I have carried out a number of tests to ascertain whether the position of the holes has any effect on the relief, as one or two early tests seemed to indicate that the box behaved somewhat like a Chladni disc, having nodes and antinodes representing the positions of maximum and minimum pressure relief. Sets of 100 1-in. holes were located on various representative portions of the box, but no pressure-change with different positions of the holes was observed. This box contained a diaphragm as described above, the holes being located in the larger compartment.

Mr. F. Forrest: A great deal of attention is now being given to the use of pulverized fuel for boiler firing in electrical generating stations. Although progress in this direction has been much greater in the United States and on the Continent than in this country, there is no doubt that many stations in Great Britain will install pulverized-fuel plants during the next few years. One of the risks attendant upon the use of pulverized fuel is the possibility of an explosion occurring if a naked light or an electric arc is brought into intimate contact with a quantity of this fuel which may, due to leakage from the fuel containers, be blown out into the atmosphere. The author states that the cloud must always be dense before the mass of dust could transmit an explosion, and Fig. 1 indicates that with about $7\frac{1}{2}$ amperes at 250 volts a dense cloud would be ignited. How dense the cloud must be before there is a risk of explosion is very difficult to define, but if the author can give some information on this point it would be of great interest to those who are considering the use of pulverized fuel for power station work.

Mr. W. W. Wood: From an examination of Fig. 9 it would appear that for each voltage and frequency there is a certain safe current limit, and below this limit the interruption of the circuit by even a slow-break open switch will not fire an explosive mixture of methane. I am not clear, however, as to how far the method of supplying the current affects the result, and I wish to raise the following points: (1) Assuming that a safe current (say, for example, 130 amperes at 20 volts and 160 periods) is being supplied from a step-down transformer and that the current is interrupted by a slow-break switch in an explosive mixture of methane, can we be certain that this will not cause an explosion? (2) Assuming that a similar safe current is being supplied from a transformer and that there is such resistance or reactance in circuit that the current cannot exceed the safe limit determined from Fig. 9, even on a short-circuit of the supply, can we take it that an open short-circuit will not fire the gas? If such safety can be assured then there are many cases where small transformers could be installed in safe places underground and used to supply lights in places where electricity could not be used under ordinary conditions. Although the safe current is equivalent to only a small amount of power, and the available amount of power for the lights would be further reduced by the resistance or reactance necessary to limit the short-circuit current to the safe figure, nevertheless there are cases where the possibility of giving light in this way would be of considerable advantage.

Mr. R. Orsettich: The investigations described in the paper are exceedingly interesting to manufacturers of electrical apparatus, in so far as they give a clear insight into the conditions which bring about the explosion of gases when such apparatus is installed in coal mines. The position with regard to manufacturing such apparatus is as follows: On one hand the mining industry requires the supply of electrical machines which must, therefore, be produced by whatever knowledge of the conditions is available; while on the other hand the Mining Regulations issued by the Home Office, as embodied in the Coal Mines Act of 1911, put very severe restrictions on the use of apparatus in coal mines, and particularly in such workings where Regulation 132 applies. This Regulation states that apparatus must be such that no open sparking is possible. The Act, however, does not define clearly what open sparking means, does not fix a limit to the application of the Regulation to any output given by the apparatus, and at the same time requires a guarantee to be given by the makers that the apparatus is suitable for working under the above conditions. A restriction of this kind would be almost equivalent to the abolition of electric applications in workings where gas may be present, and the only Regulation which helps matters at all is that which states that as soon as gas is present to an extent of 1½ per cent the electrical supply must be cut off. Manufacturers have been busy for a considerable time with the framing of some additional rules to define the above points, which at the same time would be acceptable to the Home Office authorities. Although the framing of these rules is not complete, machines have to be supplied as required by the mining industry, and it is left, therefore, to independent manufacturers to satisfy themselves that the machines are suitable to the best of their knowledge. The first step was totally to enclose the machines, both d.c. and a.c., in order to endeavour to exclude gas. It was soon found, however, that this was an impossible task because, no matter how tightly the enclosures are made, gas will enter the machine through "breathing," caused by the expansion and contraction of the air contained in the machine. It was, therefore, necessary not only to make the machine totally enclosed, but also to make the enclosures sufficiently strong to withstand a pressure of about 130 lb./sq. in. which would be produced by an explosion, and also the shock due to this pressure being suddenly applied. The use of cast iron for the enclosure of such machines, especially for larger sizes, was soon found to be impracticable, and resort had to be made to cast steel in order to obtain the necessary strength without excessive weight. The use of cast steel for all parts of the enclosure, such as bearing brackets, covers, inspection doors, etc., would not only increase the cost of the machines but would also make their delivery impossible in most cases, seeing that such parts are not stocked and that the quantities required are subject to a varying demand. In getting out such designs some additional points must be taken into account, such as the possibility of an explosion blowing out the oil from the bearings, and thereby causing firing of bearings through want of lubrication, also the possibility of dust being ignited where small gaps would allow the gas to escape. About the year 1907 investigations with various types of relief openings were made in Germany, and as a result the German system of enclosure was developed. This consisted in providing a number of circular or square openings in the casing; the periphery of each opening was fitted with a number of multiple gaps, consisting of thin brass plates placed a small distance from one another, the cover of the opening being solid. Such enclosures work quite satisfactorily, and the gas ignited by an explosion can escape through the gaps and is cooled sufficiently in passing along the plates to become harmless to any gas surrounding the apparatus. The main defect of this system, apart from the fact that the plates can be easily damaged, is that coal dust settles between the plates and closes the gaps and that such coal dust can be ignited by an explosion. The policy adopted by my company in producing enclosures for motors for mining work has been, first, to make them in such a way that the pressure inside should not exceed 30 or 35 lb./sq. in.; and secondly, that the relief valves used should be made in such a way that whilst cooling the gas they should always be kept free from dust, thereby avoiding danger of outside ignition. The relief valves consist of thick steel plates through which a number of very small holes are drilled, the number of holes and the area of the plates being proportionate to the volume of gas contained in the machine. A spring lid is fixed on top of the relief valve and is made to open under the pressure of the gas from the inside. The apparatus made in this way is tested by exploding a mixture of methane or pentane inside the machine by means of a sparking plug, and a test is made by endeavouring either to ignite some guncotton or petrol

fumes outside the apparatus, or else to enclose the apparatus in a second chamber which is itself filled with an explosive mixture. Already a large number of machines have been tested in this way, and a certificate is issued with the machine stating that it has passed the explosion test satisfactorily.

Mr. G. M. Harvey (*communicated*): In considering the influence of frequency, the author says nothing as to the material of the electrodes, except that they are of metal, and gives no explanation of the use of iron and nickel in Fig. 8. A curve for zinc would have been of greater interest, since the armouring of a cable is invariably of galvanized-iron wires. It would be of interest to learn whether the author has found the so-called "non-arcing" properties of zinc to affect the production of ignition. The author states that he has succeeded in firing gas by the sparks from a grindstone. This is specially important, since I understand that other investigators have completely failed to obtain ignition by this means. With regard to the devices described on page 484 for absorbing the discharge of energy from the windings of a bell, most of these possess the disadvantage that they may accidentally become inoperative, leaving the circuit in a dangerous state. In a system which I have recently patented, self-induction is entirely eliminated from the signalling circuit by introducing a thermionic valve as a relay. The circuit that is closed to give the signal is the filament circuit of the valve, while the anode current operates a sensitive, flame-proof relay and rings the bell. The note on page 485 as to the difficulty of procuring ignition by hot tungsten filaments is most comforting, but I would ask whether the author has investigated the possibility of ignition by the breakage of gas-filled lamps—a somewhat different case. The explanation on page 488 of the droop in the curve shown in Fig. 7 is somewhat difficult to grasp, and, although the author states that the circuit broken was non-inductive, I would ask whether this was actually and literally the case, since the effect would appear to be rather one of resonance, the natural frequency of the circuit being in the neighbourhood of 360 periods. This would be possible for very small values of L, although a somewhat large capacity would be required in the circuit. The voltage-rise might then be sufficient to ensure that the energy discharged at break would correspond to the dotted portion of the curve. However satisfied one might feel as to the safety of lighting the coal face with high-frequency current, it is to be feared that the practical difficulties of the scheme would be insuperable. A trailing cable supplying a coal-cutter, and lying in coils about the face, is bad enough, but if each man is to have a trailing cable attached to his lamp great confusion would result. The question of increased illumination at the face is one of extreme difficulty, owing to the total lack of reflecting surfaces. The present electric safety lamps of 1 c.p. are often trying to the eyes, and if an 8-c.p. lamp is to be placed in the lantern the concentrated light would certainly cause a glare which would be injurious to sight. To diffuse such a light at all adequately in such a small space as the lantern of a safety lamp would be almost impossible. Illumination by means of ordinary mining-type well-glass fittings, wired with armoured cable, and provided with frosted well-glasses, the whole arranged so that it can readily be advanced with the face, would be a much more satisfactory method but is at present prohibited by the Mining Regulations. With regard to electrical oscillations in cable sheaths, experiments which I have recently made show the impedance of the armouring of a cable to be lower than that of a plain tube, instead of higher as stated by the author. That the danger is a real one is shown by a case which has come to my notice, in which sparks are alleged to have been seen running along the armouring of single-core cables on a d.c. supply controlled by oil-break switches, when heavy currents were broken. The greater part of the paper appears to be a distinct challenge to the supporters of the thermal theory of ignition, and their reply will be of great interest.

[The author's reply to this discussion will be found on page 509.]

North Midland Centre, at Leeds, 18 March, 1924.

Mr. M. Wadeson: There is no doubt that the use of electricity in mines is steadily increasing, and it is to researches such as those described in the paper that one must look for information as regards the prevention of the occurrence of dangerous circumstances. It is generally on such work that regulations are framed —not always wisely—and one of the striking points which the author brings out is that direct current is much more dangerous to use than alternating current. Unfortunately, in most of the installations in which direct current has been used, the equipment has been installed in the most dangerous way, because this was generally done before the Regulations which are now in force for such installations had been drafted. I have seen a number of d.c. installations, and in many instances they were equipped with an ordinary open-type switchboard below ground, with the ordinary pattern of open-type circuit breaker mounted on the board. After what the author has said, it can easily be realized that if gas had been present there would have speedily been an explosion. I have found that on a.c. installations it is generally best to rely upon a high-pressure supply with some form of leakage trips to give the greatest freedom from breakdown. When a fault does occur the whole supply is cut off before any open sparking occurs. I think it can be said that the loss of life in coal mines from accidents of every kind which can be attributed to faulty appliances—or rather, I should say, defective appliances or faulty practice—has been steadily decreasing, but accidents due more particularly to the human element have not shown any such decrease. Very often where suitable precautions are taken to safeguard the use of electricity, the human element speedily puts those precautions out of operation. Electricity underground is generally handled by men who are unskilled in its use, and one of the first essentials

is the training of such men to understand what to do and what not to do with the apparatus. The apparatus must, of course, be made as safe to work and as fool-proof as possible. Under the head of accidents largely due to the human element come those which are concerned with haulage, and the author points out that the more efficient lighting of the main roads at those points where men are employed is undoubtedly a great factor in reducing such accidents. In addition, it is more efficient in saving time and congestion. As to the suggestions that the author makes with regard to the lighting of the coal face, of course the present Regulations would need to be amended before that would be allowed. But if his researches were to bring about such a state of affairs, I think that the coal-mining industry would owe the author a very heavy debt. One of the great economic burdens which the industry now has to bear is that due to the disease of the eyes known as miner's nystagmus, and it has been almost unanimously agreed that the primary cause of that disease is inefficient illumination, more particularly at the coal face where the illumination is low and the absorptive power of the coal is high. In an abstract of a report on signalling with bare wires, it was stated that transformers should not be used for bare-wire signalling. In the technical Press there was a letter written by the Chief Engineer of the Powell Duffryn Steam Coal Co., in which he took exception to that statement and said that he had found that transformers were not only more reliable but were safer to use than batteries. Does the author think there is any other objection to the use of transformers than the fact that the low-pressure winding may be charged to high pressure? This can, of course, be avoided by the introduction of an earth shield between the windings.

Mr. R. Holiday: I feel that the apparatus mentioned in the paper may work perfectly well in the laboratory or in the hands of a skilled workman. In practice, however, a couple of thousand of the lamp gas-indicators, say, would have to be brought out between 2 o'clock and 2.30 and placed in the lamp room where half a dozen boys would dismantle them for cleaning. What would be the condition of the little batteries and bulbs in the course of a week or so? One must look at these things from the practical everyday point of view. The collier does not, as a rule, like a new thing. I was a pioneer in introducing a number of things for electrical work at collieries, and I found that if one has sufficient enthusiasm and also sympathy with the conditions under which the man works, and lets him find out (though it takes time) that one is really wishful to make things better for him, he will finally agree to use what he calls the "new-fangled" thing. It is possible that if the indicating device of the lamp were made of a stronger pattern, the men might be led to realize that it was to their benefit. I think that the tendency nowadays is to adopt the electric type of miner's lamp and gradually to displace the oil lamp, which possesses all sorts of disadvantages. My own opinion is that the alkaline cell will be used in the future for mine lighting. Before the war we decided, because our oil lamps did not comply with the new Regulations, to install an entirely new set of lamps, and I came to the opinion that the alkaline type of cell was the best. A short time ago one of these cells which was delivered 10 years ago was unpacked and found to be in perfect condition. I do not think that any acid cell would have retained the charge for such a period. With regard to the arrangement given in the paper for connecting on to a cable at the coal face, it has to be remembered that in this district, with the thick seams, there are not likely to be so many coal-cutters. The coal-cutter is peculiarly of advantage in the thin seam where the coal is cut small by the men in order to undercut it: 25 per cent of the seam may be broken into small coal in under-cutting where the floor or top is too hard to be cut by the pick. In districts where there are thin seams the coal-cutter is of great advantage, but there does not seem to be any call for it in the thick seams. I hope that research work such as that described in the paper will induce colliery proprietors to give new methods a trial to enable those who have done the foundation work to suggest improvements to make apparatus of real safety. I feel that there is at present too great a tendency to impose new rules on collieries. For example, at the collieries with which I am connected we recently converted the whole of the plant underground from direct current to three-phase alternating current at 3 000 volts. That is the third time that the installation at that colliery has been altered to comply with new regulations.

Mr. H. Moss: The author has raised a good many points of vital interest to the mining engineer and the mining electrical engineer, but there is one thing in particular that strikes me in connection with his remarks in regard to safety lamps. Is it suggested that the little signalling device with the red lamp inside should be used by all the miners, or only in isolated instances or in certain districts where the lamp is to be made permanent during the day's work? The author suggests in one case that a bell could be connected, and I hardly think he means that the miner should walk about all day with a lamp with a bell attached to it. I assume that that particular lamp would be hung up in what would be called a gaseous or semi-dangerous position where gas was likely to appear. I am particularly impressed by the fact that the higher the periodicity the safer it is from the point of view of ignition of inflammable gas that may be present in any particular district. I understand that a plug switch is used in connection with the lighting of the coal face, so that the lamp cannot be withdrawn until the switch inside is broken. If that method were adopted I take it that in each section of the coal face the suggestion is that one of these batteries should be installed in that position so that the miner could attach his lamp to it by a suitable length of flexible cable and get a much better illumination at the working face. That would add considerably to the expense of electrical equipment in the mine, and it would entail carrying batteries back to the surface each day to be charged, or, if the supply were alternating, special cables to charge the batteries at suitable depots in the mine. I should be glad if the author would say whether the apparatus which he describes is in use in any particular mine in this country, and whether he can give any

figures as regards increased production that has been obtained by increased illumination at the coal face. I gathered from his remarks that this country is very much behind Japan, for instance, and one wonders, if electricity has all these advantages in the mine, how it is that mine-owners in this country have not adopted it on a much larger scale than they have done. I agree with a previous speaker that it is important that at all junctions on the main haulage ways a very good light should be provided for the men and boys working there. This will minimize the risk of accidents caused by collisions with loaded trucks. In common with a previous speaker, I have had experience with open-type switches and starters, and every machine 25 years ago was of the old-fashioned type. It is evident that the apparatus would not have been safe if there had been any gas present in the mine. Coal-cutting in some mines was being done rather extensively 25 years ago by compressed-air machines, and in the case of a gaseous mine one wonders whether, instead of taking the mains right up to the coal face and running coal-cutters by electricity, it would not be safer to use air-compressors driven by three-phase motors in what would be a safe district, and then to use compressed air at the coal face itself.

Mr. J. D. Walford: Mr. Holiday, who is General Manager of the colliery company with which I am engaged, has covered many of the points to which I desired to refer. I should like to mention, however, that a great many collieries which have changed over to alternating current still use direct current for signalling on the main roadways. Is there any reason why we should not use alternating current for that purpose also?

Mr. G. W. Jenkins: I take it that the 150-period 25-volt lighting system would be applicable to the roadways and haulage ways, but to my mind there appears to be some difficulty about its use. Of course it would be a complicated system of wiring, and one could not possibly transmit power at 25 volts to lamps a good distance away. It would mean the adoption of a system of transformers, and in addition, I suppose, with existing plants at 50 periods, the installation of one or more frequency-changers. A transformer has, I think, been mentioned, and brought to notice by Dr. A. Russell, which is a sort of frequency transformer in which the triple harmonic is utilized, in which case one could obtain 150 periods on a 50-period system. I should like to know if the author is in possession of any information in regard to such a transformer. The statement is made in the paper that direct current generally is unsuited to mining work. Can the author say what dangers are likely to be experienced from sparking commutators, and whether there is great danger from explosions taking place at slip-rings, because sparking does frequently occur at slip-rings on starting up? On one particular motor which I recently saw driving a haulage there were four brushes per spindle, and four spindles. Actually there was, on two spindles at all events, only one brush and in the other box three neatly-cut pieces of coal to act as brushes. This struck me as being rather dangerous. I should be glad if the author would say whether in his opinion there is a real danger of explosion from sparking in that case, or whether an explosion could only possibly occur in the event of, say, a complete flash-over.

Mr. W. H. N. James: The author mentions that the circuits from which he obtained ignition were, in certain cases, non-inductive. The term "non-inductive" must be taken in a relative sense and I should like to know if any tests have been made using circuits having different degrees of inductance. Another point is the use of the term "transient arc." Can the author give some idea of the duration of the arc covered by this expression and also say what influence the duration of the arc has on the minimum ignition current for a certain mixture? The phenomenon of ionization from a hot electrode after the arc has gone out can be very well shown with an ordinary 10-ampere d.c. carbon arc. If such an arc is blown out and the air current maintained for, say, 1 second, it will be found that the arc restarts immediately on the cessation of the air current. In regard to electrical endosmose, I think that the explanation given would have been clearer had it been mentioned that the water which takes part in the action must be positively electrified, and in this connection it may be noted that Mr. Evershed, in his paper on "The Characteristics of Insulation Resistance," * stated that water was strongly electro-positive to practically all insulating materials.

[The author's reply to this discussion will be found on page 509.]

* *Journal I.E.E.*, 1914, vol. 52, p. 51.

Scottish Centre, at Glasgow, 9 April, 1924.

Mr. S. Mavor: The author has been a pioneer in research into the phenomena of electric ignition, and the work upon which he has been engaged has very great economic as well as scientific and humane importance. He has had opportunities of investigating these phenomena under below-ground conditions and of examining the conditions in the mine after most of the serious colliery disasters in this country during recent years. The paper has appealed to me particularly in connection with the safe use of high-frequency current for underground lighting. The miner's safety-flame hand-lamp is deplorably inadequate as a means of illumination, and the miner normally works in semi-darkness. The electric hand-lamp has to a considerable extent improved the conditions, and the result of its use is to increase the miner's output by something like 10 per cent. We must go further than that, and the extremely interesting suggestion to use high-frequency current in order to make sparking innocuous opens up a new vista. The author refers specially to the importance of better lighting in the roadways. That, I think, though important, is secondary. At present the nodal points of haulage, at least in the intake airways, are fairly well lighted, but to my mind it is much more

important to have improved lighting at the working face. In these days of intensive mining, men are grouped in considerable numbers at a comparatively short length of face. This is a complete departure from the conditions in which men work individually or in pairs at considerable distances apart, and in which the use of individual lamps is unavoidable. Nowadays large outputs are got from short faces, and the illumination of these faces ought to be equal to the illumination of workshops on the surface where corresponding numbers of men are employed. Not only is the work greatly facilitated by adequate lighting but the safety of the men is greatly increased. There are several places in Scotland where conveyer faces are illuminated by lamps of 25 candle-power each, at intervals of 10 to 12 ft. To be appreciated the effect must be seen and compared with the usual conditions. Anyone who has been near the return end of a conveyer face where a dozen or more men are working with open-flame lamps knows how suffocating is the atmosphere and how low the visibility due to foul smoke. It is manifest that in abundant light and cleaner air the efficiency of labour must be greatly enhanced. In open-lamp pits the flood-lighting of conveyer faces not only is technically and economically feasible, but is with great advantage already practised. The maturing of the author's proposal will make available in safety-lamp pits also the immense advantage of flood-lighting of conveyer faces. I should like to refer for a moment to the author's very ingenious combination of an accumulator and a transformer in a miner's electric lamp. One limitation of the use of this device is that when the electric coal-cutter is stopped for adjustment the switch at the gate-end must be opened, and in such a case the transformer would be out of action; although the light from the battery would be available the superior light from the power circuit would be unobtainable at the time when it was most required.

Professor F. G. Baily: I am very interested in the account of endosmose, which I should like to hear very much more fully explained by the author. It throws considerable light on many of the difficulties which cable manufacturers must have experienced, and why cables last much longer than would be expected from experience in other cases. Cables with oiled paper were invented some years ago. Such cables were used in house installations, and some had lasted for 25 years although badly installed. On page 488 the author points out the very great effect of oxide. It seems to me that possibly if the surface is oxidized, and the arc is broken between the oxidized surfaces, the oxide will become rather more heated than the pure metal would be, the arc would break through the oxide and heat it in passage, and that heated oxide would be more capable of igniting the gas than would the metal, and would of course retain its heat longer. It is rather a different suggestion from the author's and I should like to hear his opinion of it.

Dr. S. Parker Smith: What I feel with regard to much of the flame-proof apparatus now available is that it is not properly used and cared for when underground. This doubtless results in many accidents. In consequence of such misuse or carelessness, the maker's effort becomes valueless. In response to requests, Prof. Burns and I are arranging a laboratory at the Royal Technical College for the testing of flame-proof apparatus. With regard to the breaking of the current, can the author tell us if the arc could be made less dangerous by having two switches in series as is done in certain classes of apparatus? The ideal would of course be to avoid the need of flame-proof apparatus by arranging that under no conditions whatever could an explosion occur.

Professor G. W. O. Howe: In connection with endosmose, I believe I am right in saying that in the conduit tramway system in London, where there are both positive and negative conductor rails in the conduit, the polarity is systematically changed over at regular periods, because the negative conductor gradually gets damper, whilst the positive becomes drier. When the change-over is made, the one that was wet gradually dries and the other one gets wet. I can say nothing from experience about the practical application of the appliances mentioned by the author, but I am very much interested in the scientific aspect of many of the problems put before us. The whole subject of ignition and explosion seems a great mystery and opens up an important field calling for further investigation and research of a fundamental character. The curves shown in Figs. 7 and 8 are particularly interesting. One would expect that as the frequency is increased the chances of explosion would grow less and less. I did not follow the author's explanation of the depression in the curves, and I should be very pleased if he could make it clear.

Mr. F. Anslow: It would be interesting to know how the author gets 160 periods from the ordinary coal-cutter supply, which is usually at 25 or 50 periods. It is well known that, under present conditions, electricity cannot be taken to certain places in a mine, but if the author's apparatus can be made satisfactory this regulation might be altered. In this connection I have recently had occasion to watch with particular interest the development of a special type of lamp. This is designed as a self-contained unit, operated by an air turbine driving a small generator, which is connected directly to the lamp contained in the same fitting. The periodicity is, I believe, somewhere in the neighbourhood of 400, and is thus well above the figure referred to by the author. The lamp can be connected to any compressed-air system underground, and can be used with perfect safety in places where electricity is not permitted.

The Author's Reply to the Discussion.

Professor W. M. Thornton (*in reply*): I entirely agree with Mr. Sparks that it is one of the most striking features of coal mining that accidents from causes which on investigation are found to be always present occur so seldom. There is a natural high factor of safety in mining operations, and if we could overcome

the mechanical risks due to falls of roof and on haulages, coal-mining would be much safer. I am glad to hear that Mr. Sparks does not look unfavourably on the proposal for improved lighting by low-voltage high-frequency current. This might well be tried in a mine where there is no gas, and the experience gained could then be applied to the case of fiery mines. If we are to eliminate horse haulage there must be better lighting on roads, for a horse can be stopped quickly where there is a slight fall or risk of damage, whereas mechanically hauled tubs cannot.

In reply to Mr. Nelson, my view of face lighting is that it can be done in two ways, by a fitting on or small extension from a coal-cutter to which supply is already made, or by a system similar to that now used by Mr. Mavor in non-fiery mines, the lamps being strung along a cable supported at the roof. This is found practicable, and satisfactory in the cases tried, and I believe that there will be no insuperable difficulty in extending it.

Mr. Horsley has himself suggested the remedy for those long-continued arcs which burn through insulation and when they occur are the most dangerous forms of open sparking. Automatic trip-gear has of recent years reached a high state of perfection and there should be no case where such gear is not applicable.

Mr. Melsom is right in regarding dry earth as an insulator, and it is for this reason that continuity of armouring to bank is now essential, but as most earths are at the surface and as for several feet down the earth is usually moist it is customary to regard contact to earth as dangerous both for shock and fault leakage. The earth plate shown requires watering once in several months in summer; in winter not at all. The truth is that earth currents are confined to a relatively thin layer on the surface of the ground. The order of resistance obtained from the earth plate is a fraction of an ohm under the best conditions. Mr. Higgs suggests that coke would be better than gravel for the fillings. This is only suggested as a top layer and personally I regard coke breeze as a bad thing near earth plates if it can be avoided. In regard to the influence of capacity and inductance I would refer Mr. Higgs to the list of papers given below at the end of my reply to the discussion. Capacity and inductance are of the first importance in such transient phenomena as those discussed in the paper, and in these experiments every precaution was taken to keep both of them below values which begin to have a perceptible effect on ignition.

I agree with Mr. Selvey that there are no risks in the use of electricity underground that cannot be remedied as soon as they are known. It was the object of the work described in the paper to explore ground which had not hitherto been examined, to find risks before a great disaster called attention to them. The apparatus that I have in mind to obtain high-frequency current is a Dykes transformer described on page 553 of Dr. Russell's "Theory of Alternating Currents." This four-core transformer enables a supply at any frequency to be superposed on a three-phase system for use wherever it is tapped by a similar transformer.

Mr. Hunt indicates a very wide field of investigation. The thing greatly desired is to generate electricity straight from coal without the intervention of the secondary thermal processes which accompany combustion. It is agreed that the first act in combustion is "activation" or ionization of the combining elements. This is an electrical process, and some further knowledge of the electrical phenomena accompanying combustion is to be desired. The curves in the paper show that the effect, though not simple, is regular.

Mr. Morgan raises the important point of the high voltage obtained on magneto instruments. If open sparking can occur on these they undoubtedly require to be examined, and as the armatures of such machines have a high inductance their use might prove to be risky even though the currents are small. As to earthing, I see no objection to having earth connections underground wherever possible in addition to the regulation earth at bank to which all cable sheaths are bonded. If the machines are (as is usual) star-connected it makes no difference whether the neutral point is earthed or not so far as circulating currents are concerned, but faults are more easily detected when it is earthed. It is not "putting a premium on breakdowns" to earth the neutral, but providing a path for leakage currents to the trip gear.

The system suggested by Mr. Myer is practically that used so largely in California for dust deposition, but dust is stirred up so often in a mine that no device would be practicable, nor could its insulation be maintained.

Mr. Midgley raises the question of ignition of coal dust by sparks. I think that with pulverized coal, as distinct from coal dust, there might be occluded gas released and accompanying the dust which would make the dust more inflammable, as indicated in Table 1. There is no doubt that electrostatic sparks can be obtained from clouds of dust of this kind, but not enough to ignite dust free from gas.

Mr. Dance has pointed out one of the great risks of enclosed machinery with divisions giving two distinct volumes. An explosion in one may, and does, raise the pressure in the other before its explosion, so that the resultant pressure is raised above the 110 lb. usually taken as a maximum. The maximum pressure is not proportional to the initial pressure. The relation can be written as follows: The ratio of pressure-rise equals unity plus the ratio of the rise of temperature in explosion to the temperature before ignition. This added ratio diminishes as the compression increases. There is no doubt that the modern lamp with a high-temperature filament ignites gas more readily than one with lower temperature. This has been shown by researches by Clark and Ilsley at the Bureau of Mines, U.S.A. (Bulletin No. 131).

Mr. Morton is, I venture to think, making a not uncommon mistake when he suggests that a trip gear at a distance may operate less quickly than it would if near by. It is not easy to realize that electrical action due to a fault or break of cable is almost instantaneous—certainly within 1/200 000 sec.—over any mine system. I am not in favour of bitumen cable except for alternating current and under conditions where the rise of temperature is small.

I would refer Mr. Bolton Shaw to a paper on "The Ignition of Gases by Hot Wires" (see the end of my

reply) for an answer to his question as to the influence of diameter of filament on ignition. Metal-to-metal sparks are, I believe, less dangerous than those between metal and stone, but I have not made experiments on this myself. The first earth plate made on the lines of Fig. 10 was of galvanized cast iron. It was substantial but unduly heavy for the work, and later ones were of $\frac{1}{16}$ in. galvanized iron. How long they will last remains to be seen. They will carry very large currents.

Mr. Vernier has most convincingly stated the case of alternating versus direct current on cables, and since this is, after all, the part of the electric system in mines where risk is most likely to occur at the present time with flame-proof gear coming into general use, his opinion must carry great weight with mining engineers.

The curious case mentioned by Mr. Fisher of bells being burnt out is, I think, one of what was called in the war "earth induction." The stray currents between two earthed points carrying a heavy short-circuit on the surface might well spread, or even be led by shaft lining and rails, so as to give a destructive gradient even at 120 fathoms. Mr. Fisher's experiments are very interesting. I venture to think an arc of 50 amperes or so sustained for several seconds on a 3 000-volt line might have the nature of an explosion, but this rarely occurs in a confined space. The danger from sparking at haulage ropes, due to imperfect earthing, is at least as great as that from bells in the old days.

In reply to Mr. Schuil, the pressure is between 100 and 110 lb./sq. in. when the initial pressure is atmospheric. Dr. Wheeler's recent experiments on the cooling produced by flanges confirm in every way the development of flame-proof gear by simple machined flanges first developed by Mr. Schuil for Messrs. Reyrolle & Co.

The point raised by Mr. Grover is, I take it, this: The gas in such percentages is not inflammable and is therefore not the first source of the explosion. The dust is ignited as before by arcs though not by sparks, but, when it begins to burn, the air around each particle containing gas feeds the flame exactly as gas feeds the flame in a safety lamp.

I am glad to have Prof. Poole's approval of the lamps shown, and of the suggestion to obtain more light. No one knows better than he the conditions under which coal-mining operations are carried out, and the necessity for continued investigation. As requested, I have added, at the end of my reply, a list of the papers which more or less led up to this. An electric safety lamp has been devised which will indicate the presence of pit gas, but it is not at present sufficiently robust for use in a pit. It indicates about $2\frac{1}{2}$ per cent of gas in a few seconds.

In reply to Mr. Anderson, no one appreciates more than myself the value of the work done at Eskmeals by the Mines Department. My point is that, apart from the research work proper, there are from time to time large-scale demonstrations arranged which seem to me to be designed to bring home to mining men, who might not otherwise realize the magnitude of the points at issue, the great dangers which may arise from ignited coal dust. With regard to concentric mains, which should be prohibited, I fully agree that the best solution in dealing with such systems is to carry the connection to the motor from a gate-end switch by a three-core truly flexible cable—not a stiff and unwieldy semi-flexible concentric trailer. The best way to deal with hollow fittings which may "breathe" is, in my opinion, to make the safety outer covers fit as closely as possible to the protected part and so have a small volume of inflammable gas. With such small spaces a flange with $\frac{1}{2}$ in. to $\frac{3}{4}$ in. would be safe. The cases of sparking mentioned by Mr. Anderson show the necessity for a common-sense revision of some of our special rules.

In reply to Mr. Bolton Shaw, the curves of Fig. 9 will be understood if it is noticed that at voltages of 50 and less the lines go up very steeply; they become in effect straight. Fig. 9 is the result of separate and much more difficult experiments. It is not easy to control by flexible leads currents of hundreds of amperes attached to moving contacts, nor is it easy to repeat the work in the presence of coal dust, though it will have to be done before the suggested scheme of lighting is approved. I am glad to hear that the cost is not likely to prove prohibitive. The frequency-changer I have already dealt with in my reply. The system of wiring proposed at the face is by contact blocks with short leads to the plug, or switch contacts on coal-cutters. This will not interfere with movement behind the coal-cutters and, as Mr. Bolton Shaw remarks, the small added inconvenience of such leads would be more than balanced by the gain of safe illumination.

In reply to Mr. Lee, I think that another paper must be written dealing with the proposed means of face lighting. This is rather beyond the scope of the present paper. There is no objection to bare-wire signalling on battery-bell circuits if the bells are provided with shunts or sleeves or parallel windings to suppress inductance sparks. The earth plate is made $\frac{1}{16}$ in. thick because greater thicknesses are not necessary for the purpose of earthing.

The point raised by Mr. Buchanan is interesting. I have shown elsewhere that ignition is not proportional to the power of an arc. The fact that lower-voltage circuits have, as a rule, lower impedances is in their favour. Inductance always makes ignition easier.

I welcome Mr. Corlett's valuable criticism. He is right in assuming that the suggestion to use a higher frequency applies to lighting alone. I do not believe that there would be any marked gain in safety for machines. By mechanical accidents I mean those not directly electrical, such as by shock or explosion. I should be the last to derive a general conclusion from one experiment, and that on the breaking of a cable by a wedge is only given as a single instance of a test made for a purpose. Mr. Corlett says that gas frequently comes into a place without warning. There is then the greater reason for the use of warning lamps such as those shown. As to the flame from a heavy short-circuit inside a switchbox, I have known the cover of an enclosed switch of the old wall type in a mine to be blown from its bolts and shattered by a short-circuit in a haulage house a long way from bank. In such cases there is nearly always a prolonged arc and heating of the metal. The system of frequency transformation

advocated previously would do much to make the difficult case mentioned by Mr. Corlett a more economical proposition rather than the motor-generators, frequency-changers and the double system of wiring, which is not necessary on the Dykes scheme.

In reply to Dr. Garrard, my view of chemical action from the physical side is that, since all atoms are electrical, chemical combination must start by a change of electrical conditions—probably in the valency electrons at their surfaces. Catalytic action is, in my opinion, only another name for ionic effects, which do not themselves involve molecular change in the ionizer. The electrical methods which have been devised for the indication of gas in pits are unfortunately not in common use. They are capable of great sensitiveness, but are rather delicate and bulky as at present made. It is necessary to make use simultaneously of all methods for preventing open sparking or for lessening its danger. If this is done very complete protection is obtained.

Mr. Angold is right in assuming the speed of break to be that usually met in an accident—a fairly rapid separation of contact. What may be called "scraping contacts," i.e. slowly separated surfaces scraping at the points of separation, are the worst cases, but no two can be made alike. For the purpose of comparison of the influence of the various electrical factors which had not been previously known, a break was chosen which is a simple separation, without scraping, of current-carrying poles.

I do not think that Prof. Cramp is right in assuming that the discharges were oscillatory. There is no evidence of high-frequency oscillation in any of the many oscillograms taken of these sparks. In one case special search-coils were wound around a cable for the purpose of examining whether such oscillations were present. This is referred to in section (9) of the paper. Prof. Cramp will find at the end of my reply, papers, especially the earlier ones, in which the various points he raises were examined, e.g. size and material of poles. One point of interest is that the least smear of mercury on the surface of a contact greatly increases the risk of ignition. The thermal theory does not account for this.

Mr. Wilson is right in his view that the cable on a direct-current system which gives way from moisture is always the negative. I agree with him that the actual tests of flame-proof gear, though beyond the scope of this paper, should be made with plenty of power behind the electrical circuit. His observations of the relief methods in such gear are most interesting.

In reply to Mr. Forrest, several severe accidents have occurred due to flame and arc ignition of dust in coal bunkers or on screens at collieries, and the U.S.A. Bureau of Mines has recently issued a report on the ignition of pulverized coal by transient arcs in which the conclusions reached in the first of the list of papers at the end of my reply are substantiated. As a rule the dust cloud must be very dense at the point of ignition, more so than in an extended explosion.

Mr. Wood is correct in taking the limit to be that which when the current is alternating will not fire the mixture however slowly (within reason) the poles are separated. In answer to his first question I would say that, provided there is a time-constant of the order of 1/1 000 sec., the circuit is safe. The reactance of a circuit is not at all a good means of limiting the current in these timing cases; a buffer resistance is much better.

Mr. Orsettich is correct in contending that at present there is a margin of interpretation of the special rules for the use of electricity in mines. Gas cannot be excluded from machines, but the tendency at the present time is not to encourage the use of high-powered machines where there is possibility of gas occurring. Relief valves are a convenient means of dealing with an established ignition. The object of the paper was to find the limits of ignition.

In reply to Mr. Harvey, the materials of the poles have influence on break sparks but not on jump sparks. Bells with shunted windings have been running now for a good many years and on inspection show no signs of loose contacts. One might as well say that bells should not be used at all because their windings might break; one knows from experience that they do not. I doubt whether thermionic valve relays will come into common use below ground in mining, but the idea is most interesting. The drop in the curve of Fig. 7 is not due to electrical resonance; it was obtained from a number of different machines with presumably different electrostatic capacities, though these were not measured, but the conclusive argument that it is not electric resonance is that the curve reverts with remarkable suddenness to the original values continued. The practicability of face lighting is not a question of theory. It has been proved by Mr. Mavor, and instead of 8-c.p. lamps "certainly causing a glare injurious to sight" the reverse is found to be true.

Mr. Wadeson touches one of the most difficult points in the use of electricity in mines, viz. the gradual replacement of obsolete machinery on systems. The general consensus of opinion, apart from research, is that alternating current gives less trouble in mines and is altogether more convenient except where fine speed-control is necessary. A system of signalling transformers can be made safe by the use of non-inductive shunts of fairly high resistance at regularly spaced points along the line. To lessen the risk of faults between windings, an earth shield could be made to trip the primary circuit before the low-pressure side was affected.

Mr. Holiday does not like the electric warning lamp, and I agree that there would have to be a special lamp cabin and special treatment would have to be taught. But one of the other types shown would not meet with the objection of fragility. If these lamps come into use it will probably be found that the extinguisher type will be liked best and that the electric-warning type will be kept for use in places which require special watching when men are not present, as Mr. Moss asks. The bell for warning would of course be semi-permanent, at a gate-end for example. I am sorry that I am unable to quote a case of the installation of the high-frequency system or of the special lamp bases, but the Mavor and Coulson system has many features in common—flood lighting at the face, for example—and the higher frequency could well be tested under appropriate conditions in a naked-light mine to obtain figures as to reliability and convenience. The proposal is too recent for such

a scheme to have been carried into practice. Several inquiries have been made, but the mines all have gas and the Mines Department has not yet been approached in the matter.

In reply to Mr. Walford, alternating-current signalling is in use but requires safeguards due to the inductance of the circuits. The present position is that bare-wire a.c. signalling is not regarded as satisfactory.

The transformer referred to by Mr. Jenkins is that mentioned in my reply to Mr. Selvey. Both commutator sparking and slip-ring sparking come within the danger limit of the currents examined; the only thing to do with such apparatus is to enclose it.

The transient arcs mentioned by Mr. James have a duration of from 0·002 to 0·02 sec., depending on the voltage. The case he mentions of low-voltage arcs striking across a gap between hot carbons which would require when cold several thousand volts, is a decisive indication of the intense ionic activity in gases near red-hot poles. Water in endosmose behaves as if positively electrified, that is, the whole stream begins to move as soon as the field is applied.

I am very glad to have Mr. Mavor's approval of the low-voltage high-frequency scheme of underground lighting. No one has done more than he for the improvement of colliery lighting, especially at the face, and all the advantages he claimed in cleanliness of air and efficiency of labour are undoubted. My suggestion to use the coal-cutter as the point of attachment was to save running lighting cables from the gate end, but if a marked advantage were obtained from the use of separate cables I have no doubt they would soon be adopted.

Prof. Baily's suggestion that the oxide might act as an accelerator, by reason of its higher resistance or temperature, must be considered. A thick film would undoubtedly have the effect which he indicates, but adsorbed oxygen would not, I think, lead to a measurably higher temperature at the point of break of circuit.

In reply to Dr. Smith, I am strongly of opinion that electrical machinery underground requires more inspection and general supervision than is commonly given to it. There is almost more in maintenance than in design. Two switches in series should be equivalent to halving the voltage-rise at the end, and this would help, though all power circuit-breakers are best kept within flame-proof covers.

Prof. Howe calls attention to Fig. 7 and asks for a further explanation. I regard the drop in the curve as due to ignition of the gas by the hot metal exposed after the arc has been cut off and before the hot spot where the arc has been has cooled down, as it does very rapidly. Ignition by white-hot metal, is, I believe, easier than by the surface of a flame of the same temperature and area. As the frequency is raised, the current first has to be increased to reach the critical temperature of thermionic discharge activation and ignition while the arc lasts. The time of duration of each arc is inversely proportional to the frequency; and at the higher frequencies the faster the arc is shut off the quicker is the access of the gas to the white-hot metal, and the more easily ignition occurs. Here are clearly the conditions for a maximum. The argument that it is ignition from the hot metal that causes the dip is that as the frequency is raised, the igniting current falling in value should begin to fail to heat the metal to the limit of thermionic discharge to cause ignition in the time of one quarter-period (the greatest duration of an arc), as in fact it does. It is well known that thermionic discharge fails with startling suddenness as the temperature is lowered, and I regard the necessity to increase suddenly to high values at a frequency of 380 the current required for ignition as due to this failure of the thermionic discharge.

Mr. Anslow's query as to frequency I have answered earlier. The compressed-air electric lamp is a most interesting development, and I should much like to see one. If the voltage at break of the inductive generator circuit exceeds 25, i.e. the arcing voltage, there may be risk of ignition. It would be interesting to examine such a lamp as a source of ignition.

PROCEEDINGS OF THE INSTITUTION.

SPECIAL GENERAL MEETING OF CORPORATE MEMBERS, 28 FEBRUARY, 1924.

(Held in the Institution Lecture Theatre.)

Dr. A. Russell, President, took the chair at 5.30 p.m.

The notice convening the meeting was taken as read.

The following Resolution was proposed by the President :—

"That the following be substituted for Bye-law 9 of the Bye-laws of the Institution :—

"9. (*a*) An Honorary Member shall be entitled to the exclusive use after his name of the initials 'Hon. M.I.E.E.'; a Member of the initials 'M.I.E.E.'; an Associate Member of the initials 'A.M.I.E.E.'; an Associate of the initials 'Associate I.E.E.'; a Graduate of the initials 'Graduate I.E.E.'; and a Student of the initials 'Student I.E.E.'

"(*b*) Every Member and Associate Member is, and is entitled to describe himself as, a Chartered Electrical Engineer, and in using that description after his name shall place it after the designation of the class in the Institution to which he belongs, stated in accordance with the following abbreviated forms, namely, M.I.E.E. or A.M.I.E.E., as the case may be.

"(*c*) A Member or Associate Member practising

(i) under the title of, or as an officer or employee of, a Limited Company authorized to carry on the business of an electrical engineer in all or any of its branches, or

(ii) in partnership with any person who is not a Member or Associate Member of the Institution under the title of a Firm

shall not use or permit to be used after the title of any such Company or Firm the designation 'Chartered Electrical Engineer' or 'Chartered Electrical Engineers' or describe or permit the description of such Company or Firm in any way as 'Chartered Electrical Engineer' or 'Chartered Electrical Engineers.'

"(*d*) No person shall adopt or describe himself by any other description or abbreviation to indicate the class to which he belongs than is provided in this Bye-law for such class."

The Resolution, after being seconded by Sir James Devonshire, K.B.E., was carried unanimously, and the meeting terminated at 5.50 p.m.

712TH ORDINARY MEETING, 28 FEBRUARY, 1924.

(Held in the Institution Lecture Theatre.)

Dr. A. Russell, President, took the chair at 6 p.m.

On the motion of Sir James Devonshire, K.B.E., seconded by Mr. R. T. Smith, a hearty vote of congratulation was accorded the President on his nomination for a Fellowship of the Royal Society of London.

The minutes of the Ordinary Meeting of the 14th February, 1924, were taken as read and were confirmed and signed. A list of candidates for election and transfer approved by the Council for ballot was taken as read and was ordered to be suspended in the Hall.

A list of donations to the Benevolent Fund (see pages 299–300) was taken as read and the thanks of the meeting were accorded to the donors.

A paper by Mr. A. S. FitzGerald, Associate Member, entitled "The Design of Apparatus for the Protection of Alternating-Current Circuits" (see page 561), was read and discussed.

On the motion of the President a vote of thanks to the author was carried with acclamation, and the meeting terminated at 7.50 p.m.

37TH MEETING OF THE WIRELESS SECTION, 5 MARCH, 1924.

(Held in the Institution Lecture Theatre.)

Mr. E. H. Shaughnessy, O.B.E., took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section held on the 6th February, 1924, were taken as read and were confirmed and signed.

A paper by Commander J. A. Slee, C.B.E., R.N. (Ret.), Member, entitled "Development of the Bellini-Tosi System of Direction-Finding in the British Mercantile Marine" (see page 543), was read and discussed.

On the motion of the Chairman a vote of thanks to the author was carried with acclamation, and the meeting terminated at 8 p.m.

713TH ORDINARY MEETING, 6 MARCH, 1924.

(Held in the Institution Lecture Theatre.)

Dr. A. Russell, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting of the 28th February, 1924, were taken as read and were confirmed and signed.

Messrs. H. Jenkins and S. F. Hill were appointed scrutineers of the ballot for the election and transfer of members and, at the end of the meeting, the result of the ballot was declared as follows:—

ELECTIONS.

Associate Members.

Barnett, Cecil John.
Edes, Noel Hamilton, Lieut., R.C.S.
Finnis, Arthur Hornsby.
Richardson, Samuel Sumner, D.Sc.
Smith, Sydney Luke.

Graduates.

Akehurst, Arthur Gerald.
Cadman, Norman.
Clark, Ernest Cameron.
Devine, James Joseph.
Graham, Eric Edward.
Guilford, Alfred Leslie, B.Sc.Tech.
Holdsworth, John Evelyn.
Nunn, Charles.

Students.

Addison, James Donald.
Alford, Frederick Albert H.
Allan, Robert Hector.
Angus, James Houston.
Ashworth, Graham.
Barnes, Richard Wynne.
Bates, Albert Edward.
Beck, Arthur Cecil.
Bedingfield, William King.
Benham, Cedric Minett.
Bentley, John.
Berindei, Matei.
Bhavnani, Hashmatrai Khubchand, B.Sc.
Bishop, Geoffrey.
Botcharsky, Constantin.
Bramley, John Henry.
Brownlie, James Millar.
Bryan, Leslie William.
Caley, Leonard Percy.
Chase, John Joseph.
Clifford, Albert Edward.
Connelly, Thomas Maurice.
Cornish, Henry Edmund.
Cox, Arthur Gerald.
Crake, Wilfred St. Maur E.
Crisp, John William.
Darby, William Joseph J.
D'Cruz, Cyril.
Douglas, Thomas Kenneth A.
Ferlie, George Balfour.
Firth, Allan Mitchell.
Fischer-Webb, Denis.
Flett, Robert Garrioch.
Foster, Horace George.
Froggatt, Arthur.
Fryer, Ronald Waring.
Gardiner, Herbert William B., B.Sc.(Eng.).
Gray, Albert Hilliard, M.Sc.
Gurney, William Albert J.
Hawkins, John Mortimer.
Heron, Thomas.
Hughes, Leslie Ernest C.

Students—continued.

Humphriss, Eric Allan.
Jelly, William Edwin.
Jervis, Walter, Junr.
Jones, Reginald Ernest.
Kay, Dudley.
Kelly, William.
Krestovnikoff, Igor.
Lappin, Henry.
Leman, Hugh Spence.
Mackenzie, Ian.
Mahajan, Lochan Singh.
Meers, Richard Adney.
Middleton, Alex.
Milner, Ewart Guy.
Minchin, Cecil William H.
Moes, Gerlacus.
Mudford, Francis Edwin.
Murray, George Andrew.
Northcote, John Wilfrid S.
Pearce, Fred Esmond.
Penny, John Carlton.
Phelps, John Lecky.
Plumbly, Richard William.
Rendle, Patrick Russel.
Sabikhi, Nihal Chand.
Short, Harry Redfern.
Sinclair, Ernest Morgan.
Spurr, Samuel Didsbury W.
Sykes, Herbert Archibald.
Taggart, John Douglas.
Takla, Fawzy.
Thomas, Ernest.
Weston, Harold Norman.
Wilkinson, Frank.
Wilson, William Frederick.
Woolgar, Leslie Vincent.
Young, Frank.

Associate.

Nash, Sir Philip A. M., K.C.M.G., C.B.

TRANSFERS.

Associate Member to Member.

Davey, Frank William.
Pearce, James George, B.Sc.
Skeates, Conrad Clemmans.
Stewart, Charles Lionel E.

Graduate to Associate Member.

Cairns, Archibald McFarlane, Capt. R. E., B.Sc.(Eng.).
Noor-el-Deen, Youssef.

Student to Associate Member.

Devonald, Norman.
Rose, Victor.
Spilsbury, Robert Samuel J.
Underwood, Cyril Lancelot.

Associate to Associate Member.

Nicol, Edward Watson L.

Student to Graduate.

Bellamy-Law, John William.
Bonny, Arthur George A.
Calder, John Maxwell.
Colquhoun, James Browne.
Conly, William Peter, B.Sc.(Eng.).
Datta, Narendra.
de Steiger, Frederick Bernard.

Student to Graduate—continued.

Dunlop, Robert Paterson.
Jackson, Horace.
Jones, Arthur Thomas.
Maguire, Austin Joseph (B.Eng.).
Morgan, Ivor.
Pound, Edwin Thomas.
Sheppard, Maurice William.
Smart, Henry Prescott.
Thompson, George.
Williams, Charles Branton.

A paper by Messrs. P. E. Erikson, Member, and R. A. Mack, Associate Member, entitled "Transmission Maintenance of Telephone Systems," was read and discussed.

On the motion of the President a vote of thanks to the authors was carried with acclamation, and the meeting terminated at 7.45 p.m.

714TH ORDINARY MEETING, 20 MARCH, 1924.

(Held in the Institution Lecture Theatre.)

Dr. A. Russell, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting of the 6th March, 1924, were taken as read and were confirmed and signed.

A lecture (with demonstrations) entitled "The Nature and Reproduction of Speech Sounds (Vowels)" was delivered by Sir Richard Paget, Bart.

On the motion of the President a vote of thanks to the lecturer was carried with acclamation, and the meeting terminated at 7 p.m.

715TH ORDINARY MEETING, 27 MARCH, 1924.

(Held in the Institution Lecture Theatre.)

Dr. A. Russell, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting of the 20th March, 1924, were taken as read and were confirmed and signed.

A list of candidates for election and transferred approved by the Council for ballot was taken as read and was ordered to be suspended in the Hall.

A list of donations to the Benevolent Fund (see page 381), was taken as read and the thanks of the meeting were accorded to the donors.

The President announced that a portrait in oils of the late Willoughby Smith (President 1883) had been presented to the Institution by his sons, Mr. W. O. Smith and Mr. W. S. Smith, and the thanks of the meeting were accorded to the donors.

The President read an Order received from the Lords of the Privy Council, allowing the new Bye-law No. 9 (see page 381).

A paper by Lieut.-Col. H. E. O'Brien, D.S.O., Member, entitled "The Future of Main-Line Electrification on British Railways," was read and discussed. On the motion of the President a vote of thanks to the author was carried with acclamation, and the meeting terminated at 7.45 p.m.

38TH MEETING OF THE WIRELESS SECTION, 2 APRIL, 1924.

(Held in the Institution Lecture Theatre.)

Mr. C. C. Paterson, O.B.E., took the chair at 6 p.m., in the unavoidable absence of Mr. E. H. Shaughnessy, O.B.E., Chairman of the Section.

The minutes of the meeting of the Wireless Section held on the 5th March, 1924, were taken as read and were confirmed and signed.

A paper by the Research Staff of The General Electric Co., Ltd., presented by Messrs. M. Thompson and A. C. Bartlett and entitled "Thermionic Valves with Dull-Emitting Filaments," was read and discussed.

On the motion of the Chairman a vote of thanks to the authors was carried with acclamation, and the meeting terminated at 7.20 p.m.

THE DETERMINATION OF RESONANT FREQUENCIES AND DECAY FACTORS.*

By Professor E. MALLETT, M.Sc., Member.

(*Paper first received 26th September, and in final form 31st December, 1923.*)

SUMMARY.

Simple resonance curves plotted vectorically are approximately circular in form. The paper shows how the circle can be derived from the ordinary resonance curve by a simple graphical construction, and how from the derived circle and the original resonance curve a straight line can be drawn from which the resonance frequency and the damping are at once determined.

The constructions developed are explained by their application to telephone-receiver impedances and to electrical circuits.

TABLE OF CONTENTS.

1. SYMBOLS USED IN THE PAPER.

Z = modulus or size of total impedance of telephone receiver.
ψ = angle of impedance of telephone receiver.

Z_d = size of receiver impedance with diaphragm damped.
θ = angle of receiver impedance with diaphragm damped.

Z_r = size of receiver impedance due to motion of diaphragm.
χ = angle of receiver impedance due to motion of diaphragm.

A = size of force factor.
β = angle of force factor. (Defined by expression: Pull on diaphragm = $A|\underline{\beta} i$.)

z = size of mechanical impedance of diaphragm.
α = angle of mechanical impedance of diaphragm.

r = mechanical resistance of diaphragm.
m = equivalent mass of diaphragm.
s = stiffness coefficient (restoring force per unit deflection).
$Z' = Z/Z_d$ = ratio of the sizes of the impedances with the diaphragm free and damped respectively.
Δ = decay factor = $r/(2m)$.
i = current into receiver with diaphragm free.
i_d = current into receiver with diaphragm damped.
e = voltage across receiver (kept constant).
f = frequency.
f_0 = resonant frequency.

2. INTRODUCTION.

In a paper* by Professor J. T. MacGregor-Morris and the present author in which the ratio of the frequencies of some of the higher modes of vibration to that of the fundamental mode was measured, a difficulty arose in determining the exact value of the latter in the absence of a sand picture and of a sharply defined maximum sound. A rough solution only was obtained by drawing the curve of Fig. 1, which shows the current, i, in the receiver plotted against the frequency, f, and taking as the resonant frequency the point where the curve AB crosses the dotted line (obtained with the diaphragm prevented from vibrating).

If apparatus for setting up an alternating-current bridge had been available, the method described † by A. E. Kennelly and G. W. Pierce could have been used.

In this method, impedance measurements (in the form $A + jB$) of the telephone receiver are made, first with the diaphragm free and then with the diaphragm damped, and it is found that the vector difference of the two plotted vectorially has a circular locus. Resonance occurs at the diameter of the circle through the origin, and the damping is determined from the frequencies at the ends of the diameter at right angles. The theory of the telephone receiver is developed in a

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

series of papers by Kennelly and his various co-workers,* and this is used in what follows.

The present paper arose out of the desire to avoid bridge methods, which demand expensive apparatus and somewhat laborious calculations, and if possible to use a curve similar to that of Fig. 1, that is, drawn from current measurements without any knowledge of phase angles, to obtain the information required as to the resonant frequency and the damping. It was thought

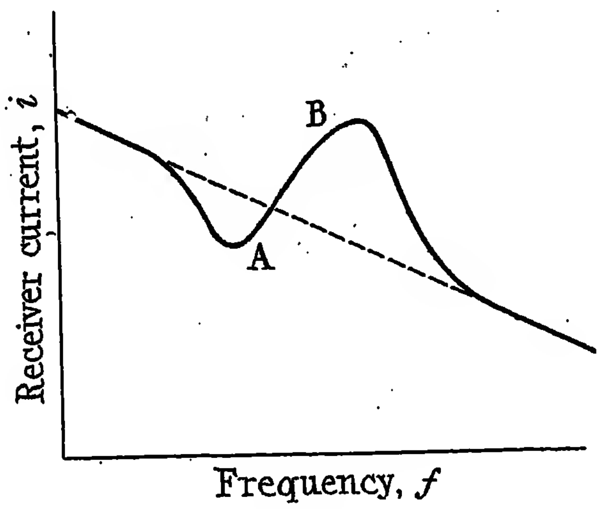

FIG. 1.

that if such a method could be established it would be especially useful at higher and perhaps quite high frequencies, where bridge methods are extremely difficult.

3. Outline of Theory.

By impressing a constant voltage v of known and variable frequency on the terminals of a receiver, and measuring the resulting current i, the size Z of the

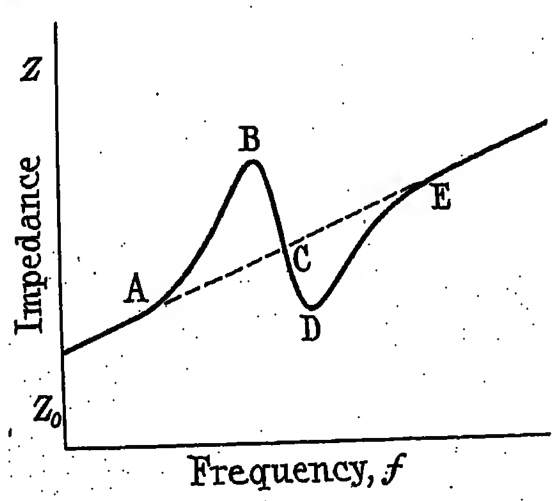

FIG. 2.

impedance of the receiver is determined as the ratio v/i, but not its phase angle. A curve similar to ABCDE of Fig. 2 is obtained on plotting Z against the frequency. If the diaphragm were prevented from vibrating the curve would be ACE, and from many experimental results it appears that over the range AE this curve is approximately a straight line.† Moreover, it is found that the angle of the impedance represented by ACE is approximately constant over this range, so that the impedance with the diaphragm damped (or in the absence of the resonance) may be written $Z_d|\underline{\theta} = (Z_0 + \omega Z_1)|\underline{\theta}$, where Z_0 is the intercept of the line ECA on the OZ axis, Z_1 is the slope of the line, and θ is the constant angle of the impedance. The total impedance of the receiver with the diaphragm

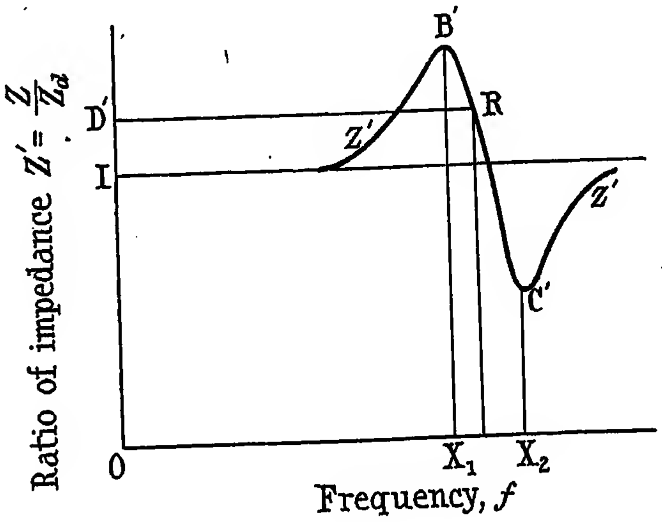

FIG. 3.

free to vibrate may be written $Z|\underline{\psi} = Z_d|\underline{\theta} + Z_r|\underline{\chi}$, where $Z_r|\underline{\chi}$ is that part of the impedance which is due to the motion of the diaphragm. This Kennelly has shown to be

$$Z_r|\underline{\chi} = \frac{A^2}{z}\,\overline{|2\beta + \alpha}$$

where A is the force factor and $|\underline{\beta}$ its angle, and $z|\underline{\alpha}$ is the mechanical impedance of the diaphragm, given by

$$z|\underline{\alpha} = r + j\left(m\omega - \frac{s}{\omega}\right) \quad . \quad . \quad . \quad . \quad (1)$$

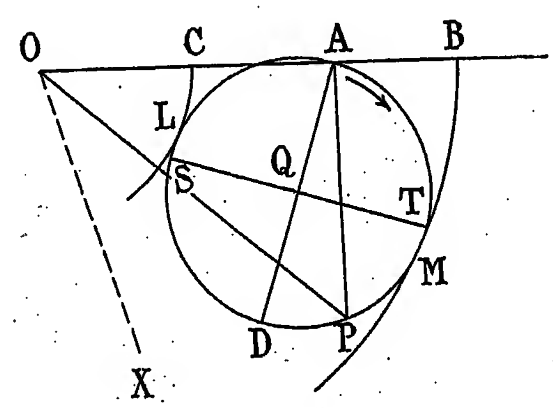

FIG. 4.

where r = total equivalent mechanical resistance of the diaphragm, and is of the form $r_1 + \omega r_2$; m is the equivalent mass and s the stiffness coefficient, both very nearly independent of the frequency.*

So we may write for the total impedance of the telephone receiver

$$Z|\underline{\psi} = Z_d|\underline{\theta} + \frac{A^2}{z}\,\overline{|2\beta + \alpha}$$

* A summary appears in the *Post Office Electrical Engineers' Journal*, 1923, vol. 16, pt. 2, p. 144. A complete account is given in a recently published book on "Electrical Vibration Instruments," by A. E. Kennelly.

† A. E. Kennelly and H. A. Affel: "The Mechanics of Telephone-Receiver Diaphragms, as derived from their Motional-Impedance Circles," *Proceedings of the American Academy of Arts and Sciences*, 1915, vol. 51, p. 419.

* See A. E. Kennelly and H. Nukiyama, *Transactions of the American Institute of Electrical Engineers*, 1919, vol. 38, pt. 1, p. 419.

of which we have measured Z, and can either infer Z_d by covering a sufficient frequency-range with the Z measurements, or measure it directly by damping the diaphragm. We have, however, no knowledge of the angles.

Dividing throughout by $Z_d\underline{|\theta}$ we obtain

$$\frac{Z}{Z_d}\underline{|\psi - \theta} = 1 + \frac{A^2}{Z_d{}^2}\overline{|2\beta + \alpha + \theta} \quad . \quad . \quad (2)$$

This expression gives the key to the method. Find the ratio $Z/Z_d = Z'$ for various frequencies, and draw in the direction AMDLA. Z' is, by construction, a maximum at OM and a minimum at OL, and resonance occurs approximately at the diameter AD. The frequency at which resonance occurs is ascertained by finding the corresponding point on Fig. 3. Set up OD′ in Fig. 3 equal to QD in Fig. 4, and draw a horizontal through D′ to meet the B′C′ curve in R. Then D′R is a measure of the resonant frequency.

It is clear also that the angle BAD is equal to $2\beta + \theta$, while the angle DAP is α and the angle AOP is $\psi - \theta$. To convert Fig. 4 to an actual impedance diagram of the receiver, it would be necessary to draw

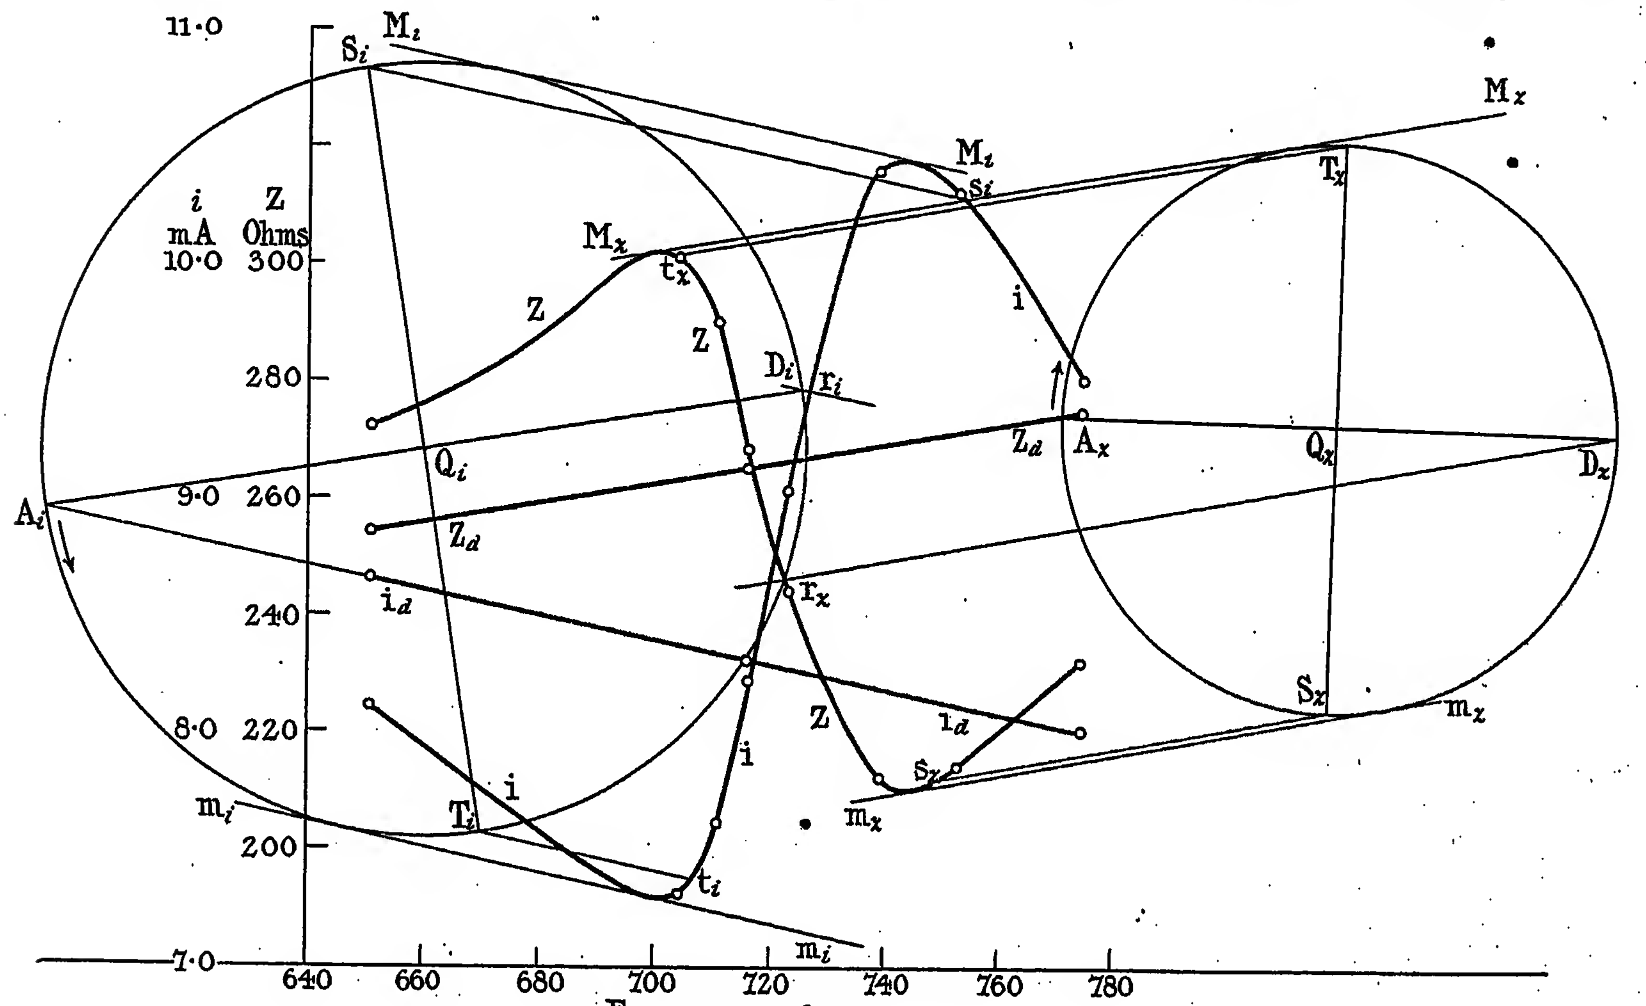

FIG. 5.

a new curve (Fig. 3) of Z' against f. The ordinates are seen from Equation 2 to be the size of the vector sum of unity and $\frac{A^2}{Z_d{}^2}\overline{|2\beta + \alpha + \theta}$. This last expression has, at any rate for frequencies not far removed from resonance, very nearly a circular locus, as the alterations of Z_d are small compared with those of z. So to construct the vector diagram from which Fig. 3 may be derived, we set off in Fig. 4 OA = unity (OI of Fig. 3), OB = the maximum ordinate X_1B' of Fig. 3, and OC = the minimum ordinate X_2C'. With O as centre and OC, OB as radii draw arcs CL and BM. Draw a circle to touch these arcs at L and M and to pass through the point A. Let the centre of this circle be Q and its diameter through A be AQD. Then the right-hand side of Equation (2) is given by OP, where OP is any vector drawn from O to meet the circle in P. As the frequency increases from a low value the point P starts from A and describes the circle a line OX so that the angle XOA $= \theta$, to give the new reference line, and to multiply each vector OP by the corresponding value of Z_d.

From the circle AMPLA the value of $\Delta = r/2m$, the decay factor, can be found. Draw a diameter at right angles to AD, cutting the circle in T and S. Find the corresponding points T′ and S′ in Fig. 3 and hence the frequencies f_t and f_s at which the values of α are $+ 45°$ and $- 45°$ respectively. Then $\Delta = \pi(f_s - f_t)$. A better method not depending on two points alone is developed later, however, in showing how far the assumptions made above are justified in an actual case.

4. Application of the Method to Some Actual Measurements.

The method thus arrived at will now be applied to some actual measurements. The current supply to the receiver was obtained from a low-frequency valve

oscillator, coupled to the receiver through a valve amplifier so that its frequency calibration should not be upset by a varying load. The voltage across the receiver was measured by means of a calibrated rectifying valve and kept constant by means of a rheostat in series with the receiver. The current through the receiver was measured by a hot-wire milliammeter (Duddell) and a few points were obtained with the receiver diaphragm damped with the finger. The readings are given in cols. 1, 2 and 3 of Table 1 and

TABLE 1.

are plotted as the i curve and the i_d curve in Fig. 5. The value of Z is entered in col. 4, and that of Z_d derived from the i_d curve in col. 5. In col. 6 is entered the value of the ratio $Z' = Z/Z_d$, and this is plotted against the frequency in Fig. 6. In this figure the construction described above is carried out to obtain the circle, and from this circle the resonant frequency and the decay factor can be obtained.

In order to see how far this circle does actually represent the conditions as the frequency changes, a connection must be found between the frequency and the position of the corresponding vector. It is known [see Equation (1)] that the angle of the mechanical impedance of the diaphragm α is given by

$$\tan\alpha = \frac{m\omega - (s/\omega)}{r}$$

whence $$\omega^2 - \frac{r}{m}\tan\alpha\omega - \frac{s}{m} = 0$$

and $$\omega = \frac{r}{2m}\tan\alpha \pm \sqrt{\left(\frac{r^2}{4m^2}\tan^2\alpha + \frac{s}{m}\right)}$$

For values of α up to, say, 75°, $r^2/(4m^2)\tan^2\alpha$ is much smaller than s/m in the telephone receiver case and may be neglected. Further, $\Delta = r/2m$ and we may write

$$\omega = \sqrt{\frac{s}{m}} + \Delta\tan\alpha$$

That is to say, the relation between ω and $\tan\alpha$ should be a straight line, the intercept of which on the ω axis ($\tan\alpha = 0$) gives the value ω_0 corresponding to the resonant frequency, and the slope of which is equal to Δ. If f is plotted instead of ω, the intercept is f_0 and the slope $\Delta/2\pi$.

Points on this line are found from Fig. 6 and from

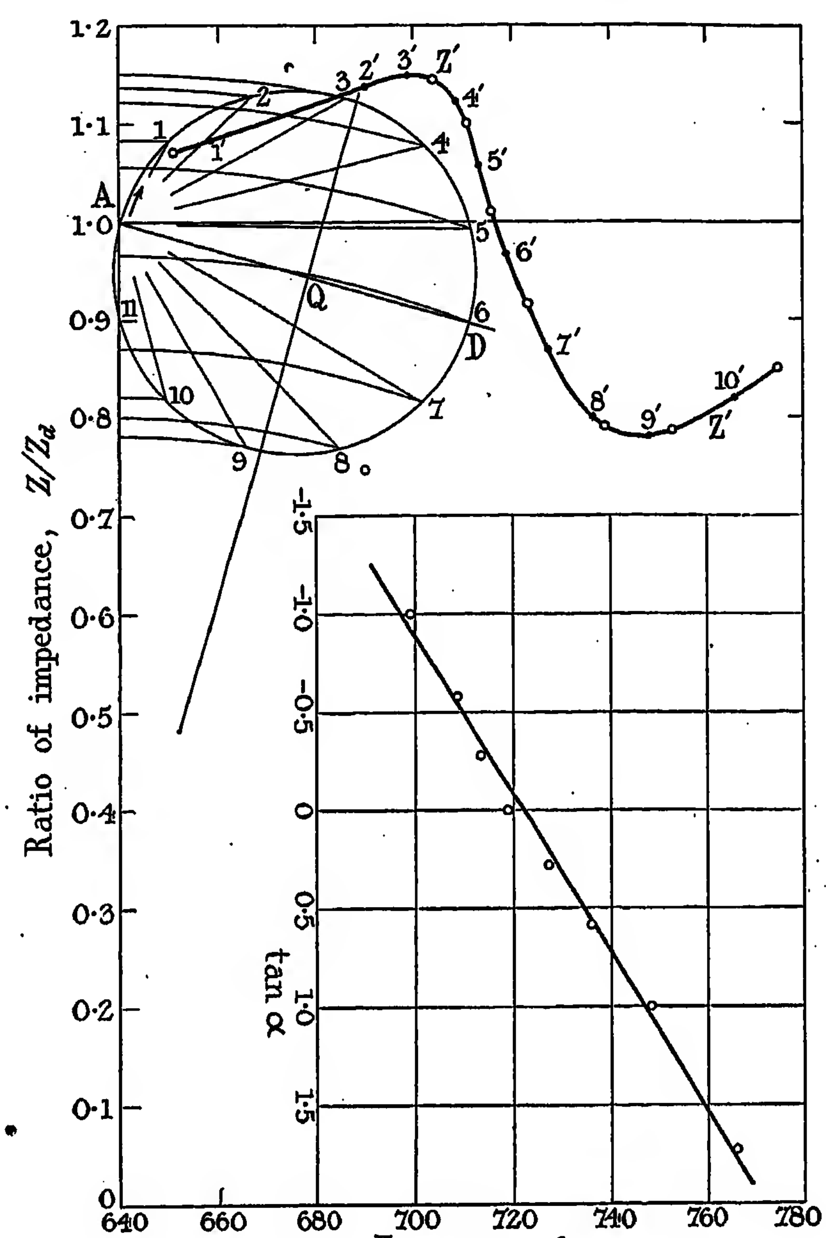

FIG. 6.

Table 2 as follows. Lines are drawn from A making angles with AD of 75°, 60°, 45°, 30° and 15° on each

TABLE 2.

side and cutting the circle in the points 1, 2, 3, . . . 10. These points are the reference numbers of col. 1 in Table 2, col. 2 gives the angle α, and col. 3 its tangent. The frequencies are ascertained by finding the corresponding points on the resonance curve, i.e. by drawing arcs with O1, O2, etc., as radii and O as centre to meet the axis OY in points through which horizontal lines are carried to meet the resonance curve in the points 1′, 2′, 3′, 4′ . . . 10′. The frequencies at these points are entered in col. 4. The curve between tan α and f is plotted in the lower part of Fig. 6, using a vertical scale for tan α and the original frequency scale. It is seen that the points closely approximate to a straight line from 3 to 10 inclusive, and from the line it appears that the resonant frequency is 722 and that

$$\Delta = 2\pi \times \text{slope} = 2\pi \times 25 = 157$$

5. Graphical Construction from Current Curve and Current Circle.

An examination of the results so far obtained suggests that the whole of the work may be done graphically from the current/frequency readings. For, since

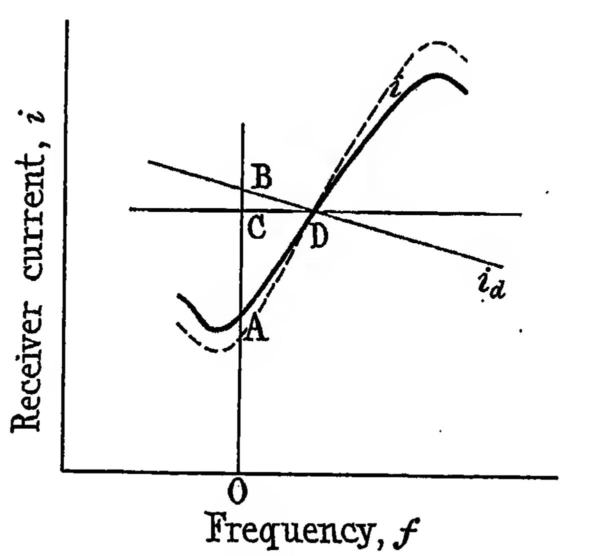

Fig. 7.

$i = e/Z = e/(Z_d\underline{|\theta} + Z_r\underline{|\chi})$ and, with diaphragm damped, $i_d = e/(Z_d\underline{|\theta})$

$$\frac{i}{i_d}\angle = \frac{Z_d\underline{|\theta}}{Z_d\underline{|\theta} + Z_r\underline{|\chi}} = \frac{1}{1 + \frac{Z_r}{Z_d}\underline{|\chi - \theta}} = i'\angle$$

Since $1 + \frac{Z_r}{Z_d}\underline{|\chi - \theta}$ has approximately a circular locus, so also has its reciprocal $1\Big/\left(1 + \frac{Z_r}{Z_d}\underline{|\chi - \theta}\right)$. The latter circle (which will be called the current circle) can be drawn from the $(i/i_d, f)$ curve in exactly the same way as the original circle (which will now be called the impedance circle) was drawn from the $(Z/Z_d, f)$ curve, and the impedance circle (its reciprocal) obtained by the method of inversion.*

Also, since the variations of i_d over the frequency-range required are small, and the change of i is only a fraction of the total i, the division i/i_d may be carried out by a simple subtraction. Through the point D (Fig. 7) where the i_d curve cuts the i curve draw a horizontal straight line. At any ordinate OACB, OA $= i$, and OB $= i_d$,

$$\therefore \frac{i}{i_d} = \frac{\text{OA}}{\text{OB}} = \frac{\text{OA}}{\text{OC} + \text{CB}}$$
$$\doteqdot \frac{\text{OA} - \text{CB}}{\text{OC}}$$

since CB is small compared with OA and OC, and OA does not differ greatly from OC. Hence, if the scale is so chosen that the length OC is unity, the ratio i/i_d is obtained simply by subtracting the intercept CB from OA on the left-hand side of the point where the i and i_d curves cross, and adding it on the right. (Or, in other words, taking the intercept between the i and i_d curves and subtracting it from or adding it to the height of the horizontal line, as the case may be.)

This is done in Fig. 8 to obtain the points 1, 2, 3, 4, 5, 6, 7 and 8 from the original i/f and i_d/f curves. The points 1, 2, 3, etc., are obtained from the actual observation points on the i/f curve. From this curve the circle A_i 1′, 2′, 3′, . . . 8′ is drawn as before. This is the "current" circle $1\Big/\left(1 + \frac{Z_r}{Z_d}\underline{|\chi - \theta}\right)$ with scale $OA_i = 1$.

To invert this through its centre Q_i draw a straight line OQ_i cutting the circle in a_i and b_i. Scale off the lengths $Oa_i = 7{\cdot}2/8{\cdot}3$ and $Ob_i = 10{\cdot}62/8{\cdot}3$. Then marking off $Oa_z = 8{\cdot}3/7{\cdot}2 = 1{\cdot}151$ and $Ob_z = 8{\cdot}3/10{\cdot}62 = 0{\cdot}78$ along the same line OQ_i gives two points, a_z and b_z, on the inverted circle. A further point A_z will be $1/OA_i$ on the OY axis, and this length, OA_z, is unity. So make OA_z unity on any suitable scale (of course marking off Oa_z and Ob_z to the same scale), and draw the circle $a_zb_zA_z$ with centre Q_z. Then this is the impedance circle obtained before, viz. $1 + \frac{Z_r}{Z_d}\underline{|\chi - \theta}$.

To obtain points on the curve between f and tan α it is necessary to proceed from the impedance circle via the current circle to the resonance curve, or vice versa. The points 1′, 2′, 3′, . . . 8′ on the current circle corresponding to the points 1, 2, 3, . . . 8 on the resonance curve are found by drawing horizontals through the latter points to meet OY, and through the points of intersection drawing arcs with centre O to meet the circle. The corresponding points on the impedance circle are found by drawing rays O1′, O2′, O3′, . . . O8′ to meet the impedance circle in 1″, 2″, 3″, . . . 8″. A straight line is now drawn perpendicular to the diameter A_zQ_z at a distance A_zO''' equal to unity, and the rays A_z2'', A_z3'', etc., meet this line in the points 2‴, 3‴, 4‴, . . . 8‴. Then the lengths O‴2‴, O‴3‴, O‴4‴ . . . are the values of tan α corresponding to the frequencies at the original points, 1, 2, 3, etc. Points on the f/tan α curve are obtained in the lower part of the diagram by marking off the lengths O‴2‴, O‴3‴, etc., vertically, and drawing horizontals

* Miles Walker: *Electrician*, 1923, vol. 90, p. 215.

through the points obtained to intersect the verticals through the points 2, 3, 4 . . . 8. It is seen that the points so obtained lie very nearly on a straight line, and lines $f/\tan\alpha$ of Figs. 6 and 8 are identical, though in the latter case the actual observational points are used, and in the former α is taken at definite values.

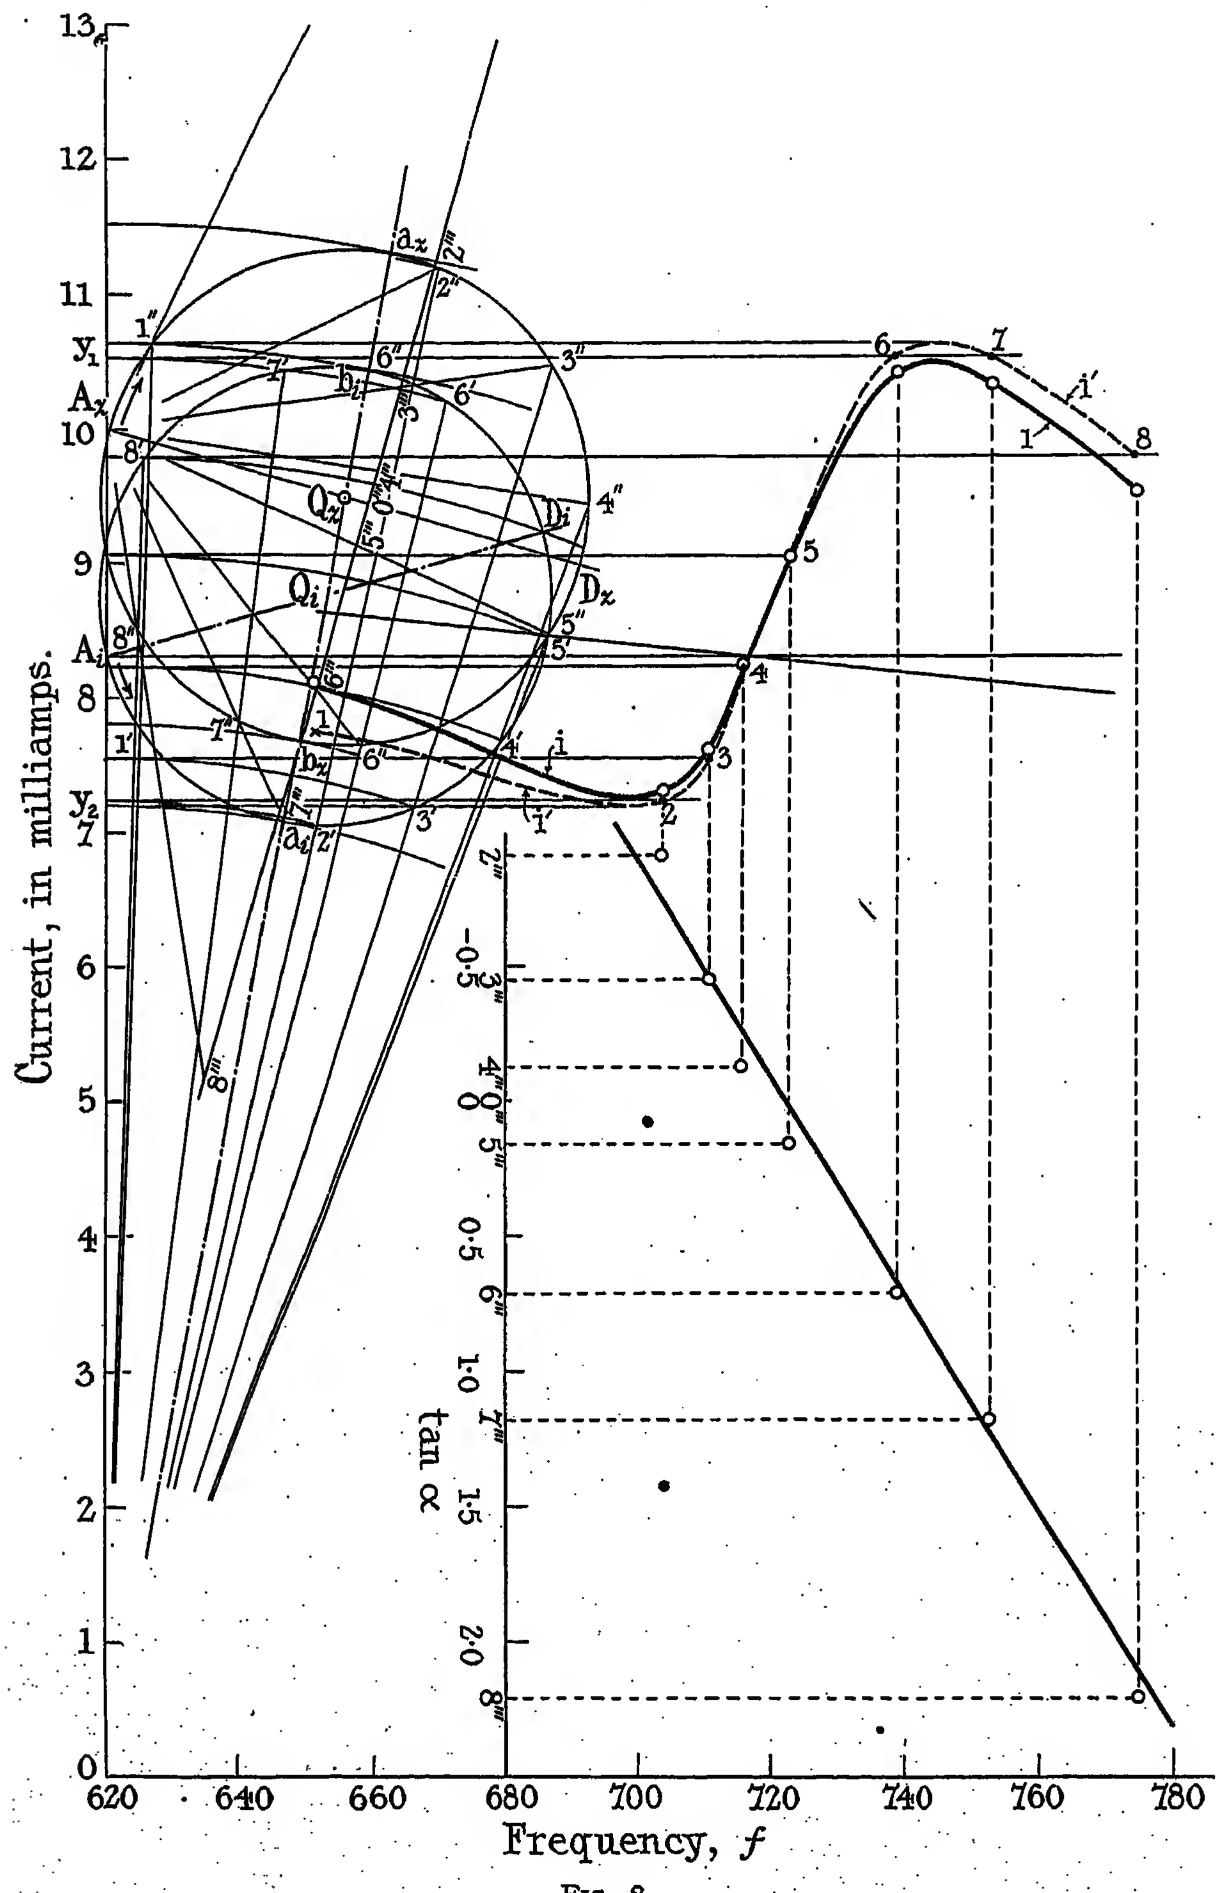

Fig. 8.

and the resonant frequency and decay factor obtained from the latter are the same as those previously obtained. In fact, the same scale having been chosen for the impedance circle as before, the impedance circle

The impedance-circle scale could of course be chosen so as to make the two circles coincide, and this would generally be done if f_0 and Δ were required for a number of curves. It is thought, however, that in

explaining the method the construction of two separate circles leads to greater clearness.

6. More Approximate Simple Methods in Special Cases.

In cases where the alteration of impedance is small compared with the whole impedance, i.e. when the point O is a considerable distance from the circle compared with its diameter, the arcs drawn with centre O to the circle are practically straight lines at right angles to the axis OY. In other words, the points on the circle corresponding to the points on the modified resonance curve (Z' or i') are obtained by direct projection from the latter at right angles to OY to meet the circle. Further, instead of drawing the modified resonance curve the circle may be tilted round by drawing it between the lines MM, mm, parallel to the Z_d line and tangential to the resonance curve as indicated in Fig. 9.* The point A where the line Z_d meets the circle corresponds to the previous point A, AD is the diameter, and a line through D parallel to MM to meet the circle in r determines the resonant frequency f_0. Obviously in this case f_0 can be found without drawing the circle, by drawing a line RR parallel to Z_d and at the same distance from mm that Z_d is from MM, to meet the curve in r. Also, having drawn the circle, Δ can be found from the quadrantal points simply by drawing a diameter at right angles to AD meeting the circle in T and S, and through T and S drawing parallels to MM to meet the resonance curve in the corresponding points t and s, at frequencies f_1 and f_2. Then $\Delta = \pi(f_2 - f_1)$. Or the construction described above may be used to obtain the line $f/\tan\alpha$, all projections from the curve to the circle being made parallel to mm.

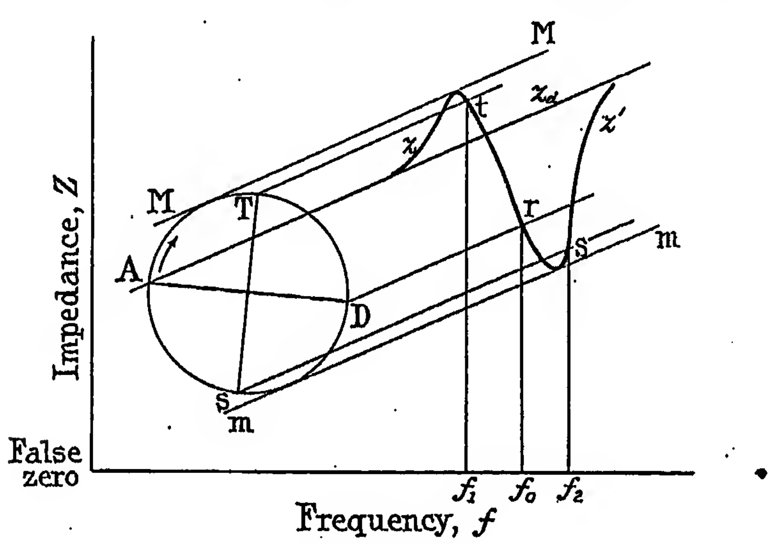

Fig. 9.

Working from the current curve instead of the impedance curve, the construction is precisely the same. Taking for simplicity the modified resonance (current) curve, the current circle is drawn between the horizontal lines MM and mm. The scale of the impedance circle is so chosen that the two circles coincide (though they are shown separately in Fig. 10 for clearness). Since the origin O is assumed to be at a great distance the invertion from one circle to the other is carried out by drawing lines parallel to OY, as approximately the same thing as drawing rays from O. Thus the diameter A_zD_z, which determines the resonance frequency, corresponds nearly to the diameter A_iD_i, and the quadrantal points S_z and T_z to the points S_i and T_i which are also quadrantal. The construction described in the previous paragraph can therefore be used on either the impedance or the current curve, though the accuracy will be rather greater in the former case.

Even in the experimental case given, where the resonance impedance range is about one-third of the whole impedance, this simple method for the resonance frequency leads to good results. Carried out on the impedance curve of Fig. 5, a value of f_0 of 722 is found, and on the current curve, 726. For Δ, from the impedance circle as drawn the quadrantal frequencies are 703 and 750, giving $\Delta = \pi(750 - 703) = 148$. In the case of the current circle they are 707 and 754, leading to the same result. So that the agreement with

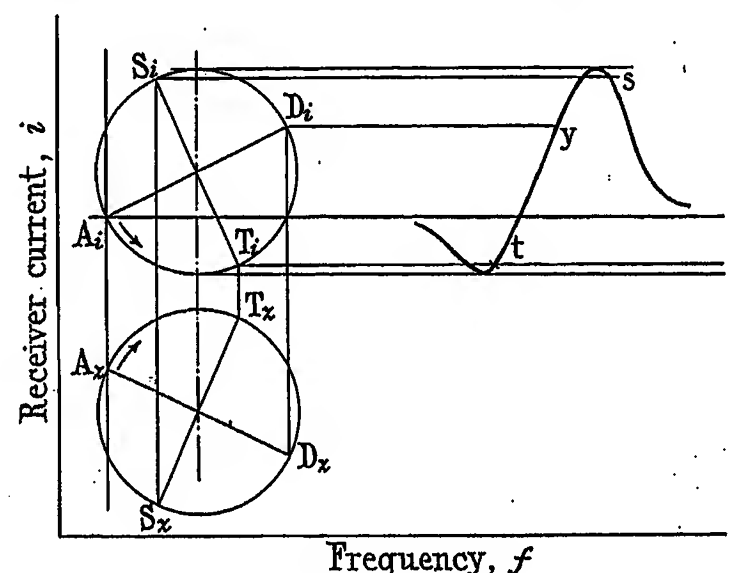

Fig. 10.

the value obtained by the more accurate method is not so good as in the case of f_0.

In the case of the higher modes of vibration of a receiver diaphragm, where the effect of the resonance on the impedance is not nearly so marked, the simpler method will be quite satisfactory. Curves obtained in two cases, those of two nodal diameters and one nodal circle, are reproduced in Fig. 11 and it is found that in the former case $f_0 = 2\,240$ and $\Delta = 116$, and in the latter $f_0 = 2\,990$ and $\Delta = 138$.

7. Other Applications.

The methods developed have applications in other directions apart from the telephone receiver. For instance, the simple resonance curve drawn from the relation $i = \dfrac{e}{R + j[\omega L - (1/\omega C)]}$ (Fig. 12) is a special case in which the circle is drawn with the diameter AD vertical and the point A at O, and the diameter is equal to the height of the resonance. Drawing the diameter ST to obtain the quadrantal points, and arcs TT′, SS′ with centre A and radius AT to meet AD in T′ and S′ (coinciding), the points s and t on the

* This involves a reduction in the size of the circle in the ratio of 1 to cos γ (γ is the angle the line makes with the horizontal). Z' is measured as the perpendicular distance from a new OX axis parallel to Z_d and cutting the original axis at the point where it is met by the line at right angles to Z_d through K.

resonance curve are obtained by projection. This construction is obviously in agreement with the well-known rule of drawing the line st at a height $= i_{max.}/\sqrt{2}$. But instead of depending on these two points alone the construction described for finding the line $f/\tan\alpha$

The value of Δ derived from the line $f/\tan\alpha$ is $16\cdot14$ and that calculated from $\Delta = R/2L = 16\cdot10$, in close agreement.

Another electrical case which is very similar to that of the telephone receiver is the one indicated in Fig. 13.

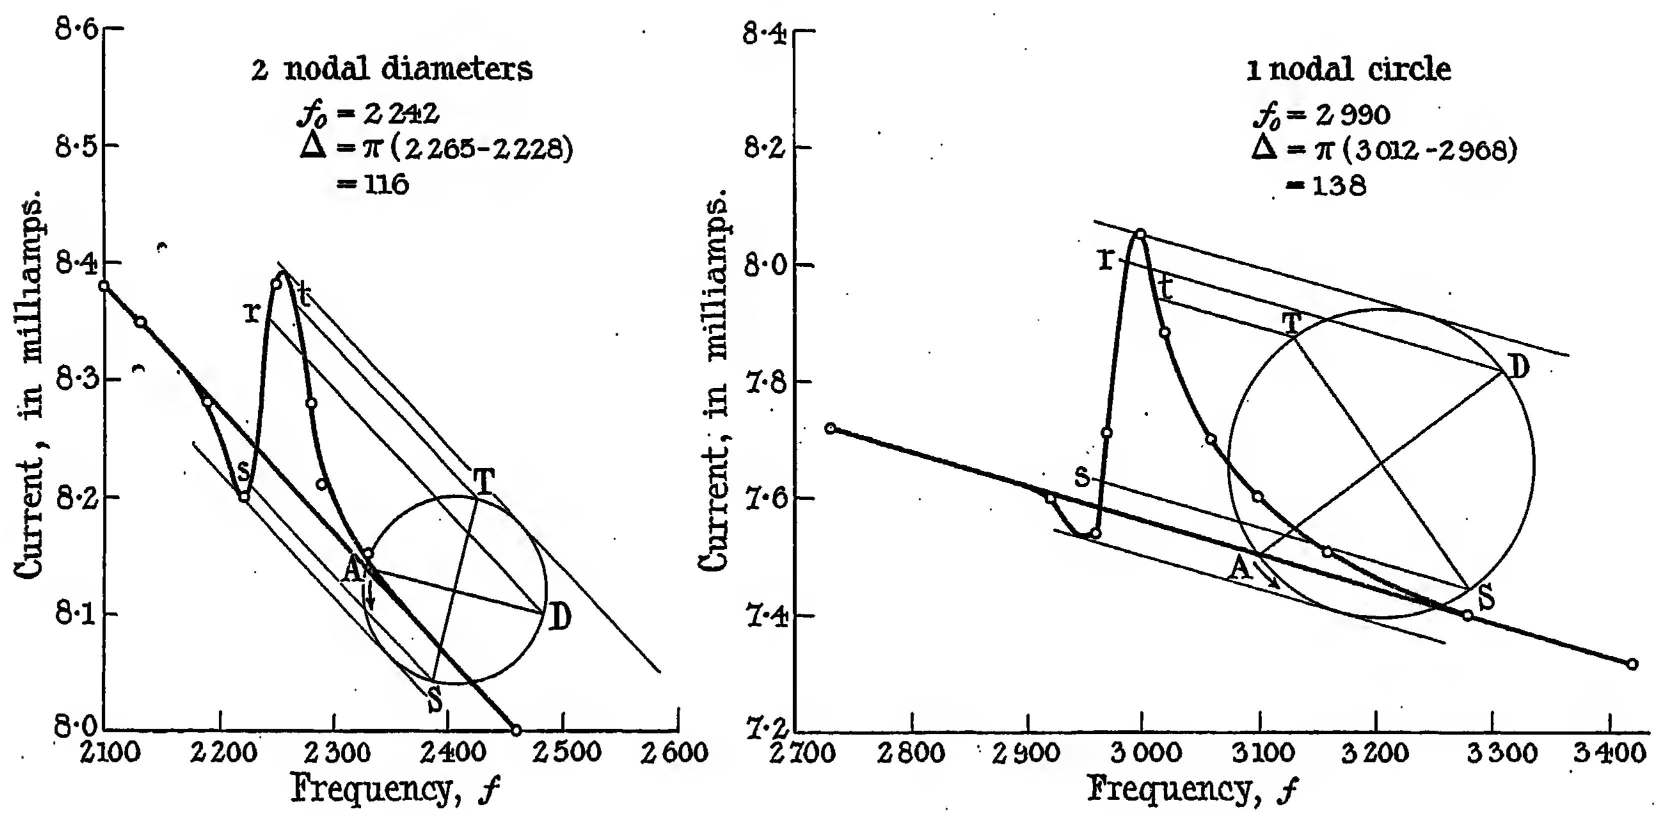

FIG. 11.

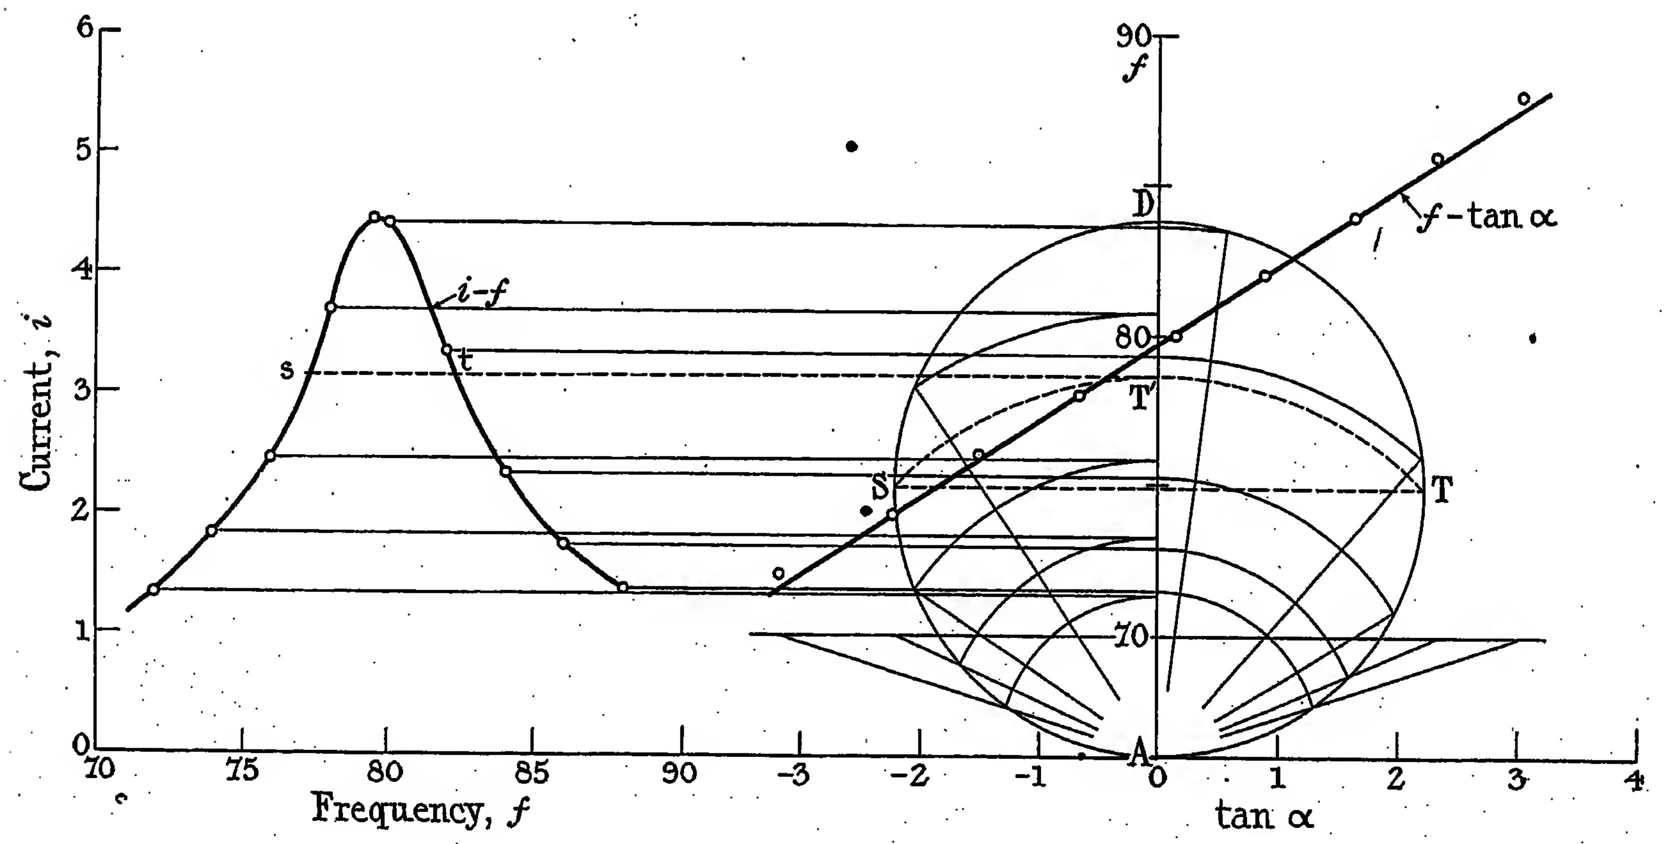

FIG. 12.

is carried out and Δ obtained from its slope. This leads to more accurate results, and at the same time is a check on the accuracy of the readings from which the resonance curve is drawn. In the case illustrated $R = 4\cdot5$ ohms, $C = 28\cdot6\mu$F and $L = 0\cdot14$ H.

The currents i_1, i_2 in the two circuits are obtained from the equations

$$v = Z_1 i_1 + j\omega M i_2$$

and

$$0 = Z_2 i_2 + j\omega M i_1$$

Eliminating i_2 we get

$$v = Z_1 i_1 + \frac{\omega^2 M^2}{Z_2} i_1$$

or

$$i_1 = \frac{v}{Z_1 + (\omega^2 M^2 / Z_2)}$$

TABLE 3.

1	2	3	4
f	i_1	i_d	$Z' = \frac{i_d}{i_1}$
p.p.s.	mA	mA	
60	0·73	1·26	1·73
62	0·63	1·20	1·90
64	0·52	1·16	2·23
66	0·60	1·12	1·87
70	1·80	1·06	0·59
71·8	2·20	1·03	0·47
74	2·20	1·00	0·45
78	1·80	0·97	0·54

being sufficiently constant over a frequency-range near resonance for the locus of Z' to be very nearly circular.

The construction has been applied to some experimental results for a circuit of this type given by

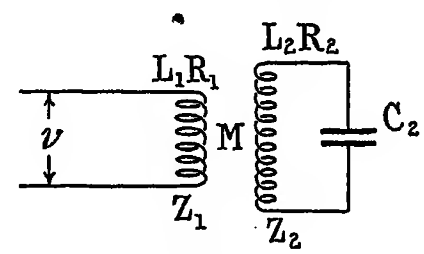

FIG. 13.

Morecroft.* The constants of the secondary circuit are $L_2 = 0{\cdot}206$ H, $C_2 = 28{\cdot}6\ \mu$F, $R_2 = 7{\cdot}2$ ohms. whence

$$f_0 = \frac{1}{2\pi}\sqrt{\left(\frac{1}{C_2 L_2}\right)} = 65{\cdot}8 \quad \text{and} \quad \Delta = \frac{R_2}{2L_2} = 17{\cdot}5$$

Cols. 1, 2 and 3 of Table 3 give the experimental values of the frequency and the corresponding current in the primary circuit first with the secondary circuit in position and secondly with it removed. Col. 4 gives the calculated value of $Z' = i_d/i_1$ and this is plotted

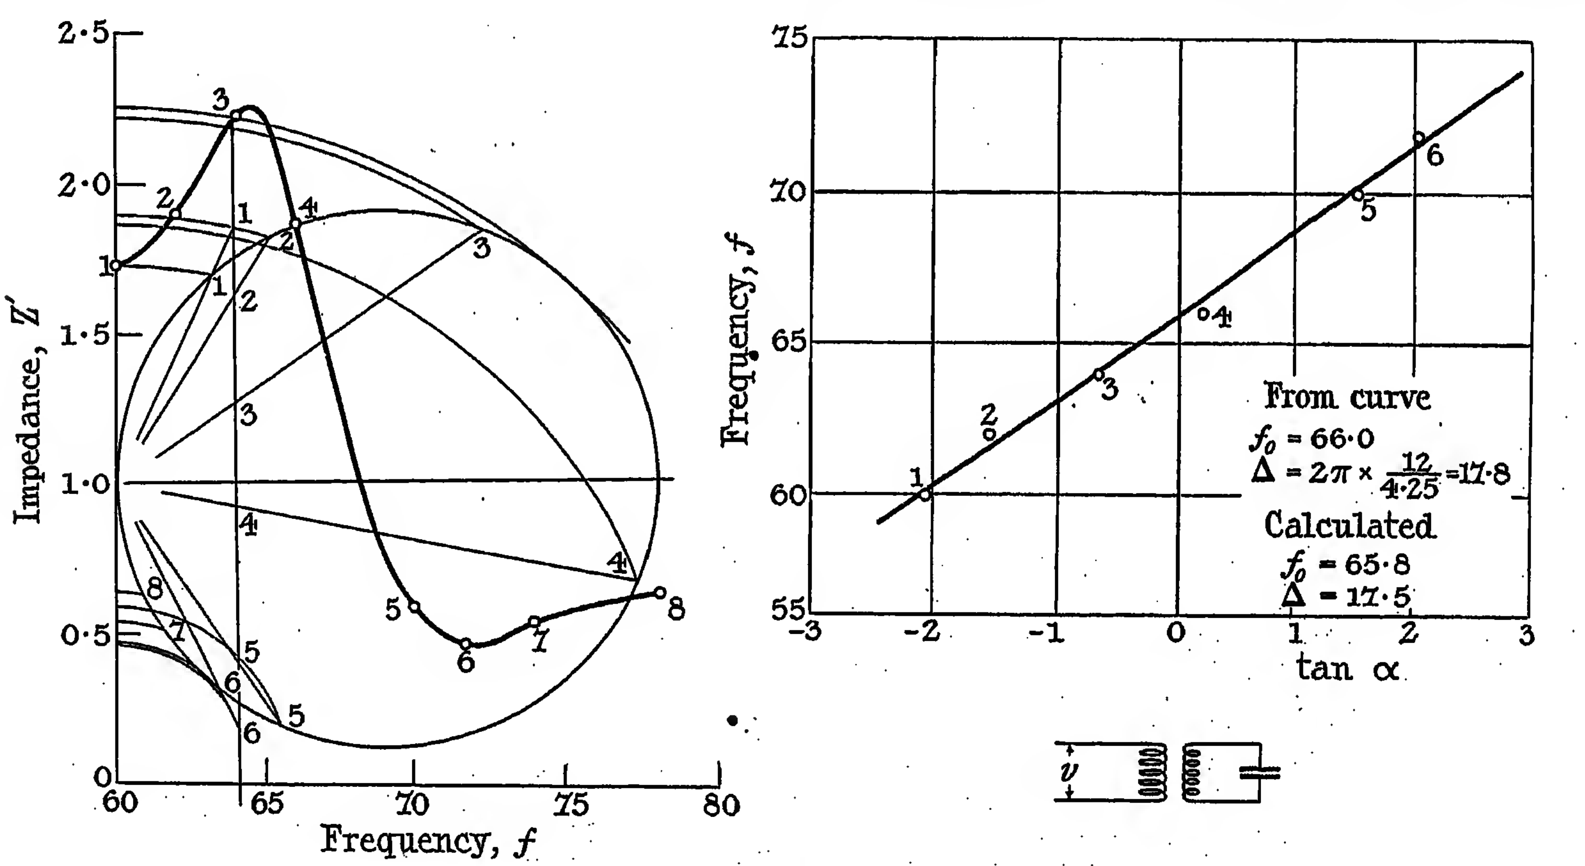

FIG. 14.

If the secondary circuit is removed we have $i_d = v/Z_1$, so that

$$Z' = \frac{Z}{Z_d} = \frac{i_d}{i_1}$$

$$= 1 + \frac{\omega^2 M^2}{Z_1} \times \frac{1}{Z_2}$$

This is of similar form to the telephone receiver Equation (2), and, provided that the resonance is fairly sharp (which will be the case in most telephone and high-frequency circuits), $\omega^2 M^2 / Z_1$ can be regarded as against frequency in Fig. 14. Here the construction as previously described is carried out for the impedance circle and the line $f/\tan\alpha$, and from the latter are obtained the values $f_0 = 66{\cdot}0$ and $\Delta = 17{\cdot}8$, in good agreement with the calculated values.

The method can be applied to the measurement of high-frequency resonances and resistances, of circuits or of coils alone. A great advantage is that a knowledge of the primary impedance and of the coupling is unnecessary. Experiments are being made to ascertain its value in this direction.

REPORT OF THE COUNCIL FOR THE YEAR 1923–1924 PRESENTED AT THE ANNUAL GENERAL MEETING OF 8 MAY, 1924.

CONTENTS.

REPORT.

The Council, at the Fifty-second Annual General Meeting of the Institution of Electrical Engineers, present to the members their Report for the year 1923–24, covering approximately the period from the 1st April, 1923, to the 31st March, 1924.

The continued progress and prosperity of the Institution during the period under review afford much satisfaction to the Council.

(1) "Chartered Electrical Engineer."

A new Bye-Law sanctioning and regulating the use of the designation "Chartered Electrical Engineer" by Members and Associate Members of the Institution, which was passed at a Special General Meeting of Corporate Members held on the 28th February, 1924, was allowed at a Meeting of His Majesty's Privy Council held at the Council Chamber, Whitehall, London, on the 20th March, 1924, and came into operation on the latter date.

The privilege is one which attaches to Members and Associate Members as individuals. The Council feel confident that they will receive the support of all members in preserving the strict use of a title which confers an honourable distinction.

(2) Liquidation of the Old Institution.

The final winding-up of the old Institution, made necessary by the incorporation under Royal Charter, was effected at a Special General Meeting of Corporate Members and Associates held on the 19th July, 1923.

(3) Membership of the Institution.

The changes in the membership since the 1st April, 1923, are shown in a table given in Appendix A.

The following table shows the growth of membership for the last few years :—

Year	Membership	Increase or Decrease
1914	7 045	− 39
1915	6 811	− 234
1916	6 676	− 135
1917	6 613	− 63
1918	6 667	+ 54
1919	7 023	+ 356
1920	8 146	+ 1 123
1921	9 449	+ 1 303
1922	10 275	+ 826
1923	10 911	+ 636
1924	11 415	+ 504

It will be seen from the above that the rate of increase of the membership of the Institution is well maintained.

The largest increase has taken place in the class of Students, of whom a large number are following courses of instruction leading to certificates and diplomas, the possession of which will entitle the holders to exemption from the Associate Membership Examination.

(4) Annual Subscriptions.

At the last Annual General Meeting, the then President announced that the Council had decided, under the powers conferred upon them by Bye-Law 27, to reduce the annual subscriptions of Corporate Members by ten shillings and those of Graduates by five shillings from the 1st January, 1924.

(5) Examinations.

The Associate Membership Examination was held in April and October 1923 in London, Chatham, Birmingham, Manchester, Newcastle-on-Tyne, Cardiff, and Glasgow, and also in New Zealand and South Africa. The candidates examined included a number of officers of the Corps of Royal Engineers, who sat for the examination for the purpose of qualifying for "Engineer Pay."

For the purpose of qualifying for "Signal Pay," officers of the Royal Corps of Signals were also examined by the Institution in the "Theory of Electrical Military Signalling" at the Signal Service Training Centre, Maresfield Park Camp, Sussex, in August 1923 and February 1924.

A certain number of candidates submitted theses and papers during the year in lieu of the examination.

(6) Honorary Members.

The Council have pleasure in recording that, as announced at the Ordinary Meeting of the 1st November, 1923, they have elected Colonel Rookes Evelyn Bell Crompton, C.B., to be an Honorary Member of the Institution. Colonel Crompton became a member of the Institution in 1880 and was President in 1895 and 1908.

There are now ten Honorary Members.

(7) Honours and Distinctions Conferred on Members.

Since the last Annual Report the following honours have been conferred on members :—

Knighthood.
Barker, R. C., C.I.E. (Member).
Hume, G. H. (Member).

C.B.
McClelland, W., O.B.E. (Member).

C.M.G.
Butters, J. H., M.B.E. (Member).

O.B.E.
Fuller, Major A. C., R.C.S. (Associate Member).

M.B.E.
Butters, J. H. (Member).

The President of the Institution has been nominated for election as a Fellow of the Royal Society.

(8) Faraday Medal.

The third award of the Faraday Medal has been made by the Council to Dr. S. Z. de Ferranti, Past-President.

(9) War Memorial.

The War Memorial Book containing the biographical notices and portraits of the members of the Institution who fell in the war of 1914–1918 is in the press and will be published shortly.

(10) Deaths.

The Council regret to have to record the deaths of the following 55 members of the Institution during the year :—

Honorary Member.

Leblanc, Maurice.

Members.

Ayrton, H. (Mrs.).	Mitchell, H. E.
Chew, W.	Rawson, F. L.
Clarke, E. F.	Smith, D. C.
Dearlove, A. L.	Steinmetz, Prof. C. P.
Dixon, R. E.	Thomson, H. Lyon.
Gott, A. E.	Thorp, E. L.
Grant, A. E.	Tobler, Prof. Dr. A.
Head, H. C.	Turnbull, R. T.
Heaviside, A. W., I.S.O.	Ullett, J. W.
Kidd, G. W.	Wilkinson, H. T.
Layton, G.	Yale, T. P. O.

Associate Members.

Andrews, J. L.	Kerr, J. A. W.
Ascoli, G. H. D., M.C.	Kirloskar, V. G.
Bishop, O. H.	McIntosh, A.
Cawood, S. D.	Mallalieu, V.
Day, F.	Martin, C.
Garstang, F. L.	Owen, C. M.
Handley, G. W.	Pauls, S.
Hement, T. C.	Rowell, W. N.
Hounsfield, F. C.	Swire, S.
Hughes, A. S.	Wallwork, T.

Williamson, A.

Graduate.

Slater, J. T. L.

Students.

Imeary, R. K. — MacKenzie, K. S.

Nicholas, J. D.

Associates.

Benest, H.	Dennison, J. D.
Clapperton, G.	Donnison, F. A.
Crawford, F. C.	Mostyn, R. J. F.

Nicholl, H.

The Council particularly deplore the loss to Electrical Engineering caused by the deaths of Monsieur Maurice Leblanc (elected Hon. Member, 1915), Mrs. H. Ayrton (elected Member, 1899), Mr. A. W. Heaviside, I.S.O. (Chairman of the Newcastle Local Section, 1900–1; awarded Fahie Premium, 1892), and Prof. C. P. Steinmetz (elected Member, 1912).

(11) Institution Building.

A very large number of meetings of kindred societies have been held in the Institution building during the past twelve months and it has been a pleasure to the Council to have been able to grant the use of the premises for this purpose. In particular, mention

should be made of the Jubilee Celebrations of the Physical Society of London, which were held on the 20th, 21st and 22nd March, 1924.

(12) MEETINGS.

Four hundred and eight meetings have been held during the past twelve months and a complete statement is contained in Appendix B.

(13) PREMIUMS.

The following Premiums for papers have been awarded by the Council :—

The Institution Premium (*value* £25).

Lt.-Col. H. E. O'BRIEN, D.S.O.	"The Future of Main-Line Electrification on British Railways."

The Ayrton Premium (*value* £10).

A. BACHELLERY.	"Electrification of the French Midi Railway."

The Fahie Premium (*value* £10).

P. E. ERIKSON and R. A. MACK.	"Transmission Maintenance of Telephone Systems."

The John Hopkinson Premium (*value* £10).

A. S. FITZGERALD.	"The Design of Apparatus for the Protection of Alternating-Current Circuits."

The Kelvin Premium (*value* £10).

H. M. BARLOW, B.Sc. (Eng.), Ph.D.	"An Investigation of the Friction between Sliding Surfaces."

The Paris Premium (*value* £10).

H. MARRYAT.	"Electric Passenger Lifts."

The Webber Premium (*value* £10).

S. C. BARTHOLOMEW.	"Power Circuit Interference with Telegraphs and Telephones."

A Premium (*value* £10).

E. A. WATSON, O.B.E.	"Permanent Magnets, and the Relation of their Properties to the Constitution of Magnet Steels."

A Premium (*value* £5).

E. A. CLAYTON, D.Sc. (Eng.).	"A Mathematical Development of the Theory of the M.M.F. of Windings."

A Premium (*value* £5).

Prof. W. CRAMP, D.Sc., and Miss N. I. CALDERWOOD, M.A., B.Sc.	"The Calculation of Air-space Flux."

A Premium (*value* £5).

F. J. TEAGO, M.Sc.	"The Nature of the Magnetic Field produced by the Stator of a Three-phase Induction Motor."

WIRELESS SECTION PREMIUMS.

A Premium (*value* £10).

L. B. TURNER, M.A.	"The Relations between Damping and Speed in Wireless Reception."

A Premium (*value* £10).

R. H. BARFIELD, M.Sc.	"Some Experiments on the Screening of Radio Receiving Apparatus."

A Premium (*value* £5).

C. E. HORTON.	"Wireless Direction-Finding in Steel Ships."

A Premium (*value* £5).

E. B. MOULLIN, M.A.	"Atmospherics, and their Effects on Wireless Receivers."

The award of Premiums for papers read before the Students' Sections will be announced later.

(14) ORDINARY MEETINGS.

Before the commencement of the Session a circular was sent to members in the London area with the object of ascertaining the most convenient hour for the Ordinary Meetings. The replies received showed a large majority in favour of 6 p.m. and the Council accordingly decided to continue holding the meetings at that hour.

(15) LOCAL CENTRES AND SUB-CENTRES.

The attendances at meetings of the Centres and Sub-Centres have been satisfactorily large and the interest in the discussions has been generally well sustained.

The President has attended functions or meetings at the Centres at Birmingham, Cardiff, Dublin, Glasgow, Leeds, Liverpool, Manchester and Newcastle, and the Sub-Centre at Sheffield, and on each occasion he has addressed the members.

(16) LOCAL CENTRE ABROAD.

The Council have sanctioned the formation of a Local Centre of the Institution in China, with headquarters at Shanghai.

(17) WIRELESS SECTION.

The Council are gratified at the continued success of the Wireless Section. Nine meetings have been held, at which 10 papers were read.

(18) INFORMAL MEETINGS.

During the Session 13 meetings were held, being two more than last session. The average attendance per meeting has materially increased.

That the subjects discussed have met with approval has been shown by the keenness of the debates, and there is no doubt that the Informal Meetings are serving a very useful purpose.

(19) STUDENTS' SECTIONS.

A very full programme of meetings, visits to works, and social functions was carried out during the Session by the eight Students' Sections now in existence,

viz. in London, Birmingham, Glasgow, Leeds, Liverpool, Manchester, Newcastle and Sheffield.

Addresses to the London Students' Section were given by the President and Mr. C. F. Elwell, Member.

A Students' visit to Belgium and Holland took place from July 24th to August 4th, 1923. The following works, etc., were visited: at Antwerp, Minerva Motors & Bell Telephone Manufacturing Co.; at Liége, Messrs. Cockerill's Steel Works, Les Cristalleries du Val St. Lambert, and the University; at Kostwijk (Holland), the Radio Station. The party also called at Brussels, Eindhoven, Apeldoorn, Amsterdam and The Hague. At Liége the British Consul arranged for members of the party to become Honorary Members of the Anglo-Belgian Club. The tour was extremely successful, 40 Students taking part in it.

The firms named have been thanked for the courtesy shown by them on the occasion and for the facilities afforded, which very materially helped to make the visit an acknowledged success.

The Council have to thank Mr. A. C. Warren (Assistant Honorary Secretary, London Students' Section) for his valuable work in organizing the visit.

(20) Scholarships.

The following Scholarships have been awarded by the Council:—

David Hughes Scholarships.

(Value £50 each; tenable for one year.)

R. E. Banks (Birmingham University).
R. MacWhirter (Royal Technical College, Glasgow).

Salomons Scholarships.

(Value £50 each; tenable for one year.)

F. J. Lane (Leeds University).
J. Linton (Heriot Watt College, Edinburgh).

War Thanksgiving Education & Research Fund (No. 1).

A grant of £100 for educational purposes has been made this year by the Council under the provisions of the Trust Deed to A. Ramsay (Glasgow University).

(21) Coopers Hill War Memorial Prize.

The award of the Coopers Hill War Memorial Prize, which consists of a Bronze Medal, a parchment Certificate of Award and a Money Prize of £29, fell this year to the Institution and the Council selected for the award Mr. F. R. Combes for his monograph entitled "An Historical and Critical Survey of Atmospheric Electricity and Protection against Lightning."

It may here be recalled that the Prize was founded by members of the Royal Indian Engineering College, Coopers Hill, in commemoration of members of the College who fell during the late war. It consists of two awards, one of which is made annually by the Institution of Civil Engineers and the other triennially in turn by the Institution of Electrical Engineers, the School of Military Engineering, Chatham, and the School of Forestry, Oxford, for the best paper on a professional subject selected by the Council making the particular award.

(22) Conversazione.

The Annual Conversazione was held at the Natural History Museum, South Kensington, London, on the 28th June, 1923, when over 1 500 members and guests attended.

(23) Annual Dinner.

The Annual Dinner was held at the Hotel Cecil, London, on the 21st February, 1924, the members and guests present numbering 487.

An account will be found in the *Journal*, vol. 62, p. 350.

(24) Summer Meeting.

A most successful Summer Meeting, attended by some 450 members and ladies, was held from the 5th to the 8th June, 1923, at the Manchester and Liverpool Centres, two days being spent in Manchester, one in Liverpool and one in North Wales. A full and interesting programme of functions, excursions and visits to works was arranged by the Committees of the two Centres. During the Meeting the works, etc., of the following were visited:—

Messrs. R. Johnson & Nephew, Ltd., Bradford.
Messrs. Mather & Platt, Ltd., Manchester.
The No. 2 Dunlop Rubber Cotton Mills, Ltd., Rochdale.
Messrs. Pilkington's Tile and Pottery Works, Clifton Junction.
The Chloride Electrical Storage Co., Ltd., Clifton Junction.
The London, Midland & Scottish Railway Company's Power Stations at Clifton Junction and at Formby.
The Lancashire Electric Power Company's Station, Ratcliff.
The Manchester Corporation's new Generating Station at Barton, and their 33 000-volt Substation at Chorlton-on-Medlock.
The Metropolitan-Vickers Electrical Co., Ltd., Trafford Park.
The Lancashire Dynamo and Motor Co., Ltd., Trafford Park.
The *Manchester Guardian* Offices, Manchester.
The British Insulated & Helsby Cable Co., Ltd., Prescot.
The Liverpool Corporation's Lambeth-road Tramways Works, Automatic Substation, Walton, and the Lister-drive Power Station.
Messrs. Lever Brothers, Ltd., Port Sunlight.
The Automatic Telephone Manufacturing Co., Ltd., Liverpool.
The Mersey Power Co., Runcorn.
The United Alkali Co., Widnes.
The Aluminium Corporation, Ltd., Dolgarrog.
The North Wales Power Co.'s Hydro-Electric Power Station, Cwm Dyli.
Lord Penrhyn's Slate Quarries, Bethesda.

The party also visited the Laboratories of the University of Manchester, the Applied Electricity Laboratories of the University of Liverpool and the Cunard Steamship Company's s.s. "Scythia."

The thanks of the Institution have been conveyed to the foregoing, and also to the Lord Mayor and Lady Mayoress of Manchester, the Electricity and Tramways Committee of the Manchester Corporation, the Manchester Ship Canal Company, Sir H. A. Miers (Vice-Chancellor of the University of Manchester), the Lord Mayor and Lady Mayoress of Liverpool, the Tramways and Electric Power and Lighting Committee of the Liverpool Corporation and the London Midland & Scottish Railway Co., Ltd., who all extended most generous hospitality to the visitors.

The Council desire to put on record their appreciation of the work of the Committees of the two Centres and especially of the respective Chairmen (Mr. A. S. Barnard, Manchester, and Mr. B. Welbourn, Liverpool) and Honorary Secretaries (Mr. A. B. Mallinson, Manchester, and Mr. G. C. Waygood, Liverpool).

(25) Portraits of Past-Presidents.

The set of enlarged photographs of Past-Presidents has been completed and has for some months been hung in the Common Room.

(26) American Institute of Electrical Engineers.

At the Annual Convention of the American Institute of Electrical Engineers held at Swampscott, Mass., U.S.A., from the 25th to the 29th June, 1923, the Institution was represented by two of its Honorary Members as delegates, namely, Professor A. E. Kennelly and Professor Elihu Thomson.

(27) Société des Ingénieurs Civils de France.

Mr. R. T. Smith and Mr. C. H. Wordingham, C.B.E., Past-Presidents, represented the Institution at the meetings held in Paris on the 4th, 5th and 6th May, 1923, to celebrate the 75th Anniversary of the foundation of the Société des Ingénieurs Civils de France.

(28) Library.

During the year, 268 books and pamphlets have been presented to the Reference Library by members and others and 140 volumes have been purchased. An increase in attendance is recorded, the total number for the year being 2 590, of whom 178 were non-members, as against the previous highest yearly total of 2 526 in 1922-23.

The Council have pleasure in recording the continued circulation of books from the Lending Library. During the year 2 232 were issued to 897 borrowers, the corresponding numbers for the previous year being 2 213 and 814 respectively.

The Silvanus Thompson Memorial Library was formally presented to the Institution at the Annual General Meeting held on the 31st May, 1923. On the same occasion Mrs. Thompson presented to the Institution an oil painting of the late Dr. Thompson, and the Finsbury Old Students' Association a bronze bust of him.

The Institution is now the possessor of a painting of Sir Francis Ronalds at work on a catalogue of his Library, of which the Institution has the custody and use. The painting was presented by Mrs. Ortmans, a great-niece of Sir Francis.

(29) Electrical Appointments Board.

The number of applicants for posts registered on the 31st March, 1924, was 114 as against a total of 120 last year.

A classified Register of members seeking positions, containing particulars of their training and experience, is available for inspection at the Institution offices, and the Secretary of the Board will gladly put employers in touch with highly qualified electrical engineers.

The Council earnestly hope that members who are in a position to assist will not fail to make use of the Register.

(30) The Journal of the Institution.

The amount of matter published in the *Journal* continues to increase, the number of pages in the 1923 volume being 1 204 as compared with 1 002 in the previous volume. This increase is largely accounted for by the publication of a number of reports of the Electrical Research Association, in particular several dealing with overhead lines.

The net cost of printing and posting the *Journal* in 1923, after allowing for sales and the revenue received from advertisements, was £4 159, as compared with £4 604 in 1922 (1 002 pages) and £4 936 in 1921 (852 pages). As the number of copies printed increased from 10 200 in 1921 to 11 400 in 1923, the reduction in the net cost is most gratifying. The net cost per page works out at £5·79 for 1921, £4·59 for 1922 and £3·45 for 1923.

A Ten-Year Index to the *Journal* for the years 1912-21 was issued during the year.

(31) "Science Abstracts."

The Physics volume of *Science Abstracts* for 1923 contained 184 pages more than that for 1922; the Electrical Engineering volume contained 2 pages less. During the year the Committee of Management of the publication took steps to increase the revenue, with the result that the financial position is now satisfactory, and *Science Abstracts* does not appear in the accounts, as in the past, as a financial burden on the Institution.

(32) Wiring Rules.

The revision of the Wiring Rules has been completed, and the Council are gratified to be able to report that the Fire Offices have accepted the revised Rules, which will in future be known as "Regulations for the Electrical Equipment of Buildings." It is hoped to publish the Regulations before the end of June.

(33) Model Conditions of Contract.

The Council have approved and published Model Conditions of Contract for:—

(*a*) The sale of goods other than cables at home when no erection is included in the contract;

(*b*) The sale of cables at home when no erection is included in the contract.

Conditions of Contract for Export Orders are still

under consideration by a Committee appointed for the purpose.

(34) Electricity Regulations.

The draft Regulations for Low and Medium Pressure and for High Pressure Overhead Lines, prepared by the Electricity (Supply) Regulations Committee and submitted to the Electricity Commissioners were, with few alterations, approved by the Commissioners, and were published by His Majesty's Stationery Office in November 1923.

For the purpose of enabling the Council to submit a Report thereon to the Electricity Commissioners, the Committee are now engaged in the consideration of the Commissioners' Regulations (A) for securing the Safety of the Public, and (B) for ensuring a proper and sufficient supply of Electrical Energy.

(35) Committee on Electricity in Agriculture.

The Committee appointed last session are collecting information for their report to the Council.

(36) National Certificates and Diplomas in Electrical Engineering.

The joint Standing Committee representing the Board of Education and the Institution have approved for this Session 50 schools and colleges in England and Wales at which courses may be taken by students with a view to their being awarded National Certificates or Diplomas in Electrical Engineering. The names of the schools and colleges approved, together with the grade of Certificate or Diploma obtainable, have been published from time to time in the *Journal*. About 450 candidates will sit for the final examinations on this occasion.

(37) Engineering Joint Council.

The provisional constitution of the Engineering Joint Council which was set out in the last Annual Report has been finally approved and will be found in Appendix C to this Report, together with the Bye-Laws and Rules made by the Joint Council.

The Institution's representatives on the Joint Council are Mr. J. S. Highfield and Mr. Roger T. Smith, Past-Presidents.

(38) British Electrical Research Association.

The Director of the Association reports as follows:—

During the year the membership of the E.R.A. has been materially strengthened by the addition as Associate Members of representatives of suppliers and large users of electricity.

The Report on the Heating of Buried Cables has attracted world-wide attention. Progress has been made in dealing with cables for voltages above 11 000 and in further study of safe temperature limits. Work on insulating oils is being chiefly directed to a further raising of standards which is likely to be accomplished in the immediate future.

Patents have been applied for covering improvements in oil circuit-breakers calculated to increase the rupturing capacity materially without increase of size or cost. Work on overhead-line materials is being carried out with a view to further improvements in the construction of wood poles and completion of data for the calculation of wind pressures.

An extensive series of reports has now been published in the *Journal* giving instructions for the study of most of the principal insulating materials. The use of the methods advocated therein has resulted in further improvements in numerous directions.

The researches on steam turbines and steam condensers continue to yield valuable data.

The Institution has increased its annual subscription from £300 to £500, and a corresponding grant is being obtained from the Government.

Members are invited to communicate with the Director of the Association at 19 Tothill-street, Westminster, S.W. 1, on the work of the Association and all matters relating to co-operative research.

(39) British Engineering Standards Association.

A large number of British Standard Specifications dealing with electrical apparatus and machinery were published during the past year, as follows:—

B.S.S. No. 31. Steel Conduits for Electric Wiring (Revision).
B.S.S. No. 117. Drum Starters for Electric Motors.
B.S.S. No. 118. Drum Controllers for Electric Motors.
B.S.S. No. 123. Face Plate Controllers, and Resistances for Use therewith.
B.S.S. No. 124. Totally Enclosed Air-break Switches.
B.S.S. No. 126. Flame-proof Air-break Switches.
B.S.S. No. 127. Flame-proof Air-break Circuit Breakers.
B.S.S. No. 129. Contactor Controllers, and Resistances.
B.S.S. No. 130. Totally Enclosed Air-break Circuit Breakers.
B.S.S. No. 140. Liquid Starters for Electric Motors.
B.S.S. No. 141. Switch Starters (Star-delta and Series-Parallel) for Electric Motors.
B.S.S. No. 147. Multiple Switch Starters for Electric Motors.
B.S.S. No. 148. Insulating Oils for Use in Transformers, Oil Switches and Circuit Breakers.
B.S.S. No. 155. Contactor Starters for Electric Motors.
B.S.S. No. 157. Moulded Flat Top Insulating Bushes.
B.S.S. No. 158. Marking for Busbars and Connections.
B.S.S. No. 160. Slate Slabs for Electrical Purposes.
B.S.S. No. 166. List of Terms and Definitions for Radio Communication.
B.S.S. No. 167. Auto-transformer Starters (hand-operated pattern) for Electric Motors.
B.S.S. No. 173. Electric Performance of Traction Motors.

At the request of the Electrical Research Association, a Committee has recently been set up to prepare a British Standard Specification for Vulcanized Fibre.

Preparation of the Electrical Vocabulary is making steady progress and one Section of this, namely, "Radio Communication," has already been published as a separate document (B.S.S. No. 166).

(40) International Electrotechnical Commission.

A meeting of the Council of the Commission was held in Paris in December 1923, when Dr. C. O. Mailloux was elected Honorary President. Signor Guido Semenza was elected the new President and Colonel Crompton was re-appointed Honorary Secretary.

The Council of the Commission have appointed an Executive Committee consisting of the President of the Commission, the Honorary President, the Honorary Secretary and three Vice-Presidents. This Executive Committee will meet twice a year and assist the Central Office in co-ordinating the work of the National Committees.

(41) Benevolent Fund.

The Committee of Management of the Benevolent Fund of the Institution report that on the 31st December, 1923, the Capital Account of the Fund stood at £9 969 11s. 3d., and the accumulated income at £1 622 17s. 6d. The donations and subscriptions to the Fund in 1923 amounted to £636 10s. 1d.

In the course of 1923, 52 grants were made to 21 persons, amounting to a total of £1 034 2s. 4d.

With a view to stimulating and sustaining the interest of all members in the Fund it has been decided to publish in future each month in the *Journal* of the Institution a list of the contributions received during the previous month, together with the names of the contributors.

(42) Annual Accounts.

Excess of Income over Expenditure.—After making provision for contingencies as in the previous year, there is a margin to the good on the Revenue Account for 1923 of £3 957 11s. 7d. This amount, which has been carried to the credit of the General Fund, compares with £862 2s. 8d. in 1922, an increase of £3 095 8s. 11d.

Mortgages.—

	£	s.	d.
In the Accounts for 1922 these stood at	20 338	6	5
Amount of repayments during the year	5 536	7	1
They now stand at	£14 801	19	4

Assets.—Taking the Tothill-street property and the investments at cost, and the Institution building and lease, the library and furniture, etc., at the values standing in the books after writing off depreciation,

	£	s.	d.
the Assets amount to	130 437	9	11
against Liabilities	5 038	6	11
leaving a surplus of	£125 399	3	0
which, in comparison with that of the year 1922, viz.	114 399	2	1
shows an improvement of	£11 000	0	11

The balance of £125 399 3s. 0d. is made up as follows:—

Assets.

	£	s.	d.	£	s.	d.
Properties.						
Institution Building and Tothill-street Property	92 289	3	11			
Less Mortgages ..	14 801	19	4			
				77 487	4	7
Investments, Cash, etc.				44 867	15	9
Stock of Paper, Libraries and Furniture ..				8 082	9	7
				£130 437	9	11
Less *Liabilities.*						
Trust Fund Income Accounts	416	0	0			
Sundry Creditors ..	3 669	19	10			
Repairs Suspense Account	563	16	6			
Subscriptions received in advance	388	10	7			
				5 038	6	11
				£125 399	3	0

(43) The Institution and Bodies on which it is represented.

Appendix D shows in diagram form the organization of the Institution and the bodies on which it is represented.

APPENDIX A.

Membership of the Institution.

The changes in the membership since 1st April, 1923, are shown in the following table:—

	Hon. Mem.	Mem.	Assoc. Mem.	Grad.	Studt.	Assoc.	Total.	Total.
Totals at 1 April, 1923	10	1 849	4 735	1 056	2 869	392		10 911
Additions during the year:—								
Elected	..	14	74	147	661	5	901	
Reinstated	..	3	13	4	29	2	51	
Transferred to	1	44	76	92	..	1	214

APPENDIX B.

Meetings.

The following is a list of the meetings held during the past twelve months:—

Ordinary Meetings	18
Special General Meetings	2
Wireless Sectional Meetings	9
Informal Meetings	13
Council Meetings	15
Local Centres:—	
Irish	6
Mersey and North Wales (Liverpool)	8
North-Eastern	11
North Midland	9
North-Western	11
Scottish	6
South Midland	10
Western	10
Local Sub-Centres:—	
Dundee	8
East Midland	10
Sheffield	7
Tees-side	7
Students' Sections:—	
London	8
Birmingham	8
Leeds	13
Liverpool	9
Manchester	10
Newcastle	12
Scottish	5
Sheffield	7
Committees:—	
Benevolent Fund	6
Electricity in Agriculture	2
Electricity (Supply) Regulations	44
Committees (*cont.*):—	
Electricity in Mines	2
Electro-Chemistry and Electro-Metallurgy	3
Examinations (and Sub-Committee)	8
Finance (and Sub-Committee)	12
General Purposes	8
Informal Meetings	9
Library and Museum	2
Lighting and Power	3
Local Centres	5
Membership	8
Model General Conditions	3
Papers	8
Patent Law	2
Proving House	1
"Science Abstracts"	2
Ship Electrical Equipment (and Sub-Committee)	2
Telegraphs and Telephones	3
Traction	3
War Memorial	1
Wireless Section	6
Wiring Rules (and Sub-Committees)	20
Other Committees	13
Total	408

APPENDIX C.

THE ENGINEERING JOINT COUNCIL.

Established 1922.

The Engineering Joint Council has been formed under the following constitution by the following four Institutions:—

The Institution of Civil Engineers,
The Institution of Mechanical Engineers,
The Institution of Naval Architects,
The Institution of Electrical Engineers.

CONSTITUTION.

1. A Council to be entitled "The Engineering Joint Council" shall be formed. It shall consist of two members of the Council of each of the following Institutions in the first instance, appointed from time to time by their Councils severally:—

The Institution of Civil Engineers,
The Institution of Mechanical Engineers,
The Institution of Naval Architects,
The Institution of Electrical Engineers,

which shall be called the Founder Institutions.

2. The members of the Joint Council shall be appointed annually, and shall be eligible to serve for not more than four years consecutively. One of the first two appointed by each Institution shall serve for not more than two years, but shall be eligible for re-appointment for a further period of not more than four years consecutively.

3. The Chairman shall be elected annually by the Joint Council, and the Secretary of the Institution represented by the Chairman for the year shall act as Secretary of the Joint Council. The Chairman shall be chosen from the several Institutions in rotation.

4. The Joint Council shall consider matters referred to it by the Council of any one of the constituent Institutions. It shall not initiate proposals affecting the Institutions, and shall be an advisory body without executive powers.

The Engineering Joint Council have made the following Bye-Laws:—

BYE-LAWS.

I. Session and Meetings.

1. The Session shall commence on the 1st May of each year and continue until the 1st May of the following year.

2. At least two meetings in the year shall be held, one in November and the other in March, and additional meetings shall be held if and when considered desirable by the Chairman. At least two weeks' notice shall be given of the date upon which such meetings are to be held.

3. The Councils of the several Institutions forming the Joint Council shall be asked to nominate and communicate to the Secretary for that year, the names of their representatives on the Joint Council before the beginning of March in each year.

4. The Engineering Joint Council at the meeting in March shall elect the Chairman and appoint the Secretary for the Session commencing on the 1st May of that year.

5. At the commencement of the new Session the Secretary for the previous Session shall hand over to his successor in office all documents, books and papers relating to the Joint Council.

II. Proceedings of the Joint Council.

1. No decision, other than those provided for in Clauses 3 and 4 of this Section, shall be taken by the Joint Council on matters referred to them unless at least one-half of the Joint Council be present, and any decision to be effective must be confirmed at a subsequent meeting at which at least one-half of the Joint Council are present. Any such decision shall be communicated to the members of the Joint Council before the confirmatory meeting, and when confirmed shall be communicated to the Secretaries of the several Institutions represented on the Joint Council.

2. All matters other than those referred to in Clauses 3 and 4 of this Section shall be decided by a majority of those present and entitled to do so voting in favour thereof.

3. The Joint Council may admit other Institutions or Societies to representation on the Engineering Joint Council, provided that all the representatives on the Joint Council who are entitled to do so vote in favour of such admission and in like manner confirm such action at a subsequent meeting. The conditions under which any such Institution or Society shall be admitted, and the number of their representatives, if any, on the Joint Council, shall be determined by the Joint Council at the time of the admission of such Institution or Society.

4. The Engineering Joint Council may terminate the membership of any Institution or Society, admitted as in Clause 3 of this Section, if the representatives of all the other Institutions who are entitled to do so vote in favour of such a course, and in like manner confirm such action at a subsequent meeting.

5. The Joint Council shall have authority to make rules for its own guidance, provided they are not inconsistent with the Constitution and Bye-Laws.

III. The Secretary.

The Secretary shall keep all minutes of the meetings of the Joint Council, which shall be treated as confidential, and shall conduct the correspondence of the Joint Council.

IV. Expenditure.

Incidental expenses incurred by the Joint Council shall be defrayed by the Institution from which the Chairman and Secretary have been appointed for the time being, provided that the matter be brought up for consideration by the Joint Council year by year. The question of defraying extraordinary expenditure not included in the above shall be considered from time to time as it arises.

V. Withdrawal of an Institution or Society from the Engineering Joint Council.

Any Institution or Society may withdraw from membership of the Engineering Joint Council at the end of any sessional year, provided three months' written notice be given to the Secretary of the Engineering Joint Council by the Secretary of the Institution or Society concerned.

VI. Alteration of Bye-Laws.

No alteration or revision of the Bye-Laws shall become effective until it has received the approval of the Council of each of the Founder Institutions.

April 1923.

REPRESENTATION OF ENGINEERING INSTITUTIONS ON THE JOINT COUNCIL.

RULES.

The following Rules framed in accordance with the provisions of Section II, Clauses 3, 4 and 5, of the Bye-Laws, have been adopted by the Joint Council on 9th April, 1923 :—

1. For the purpose of admission to representation on the Joint Council, Institutions shall be grouped as follows :—

Group A.—Constituent Institutions, i.e. Institutions representing important branches of Engineering, who have adopted examinations or equivalent qualifications for admission to their corporate membership, and of which the number of corporate members is sufficiently large in the opinion of the Joint Council to justify admission to this Group. Institutions in this Group would have one representative on the Joint Council who will be entitled to vote.

Group B.—Affiliated Institutions, i.e. Institutions whose interests are already represented on the Joint Council (by reason of a large proportion of their members also belonging to the Founder Societies or to Constituent Institutions) and whose membership is not (in certain cases) necessarily confined to Engineers.

These Institutions shall have the right to refer questions to the Joint Council, who will invite a representative (who shall not, however, have a right to vote) to attend the meeting of the Joint Council at which such questions are under consideration.

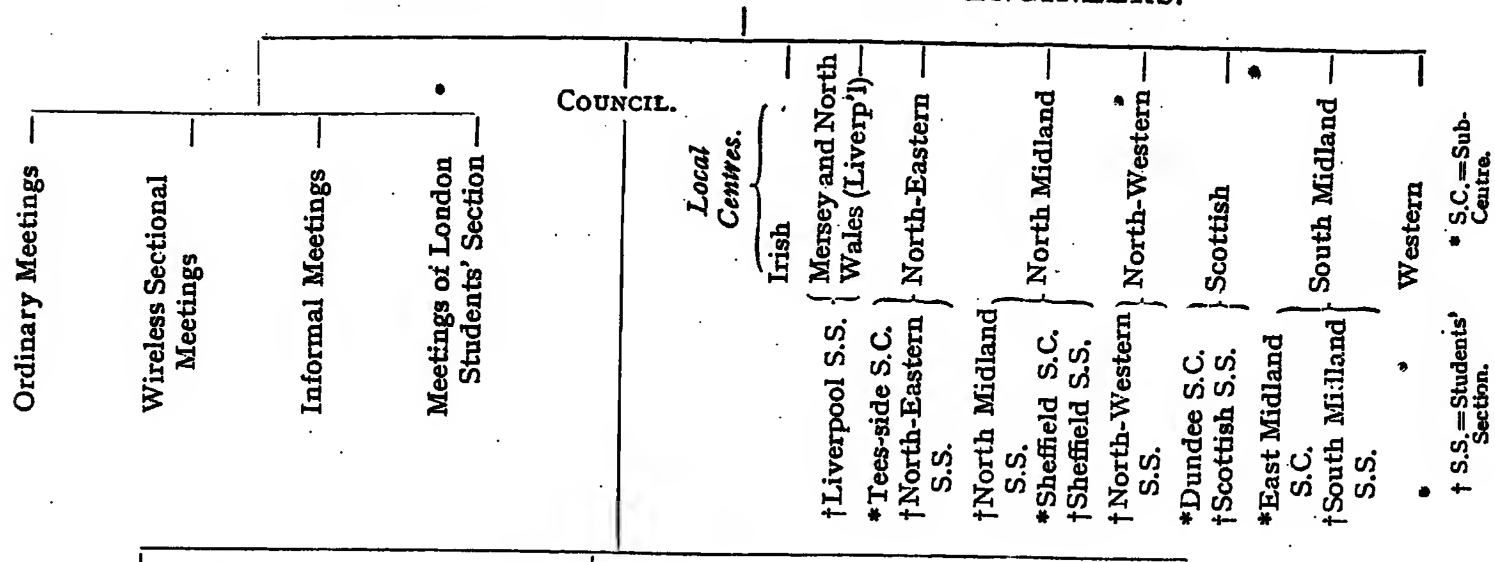
2. Institutions in Group B may be transferred to Group A (Constituent Institutions) when the standard of examinations and the number of corporate members justify such transfer in the opinion of the Joint Council.

3. Institutions desiring to be represented on the Joint Council shall make application directly to the Secretary of the Engineering Joint Council and not to the Secretary of any of the Founder Societies.

May 1923.

APPENDIX D.

THE INSTITUTION OF ELECTRICAL ENGINEERS.



Committees.
(*Standing.*)

Benevolent Fund
Electrical Appointments Board
Examinations
Finance
General Purposes
Informal Meetings
Library
Local Centres

* The above values are subject to depreciation.

We beg to report that we have audited the Balance Sheet of The Institution of Electrical Engineers, dated 31st December, 1923, and above set forth, together with the annexed Statements of Account. We have obtained all the information and explanations we have required. In our opinion the Statements are correct, and the Balance Sheet is properly drawn up so as to exhibit a true and correct view of the state of the Institution's affairs according to the best of our information and the explanations given to us and as shown by the books of the Institution.

Honorary Auditor.

DEVELOPMENT OF THE BELLINI-TOSI SYSTEM OF DIRECTION-FINDING IN THE BRITISH MERCANTILE MARINE.

By Commander J. A. SLEE, C.B.E., R.N. (Ret.), Member.

(*Paper first received* 17*th August*, 1923, *and in final form* 19*th January*, 1924; *read before the* WIRELESS SECTION 5*th March*, 1924.)

SUMMARY.

The paper gives an account of the various sources of error which have been encountered during the development of the Bellini-Tosi system of wireless direction-finding as an aid to navigation in the British mercantile marine. These errors can be isolated and their causes removed one by one.

The application of the instrument to the purposes of navigation is also dealt with, and the possible errors, external to the ship, which may be encountered are considered.

A table is attached showing the high degree of accuracy which has now been attained.

(1) RETROSPECT.

The following notes concern the development of direction-finding on the Bellini-Tosi system, in which two fixed loop aerials at right angles to one another are used in conjunction with a rotatable search coil. The results mentioned have been obtained with spark (as opposed to continuous-wave or interrupted continuous-wave) telegraphy.

The first attempts were made with loop aerials, each tuned independently to the frequency of the signal the direction of which it was desired to obtain, the loop aerials being very loosely coupled to the search coil and its circuits. This system, which had given admirable results on land, was found when fitted in an iron ship to be too difficult to work and to possess too grave errors of a quadrantal nature to be of practical value for navigational purposes, the only justification for its existence in the mercantile marine.

The method of using untuned loops, usually, though incorrectly, called aperiodic loops, was then resorted to, and promising results were at once obtained.

(2) ERRORS ENCOUNTERED.

(*a*) *Calibration error.*—In all that follows, the word "loop" is used to convey the idea of the whole arrangement used to absorb energy from the ether, including the field coil, lead-covered cable and junction boxes, as well as the simple loop itself. The capacity present in this circuit is a complex quantity, of which the greater part is the capacity between core and core of the lead-covered cable. Such a circuit has a well-marked natural frequency. The expression "simple loop" is used to denote that portion of the whole which is purposely opened out so as to enclose a considerable area.

An analysis of the nature of the errors obtained when identical loops were used brought forward the fundamental conception on which all subsequent work has been based; that is to say, the idea that the ship herself with all her rigging might be imagined to be replaced by a fictitious simple loop lying in the vertical plane and parallel to the keel line of the vessel. The action of this fictitious simple loop is taken into consideration when determining the area of the fore-and-aft loop of the complete direction-finder system.

Since this fictitious simple loop is fore-and-aft, and since its effects cannot be ignored or eliminated and must not be allowed to produce an effect equivalent to mutual induction between the two tangible simple loops of the aerial system, it is clear that one of the two tangible simple loops must be parallel to the fictitious simple loop, that is to say, fore-and-aft. Therefore the other tangible simple loop must be athwartships.

Since the tangible fore-and-aft simple loop is coplanar with the fictitious ship simple loop, there will be considerable coupling between these two, and therefore the current circulating round the tangible fore-and-aft loop will, under any given conditions, be greater in some geometrical proportion than would be expected from a consideration of the dimensions of the fore-and-aft loop alone.

If identical loops were used, the result of the above would be that the directions as observed would tend to be crowded towards the fore-and-aft line, the error being a maximum when the correct relative bearing is on the bow or quarter, and vanishing when the correct relative bearing is abeam, or ahead, or astern.

This error, which is now in practice usually given the name of "calibration error," can be completely removed by reducing the area of the tangible fore-and-aft loop, or by adding to its impedance, or by a combination of these two methods. It is usual in practice to employ the largest convenient thwartship loop (up to an area of about 400 sq. ft.), and to adjust the size of the fore-and-aft loop until a slight calibration error remains, finally removing it by adding impedance equally to the two limbs of the fore-and-aft loop.

(*b*) *Loop-tuning error.*—The previous paragraph shows that the two loops are essentially of different dimensions and therefore, in all probability, of different natural frequencies. If both the loops are very considerably different in frequency from that of the signal to be received, the current circulating in each will be almost in quadrature with the voltage applied by the incoming wave, and therefore the currents flowing round the two loops will be almost exactly in phase with one another. Further, the value of the current reached in each loop will be almost exactly proportional to the voltage applied to that loop by the incoming wave.

If the first of these two conditions (similarity of

phase of circulating currents) is not made good, the familiar rotating-field effect will be produced on the search coil. Since the position of zero coupling between the search coil and the field coils which are connected to the loops is the index by which directions are measured, the effect of such a rotating field is to fog the observation by obscuring the position of zero signals.

Also, if one loop happened to be of the same, or very nearly the same, frequency as the incoming wave, the circulating current round it would be greater, in proportion to the voltage applied, than the current in the other loop (by hypothesis of different frequency) and therefore less nearly in resonance with the incoming wave. Therefore the proportionality between impressed voltage and circulating current will be different in the two loops, and a quadrantal error similar in effect to calibration error will result. Its extent will vary with alteration of wave-length of the received signal, and will vanish if the frequency of the incoming wave is midway between the frequencies of the two loops. As such an error varies with wave-length, it is quite inadmissible. These two effects of one cause are in practice lumped together under the name of "loop-tuning error." They can be completely avoided by fitting loops of suitable dimensions in the first place, and are almost unheard-of in practice.

(*c*) *Lack-of-symmetry error.*—If we consider the current flowing in any part of a vertical loop under the influence of an incoming ether wave, it is clear that there are two distinct components. One is a circulating current round the loop. The cause of this current is as follows :—

If we imagine each half of the simple loop from apex to junction box to be replaced by its phantom vertical projection, the incoming wave will induce a voltage between the two ends of each phantom projection, the potential to which each of these four ends is raised at any instant, by effects of the incoming wave, being different. If the plane of the simple loop is not parallel to the wave-front, the voltages induced in the two phantom vertical projections will be unequal, and the difference between them is the useful voltage available for the production of a circulating current. For brevity, this current is in practice called the "loop current," and clearly the instantaneous value of the voltage causing it depends upon the height and distance apart of the phantom projections (in practice, the area of the loop) and the rate of change of intensity of electric and magnetic stresses caused by the incoming wave at the instant under consideration.

The other component is a simple alternating current flowing in both sides of the complete loop from the apex to the mid-point of the field coils, the actual current distribution being to a great extent governed by the capacity to earth of the various parts of the loop. For the sake of brevity this current is in practice called the "plain current," and the instantaneous voltage to which it is due is caused by the instantaneous value of the electric and magnetic stresses set up by the incoming wave.

Hence we see that the "loop" voltage and the "plain" voltage are in quadrature, the loop current leading or lagging relatively to the loop voltage in accordance with the electrical constants of the loop circuit, while the plain current will lead or lag relatively to the plain voltage in accordance with the electrical constants of the plain circuit.

If the construction of the loop and its attendant field coil is perfectly symmetrical electrically, the plain current will be equally divided between the two halves of the loop, and the effects of each half of the field coil on the search coil will neutralize one another.

Absence of this condition of symmetry is the most troublesome, the most common, and the most dangerous source of error. It is generally called in practice "lack-of-symmetry" error, and the satisfactory operation of direction-finders on board ship is almost entirely a question of the success with which causes tending to produce or accentuate this error can be counteracted.

In order to protect the insulation of the connections between the loops and the direction-finder instrument, and also the windings of the field coils themselves, from the effects of accumulated static charges or the induction due to transmission, the centre of each field winding was at first connected direct to earth. This direct connection accentuated the effects of lack of symmetry, and has since been replaced by a suitable inductive choke.

The causes of lack of symmetry are twofold: "permanent" lack of symmetry due to unequal distribution of any electrical dimensions between the two sides of a loop, which would result in unequal impedance in the two halves, measured from apex to mid-point; and "inductive" lack of symmetry due to re-radiation and/or induction from individual conducting portions of the ship's structure, which may have unequal effects upon the two halves of a loop. The effects of the former are apparent, irrespective of the strength of signals, but the effects of the latter increase with the strength of signals and are often only noticeable with very strong signals. This state of affairs appears to be explained as follows :—

Consider an athwartship loop which is inductively unsymmetrical, the relative bearing being considered to be right ahead. There is zero loop current in this loop, but the effect of inductive lack of symmetry is to cause an unequal distribution of plain current between its two halves, and therefore there is a magnetic coupling between the field coil and the search coil. The effects of this current may be too slight to deflect the resultant magnetic field through the field coils to any appreciable extent, and no error is then observable, but when the effect of the inductive lack of symmetry becomes sufficient to deflect the resultant magnetic field through the field coils the error begins to appear. There is, in short, a marked threshold effect observable in cases of inductive lack of symmetry. In cases of permanent lack of symmetry, the disturbance due to unequal distribution of plain current increases in the same proportion as the loop current, being due directly to the plain voltage and not to the effects of an outside conductor itself under the influence of the wave, and no threshold effect is observed. Inductive lack of symmetry is the source of the most elusive and the most dangerous errors which have been experienced in the application of direction-finding to navigation.

Having decided on the position of the loops, the next point is to decide on their form. This is a matter of but very little importance provided that extremes are avoided, but it is very desirable that there should be a pronounced geometrical apex to each loop. For sea-going work it is essential that the thwartship loop should have a well-marked apex, and it is advisable that the fore-and-aft loop should have one also. The reason is simple. Consider a flat-topped thwartship loop. If the vessel is on an even keel the top of the loop is horizontal and the electrical apex is in the centre of the horizontal limb. If now the ship heels over, even to a very small angle, the apex becomes the weather corner and symmetry is destroyed. The same applies, but in a less degree, to the fore-and-aft loop.

Lack-of-symmetry error is the only error which can make a bearing appear to be in the wrong quadrant, and lack of symmetry in the thwartship loop may well be sufficient to make a bearing appear to be on the wrong bow.

If it can be assumed that the loops are symmetrically rigged truly fore-and-aft and athwartships, and with the geometric axis of each loop directly over the point where the ends of the loop join its cable, and that they can be kept taut, then the possibility of errors due to lack of symmetry is reduced to a minimum; and as permanent lack of symmetry can be detected by easily applied internal tests of sufficient delicacy, the actual danger due to lack of symmetry in all its forms is zero.

Lack-of-symmetry error takes many forms according to its extent, and whether one or both loops are at fault. The strange diversity of results is hardly worth recording now that symmetry testing has been established, but it is worth noting that a combination of a slight lack-of-symmetry error and a slight electrostatic error often has the effect of leaving one zero accurate and sharp and the other very "woolly." It is sometimes necessary to accept this as a temporary measure, and to let well alone.

(*d*) *Plain tuning error*.—The remaining inherent error is due to the effects caused by the frequency of one loop, viewed as a simple plain aerial, being very nearly in tune with the incoming wave when the frequency of the other loop is somewhat less nearly in tune. This error is comparable with loop-tuning error and is negligible if loops of proper dimensions are used. The adoption of the inductive choke mentioned in the preceding paragraph renders the loops viewed as "plain" aerials practically aperiodic (in the true sense of the word) and is now almost unheard of. The effects are zero if perfect symmetry exists; if not, it accentuates the lack-of-symmetry error on certain waves. It is generally called "plain tuning error."

(*e*) *Electrostatic error*.—There are also two inherent instrumental errors. Of these the more important is the result of superposing the stray capacity coupling between the field coils and the search coil upon the magnetic coupling. The effect of this stray capacity coupling is to distort both positions of zero resultant coupling, and, although the line bisecting the angle between the observed zeros is at right angles to the proper zero due to magnetic coupling only, the presence of this error is detrimental to rapid and accurate work. It can be practically annihilated by the interposition of an earthed shield between the windings of the transformer connecting the search coil with the tuning condenser. It is most noticeable when the stray capacity is large in proportion to the tuning capacity, that is to say on the shorter waves, when the tuning capacity is very small. This is commonly called the electrostatic error.

(*f*) *Coupling error*.—The second instrumental error is due to the fact that as the search coil is rotated the coupling between the search coil and either of the field coils does not vary exactly in accordance with a cosine curve. By spreading out the windings of the search coil on one side of its former in a **V** shape, this error, which is never as much as 1°, can be made to reach its maximum and fall to zero eight times in the 360°, and so long as "swing" readings are used it is truly negligible, and in practice no notice is taken of it. This is the cause of the important difference in practical working between systems employing "tuned" and "untuned" loops. In the former case the arc through which the search coil can be moved, while still preserving inaudibility of a naturally good signal, is very small—perhaps only 2° to 3°—and under these conditions what are familiarly known as "sitting" readings can be taken. In the latter case the arc of inaudibility is usually 20°–40° and "sitting" readings are impossible; only swing readings can be used, and these of necessity eliminate the second instrumental error.

The colloquial term "swing readings" means observing the position of the pointer which gives equal strength of signals on either side of the arc of inaudibility, and taking the mean of these two positions as the position of true zero. It is usual to observe the position in which the signal just becomes inaudible. Bearings are perfectly reliable with vanishing points up to 60° apart.

(3) Construction of Loops.

From the foregoing it is clear that, given a properly constructed direction-finder, everything depends upon the erection of electrically symmetrical loops of the correct relative areas, the planes of the loops being necessarily vertical and at right angles to one another. One must be exactly fore-and-aft and the other exactly athwartships, but there is no reason why their planes should intersect, and no practical disadvantage is found if they do not do so, so long as the distance between their axes is small in comparison with a quarter wavelength.

It should be noted that there is no obvious theoretical reason why the fore-and-aft loop should be on the centre line of the ship, though common sense indicates that it is desirable to place it there. No experiments have been tried with fore-and-aft loops out of the centre line, as every effort has been concentrated on producing a seamanlike and trustworthy aid to navigation, and no opportunity has offered for academic investigation. One fore-and-aft loop accidentally fitted a little off the centre line gave indifferent results.

Under ordinary sea-going conditions a subsidiary difficulty is experienced. If the loops cannot be made permanent, but have to be lowered and re-hoisted

frequently, there is a great likelihood of the symmetry being destroyed in the process. This has been found to be a very real and serious cause of trouble.

Summarizing the above, it is clear that the main practical difficulty lies in the selection of a suitable position for the loops and in the appropriate arrangements for rigging them. Before selecting the position of the loops it is first necessary to decide on the position of the direction-finding instrument. As far as the mercantile marine is concerned, it is highly desirable to have the instrument in the wireless room. It should be under the charge of the telegraphist and always available for practice, and when using it he should be in his own place and not an intruder among the navigating staff. The position of the direction-finding instrument must to some extent limit the choice of positions for the loops, on account of the capacity of the connecting leads.

For this purpose twin lead-covered paper-insulated cable is used, the cores each consisting of one strand of 20 L.S.G. copper, and with this cable a total length of 100 feet is permissible from the direction-finder to the commencement of the loops. This figure is based on the assumption that the loops are to be large enough to allow good bearings to be obtained up to a distance of 100 miles on spark waves between 400 and 1 000 m, and small enough to avoid "loop-tuning" error on 400 m.

Experience shows that the larger the ship the larger should the loops be for a high degree of accuracy. Small loops, even down to an area of 70 sq. ft., have given accurate service at ranges up to 30 miles in small ships, though they are not accurate in large ships. The reason for this appears to be best explained if the state of the electric field among the rigging, funnel, boat gear, etc., of a large ship be regarded as a mass of eddies, in which loops large in proportion to their surroundings are affected by many such eddies tending to balance one another and thus give an accurate average result, whereas loops small in comparison with their surroundings are more likely to feel the effect of a single eddy and thus give inaccurate bearings.

Experience has shown that loops work well for all frequencies lower than their own natural frequency, but they are very unsatisfactory for frequencies higher than their own. Obviously, the capacity from core to core of the lead-covered cables is a very important factor in determining the "loop" frequency of each aerial, and the capacity from cores to lead covering is of similar importance in determining the "plain" frequency of each aerial. The core-to-core capacity also acts as a shunt to the field coils, and, briefly speaking, the shorter the cables the better are the results.

Having complied with the limits imposed by the permissible length of cable, a search must be made for some place where the loops can be erected and in which it will not be necessary to lower them. For work under mercantile marine conditions as outlined above (400 to 1 000 m spark), the area of the loops should lie between 200 and 400 sq. ft.

No part of the loop should come within 6 ft. of earthed metal, and if the disposition of such earthed metal is not symmetrical about the axis of the loop this distance must be increased to at least 12 ft. This figure is not yet definitely fixed, but there is clear evidence of evil effects at distances up to 10 ft., and it is quite possible that the safe distance may be as great as 20 ft.

If unsymmetrical objects, such as ventilators or hatches, are unavoidable, they must be screened by the interposition of an earthed plane—say wires 1 ft. apart —at least 6 ft. wide and symmetrically disposed on each side of the axis of the loop which it is intended to shield. Satisfactory results are obtained if the screen is midway between the nearest limb of the loop and the object from which it is to be shielded. If these precautions are neglected, evanescent errors may occur due to, for instance, the opening and shutting of large iron skylights, turning of ventilators, etc.

By far the best construction for loops, working within the limits of wave-length mentioned in this paper, is to support them on five light spars, so that the dimensions of the loop are about 8 ft. high by 30–40 ft. wide, the apex being about 6 ft. above the upper outer corners. Spars about 25 ft. long with

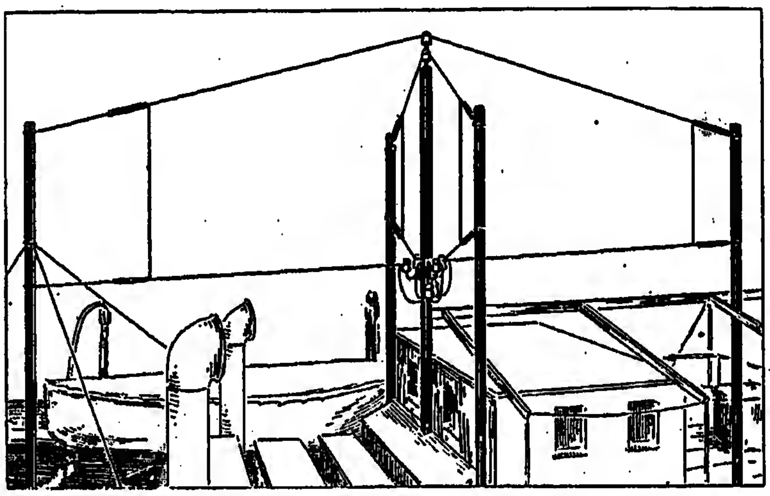

FIG. 1.—Direction-finder aerials supported on posts; s.s. "Motagua."

6-in. heel tapering to 4-in. heads will generally meet the case, or a bridge can take the place of one of the spars, or even of two of them. These spars must be placed with accuracy, the error of alignment of the sheaves not being allowed to exceed 1 in. Such an outfit can, as a rule, be made absolutely permanent, and is independent of changes of temperature and the working of the ship in a seaway. Figs. 1 to 3 show various methods of attaching aerials.

The insulation of the apex of the loops is not of very great importance, but at all other points at least a 10-in. surface should be provided.

Very considerable trouble has been experienced in the past due to injury to the lead-covered cable between the loops and the direction-finder instrument. These are now generally run in steel conduits. Armoured lead-covered cable has been tried, and is satisfactory if either the lead sheathing or the armouring can be earthed at intervals of not more than 20 ft.; but, on the whole, plain lead-covered wire in steel conduits is the most satisfactory.

The ends of the paper cable are protected by cast-iron bifurcating boxes of the usual commercial pattern.

When close to a compass wooden boxes are used. One of the minor difficulties of installing a direction-finder set in a ship is the protection of the ends of the paper-insulated cable from damp during the work of fitting.

After the loops are erected and have been proved to be geometrically correct and good for continuity and high insulation, they should be excited singly by a shunted buzzer as loops (not as plain aerials) and their wave-length checked. This should be below 400 m, preferably below 350.

The symmetry test should then be applied and, if the loops prove correct, the work of calibration can be commenced. But it is absolutely useless to attempt to calibrate until loop-tuning and lack-of-symmetry errors have been eliminated.

(4) Testing for Symmetry.

The principles on which a symmetry tester is arranged are as follows:

Consider a single loop with its field coil. Let this be excited as a "plain" aerial—say by means of a shunted buzzer connected to a straight lead between the mid-point of its field coil and earth. If the loop under test is symmetrical, current will be exactly divided between the two halves of the field coil and, consequently, there will be zero resultant magnetic coupling between the field coil and the search coil. There will be a certain electrostatic coupling between the field and search coils, which will be greatest when the search-coil windings are nearest to the field coil under consideration. If the search coil is turned round, clear signals will be heard in the telephones, and the strength of signals should be adjusted by means of the coupling to the shunted buzzer until they are just comfortably audible at the maximum positions. If, now, one side of the loop be disconnected—giving the maximum lack of symmetry—signals will become very much louder and will be audible nearly all round the scale. A very slight lack of symmetry will cause a magnetic coupling between the field and the search coils, which will have its maximum effect in the same position as the electrostatic coupling. As the magnetic coupling is dependent on the sense of the windings, and the electrostatic coupling is not, these two will be in conjunction in one position of the search coil and in opposition in the opposite position, a slight lack of symmetry being betrayed by the fact that the signals are not of equal strength when the pointer is at these two opposite positions on the scale.

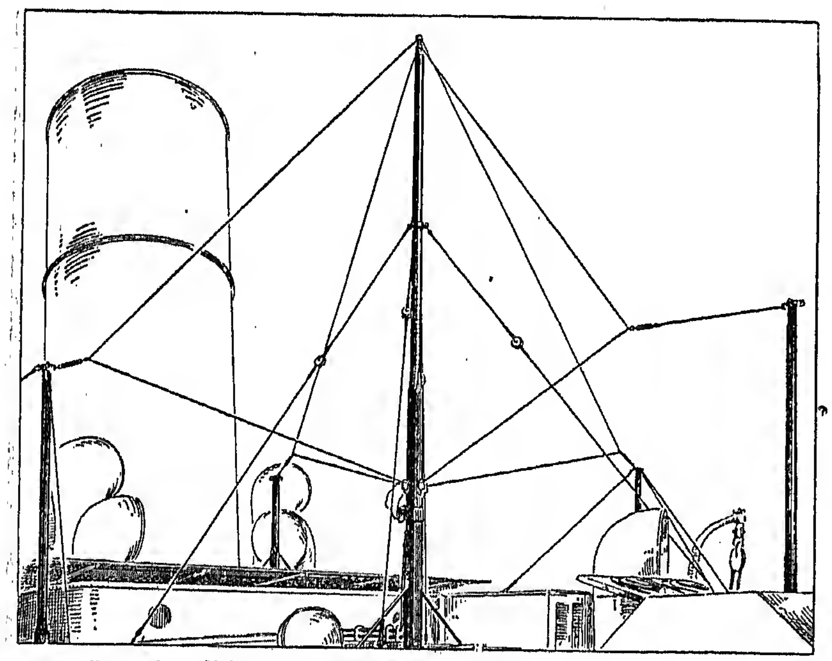

Fig. 2.—Direction-finder aerials fitted on posts; s.s. "Mooltan."

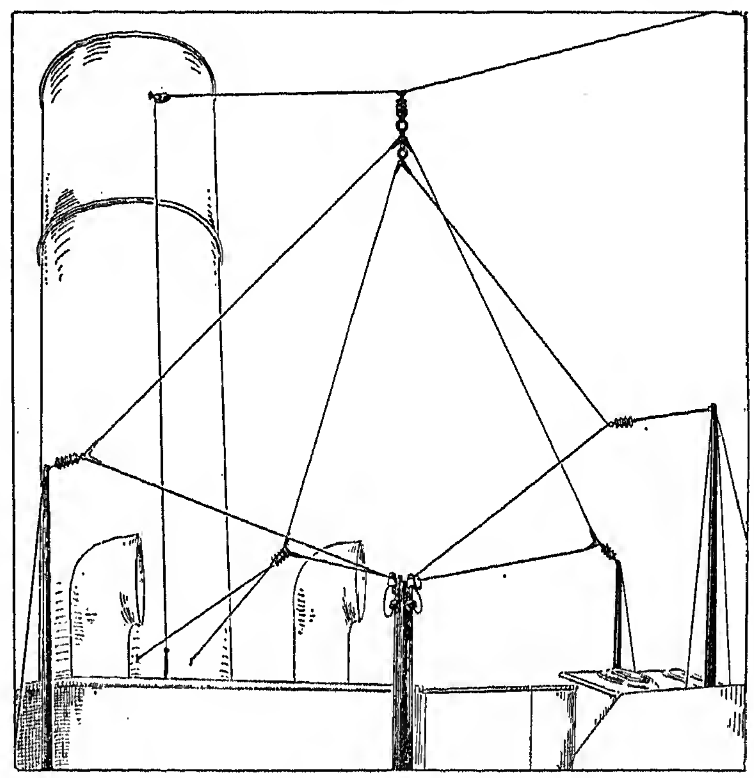

Fig. 3.—Direction-finder aerial hung from jumper stay.

When both loops are joined to their field coils and the whole system is excited through its common mid-point as above, it might be expected that signals would (under suitable conditions of buzzer coupling) be just audible when the search coil was exactly inside each field coil, so giving four positions of audibility at 0°, 90°, 180° and 270° (scale marked with 0° right ahead), but this is not the case, as the two combined electrostatic couplings have their maximum intensity at 45°, 135°, 225° and 315°. This is possibly a peculiarity of construction of the instruments with which all available experience has been gained.

Hence the result of exciting a pair of properly symmetrical loops is to produce zones of clearly audible signals when the pointer is near to 45°, 135°, 225°, 315°, with well-marked silent zones around 0°, 90°, 180°, 270°. If one of the loops is but very little out of symmetry the silent zone about one of these points is obscured, and signals at one pair of 45° are louder than at the other, with the result that signals become audible over a wide band about 0° and 180° (or 90° and 270°) with ill-defined minima between.

It has been found in practice that if the lack of symmetry is such that the zero is lost at 0°, 90°, 270° or 360° without destroying the perceptible maxima at the 45° positions, bearings will still be quite accurate when the mid-point is used unearthed, except for its static leak.

To sum up :—

(*a*) Perfect symmetry is indicated by signals of equal strength at the four 45° positions, with clear zeros between.

(*b*) Very slight lack of symmetry is indicated by signals at one pair of 45° positions being stronger than at the other pair, clear zeros still existing.

(*c*) Slight lack of symmetry is indicated by signals as at (*a*), but with the zero between the loudest positions obscured.

Bearings are still practicable under any of the above, provided that the mid-point is not earthed.

As the lack of symmetry becomes greater, the maxima at the 45° positions disappear, loudest signals appearing with the pointer at one of the 90° positions. In all cases signals are loudest when the search coil is under the field coil of the defective loop.

These symmetry tests are very critical and easy to apply. They disclose any doubtful contact or poor insulation, as well as uneven distribution of inductance or capacity. Unhappily, they do nothing towards the detection of inductive lack of symmetry of the magnitude likely to be met with at sea, which can only be tested for the observation of external bearings with very strong signals.

(5) Calibration.

Calibration is perfectly simple provided that the ship is well clear of cranes, sheds, etc. A station having a bow or quarter bearing should be selected, and if the observed bearing is too near the fore-and-aft line the fore-and-aft loop must be reduced—or the impedance increased—until the bearing is correct. If all other errors have been eliminated, the correction of a single bow or quarter bearing implies accuracy all round, but it is as well to take some check observations.

Under practical conditions the fore-and-aft loop is usually about four-fifths the area of the thwartship loop, and a reduction of 1 ft. on each side of the bottom of the fore-and-aft loop will produce a correction of about 1° in a bow or quarter bearing. Such figures are empirical and very rough, but they give some idea of the state of affairs.

Calibration can be carried out only on or very near the bow and quarter bearings.

The final external test is for inductive lack of symmetry, which should be carried out with very strong signals very nearly right ahead and on the beam. In the absence of errors due to this cause, the direction-finder can be trusted, but it must be remembered that the loops, and especially the lower parts, are almost as sensitive as a magnetic compass to the influence of external objects. A pile of Carless rafts placed temporarily under one limb of a loop, and a wet signal-halyard passing near one limb, have been recorded as producing errors of 5°, and a wire whistle-lanyard passing near one side of the fore-and-aft loop has been identified as the cause of an error of 14°.

It is well established that under conditions in which all the above can be eliminated, the errors of a Bellini-Tosi direction-finder need never exceed 1°.

When using a direction-finder in a ship at sea it is imperative that the main aerial shall be completely disconnected from earth. Otherwise, large errors of a quadrantal nature will be introduced. If the main aerial passes close to either of the loops it is not sufficient to disconnect between the transmitting apparatus and the earth connections; the main aerial must be disconnected immediately it enters the wireless room. The reason for this is that there is sufficient stray capacity in the transmitter to allow so much current to flow in the main aerial that the resultant "loop" current is affected.

Calibration cannot be completed if the ship is lying near to cranes or dock sheds, although an approximate result can be obtained. The work must be completed with the ship at sea.

The symmetry tester will reveal the impossibility of calibration. A pair of loops which give excellent results, and which test perfectly for symmetry when the ship is at sea, will appear to be hopelessly at fault if the ship is near to cranes, etc. The symptoms are different from those of slightly unsymmetrical loops—the usual effect being that the positions of all zero signals are slewed round bodily about 20°.

(6) Application.

Having established a direction-finder in correct adjustment, the problems of making full use of it as an aid to navigation can be tackled. The outstanding point is that a direction-finder takes relative great-circle bearings, that is to say, great-circle bearings relative to the keel line of the ship. These must be converted into true mercatorial bearings before they are of any use for navigation. If the ship is yawing, the observation of the direction of the ship's head at the moment when the bearing was taken may be rather vague. The usual practice is for the operator to ring a bell when the direction-finder bearing is taken and for the direction of the ship's head by compass to be noted when the bell rings; and considerable combined practice between bridge and wireless room is necessary before the gap between a good direction-finder bearing and a serviceable true bearing can be filled up.

Taking all the above into account, for the purpose of making up the attached tables bearings are reckoned as being "correct" if they do not err by more than 2° from that worked back from a recent position by observation, 1° being allowed for residual direction-finder errors and operator's observation, and 1° for errors developing in the operation of translating the direction-finder bearing into a true bearing.

Direction-finder bearings at distances of over 50 miles are not as a rule of any great service, and at distances over 100 miles they are only a rough guide. This is not because of the liability to error being increased, but because the fix so obtained is so very rough in comparison with older established methods of navigation.

The position is considerably improved in ships where a gyro-compass repeater is installed in the wireless room. In such cases a "true bearing indicator" is fitted whereby the bearing is read off on the face of the repeater instead of on the direction-finder scale, and the true bearing can be arrived at in one operation.

TABLE.

Record of Working of Ships' Direction-Finders.

Name of vessel	Date fitted	1 September to 31 December, 1921		1 January to 30 April, 1922		1 May to 31 August, 1922		1 September to 31 December, 1922		1 January to 30 April, 1923		1 May to 31 August, 1923		September to 31 December, 1923

* With reference to the last two columns, i.e. 1 May, 1923, to 31 Dec., 1923, the charts of bad bearing-arcs in St. Lawrence and English Channel districts were available, and bearings taken in these bad arcs are not included in the results given above.

† No reports received. ‡ Working satisfactorily. No details available. § Fault developed and removed.

For the first 6 months of 1924, reports were received from 69 ships showing:—

Total number of bearings taken	1 679
Total number of correct bearings	1 530
Total percentage correct..	91

It is obvious that the measurement of "direction" is in fact a measurement of the direction in which the plane of the advancing wave-front lies, and if this is not at right angles to the line of advance of the wave the direction as observed will be subject to error. Any such distortion of wave-front must introduce errors which cannot be detected at the receiver, and the well-known "land effect" and "night effect" are the common manifestation of this wave distortion. Night effect is generally accompanied by an unusual "woolliness" of zeros, but there is nothing to warn the observer of land effect except the general track of the wave when laid off on the chart. This is clearly the business of the navigating staff and not of the telegraphist, and more definite knowledge of the subject is required. Certain stations have a reputation for bad bearings, but there is not sufficient first-class evidence available to allow of a comprehensive statement being drawn up. It appears, in fact, as though land effect does not always occur, and certainly it varies considerably in extent. The general idea emerging from the records is that it occurs in two sets of circumstances:—

(a) When the line of bearing cuts a coast line—high or low—at an acute angle, say less than 20°; and

(b) When high land intervenes close to the receiver or transmitter.

It may be remarked that, so far, no effects have been associated with ice or fog banks.

An attempt has been made to overcome the difficulty of translating great-circle bearings into rhumb-line bearings by three methods: (1) Gnomonic charts are issued on which the great circles appear as straight lines; (2) a "half-convergency" table is issued from which the correction can be ascertained; (3) a "half-convergency" diagram is supplied from which the correction can be extracted. As a matter of navigation this correction is not of much value, as bearings at over 70 miles are seldom really used, and under 70 miles the correction is too small to be of any account.

It is worth noting that if two true bearings are laid off with station pointers on a gnomonic chart, the result amounts to a three-point fix, because the true north point forms the third bearing. When all is said and done, however, deep-sea navigation is not the most important zone of usefulness of a direction-finder.

The typical direction-finder as described gives an ambiguous result, there being no distinction between a bearing and its complement. In order to distinguish this point, direction-finder instruments are now fitted with a sense-finder, which is a form of the ordinary "heart-shape" receiver. As fitted in most ships the heart-shape diagram is by no means true and the zero not as a rule good, and it is only used as an indication.

It is doubtful whether this sense-finding is of much real use for fixing the position of a ship, but it is very useful when working through cross-traffic in fog and has sometimes been of great value in helping to pick up a vessel in distress which has been badly out of her reckoning and has announced a very bad position.

All remarks on direction-finding have so far been made with sole reference to spark telegraphy. Bearings taken of continuous-wave stations are very crisp and clear, but the wandering due to "night effect" takes place at times to so great an extent as to make bearings of continuous-wave stations quite useless for navigational purposes. This is usually the case after dark.

If a sense-finder is used, and if the plain component is balanced so as to give an accurate zero, then the position of that zero is not subject to wandering. The chief trouble lies in the fact that the rate of reduction in signal strength is not the same on both sides of zero, and therefore the position of zero is not midway between the vanishing points. Hence it is practically impossible to fix the position of zero of a continuous-wave signal with sufficient accuracy for navigational purposes.

The table on page 549 is a précis of the record progress made during the last two years in the adaptation of the direction-finder to the purposes of navigation in the mercantile marine. It consists of the details of the working of 12 ships taken at random from among 99, the totals for the whole 99 being shown at the foot of the columns. Some difficulty has been experienced in compiling this table, as reports are not perfectly regular and are not always fully detailed.

Bearings recorded as inaccurate include all causes of error, unless the direction-finder is definitely known to be out of action. "Night effect" is also included, but, since the approximate positions of "bad" areas have been promulgated, bearings which have been taken in known "bad" areas have been excluded from the list.

Discussion before the Wireless Section, 5 March, 1924.

Admiral of the Fleet Sir H. B. Jackson: The paper is almost supplementary to that recently read * by Mr. Horton on similar stations in the Navy. It is also supplementary to the numerous ones on errors in direction-finding stations on shore. These papers all point to this conclusion: if a direction-finding station is erected in a really good position on or very near the sea, well removed from masses of metal or from lengthy conductors, it can be depended upon to obtain accurate readings by day or night of the direction of a transmitting station at distances up to, say, 100 miles over sea, and this is independent of the type of receiving apparatus installed. I am frequently asked by shipowners and port authorities as to this, and that is the answer which I give them. I hope that the paper will enable those responsible for fitting ships and shore stations with direction-finding sets to make up their minds that they can safely do so, with the confidence that they will get good return for their expenditure;

* *Journal I.E.E.*, 1923, vol. 61, p. 1049.

but, on their part, they must allow the wireless experts a fair chance of correcting its errors and adjusting the set, just as much as they would in the case of their ship's compasses. I hope that the discussion will have the effect of enabling us to say whether continuous-wave transmission is as dependable as damped waves for direction-finding bearings directly over the sea, as the point is of great importance in view of the forthcoming International Conference on allocation of frequencies, decrements, etc., for direction-finding stations. It is difficult to understand why a continuous wave when passing over the open sea should be refracted either more or less than a damped wave of the same frequency. If it appears to be so, may not this be due to the method of reception, or to the environment of the loop, or to inadequate shielding from detached metallic masses on board, or to rolling or pitching, or, again, to changes in the conductivity of that fictitious loop formed by the ship's masts, rigging, rope gear, etc., which may have an adverse effect on the accuracy of bearings with any type of transmission? This cause of possible error has an important bearing on the point as to whether bearings had better be taken on board ship or taken on shore and signalled to the ship. There are evidently arguments in favour of each method, but I look forward with some confidence to the time when bearings will be taken on a ship without the necessity of employing special apparatus which may be affected by changes such as those mentioned by the author.

Mr. L. Bainbridge-Bell: I have followed the paper with great interest as I have been working for some time on similar problems. I have, however, always worked with rotating coils which move in the actual field due to the incoming waves, and not in an artificial field such as is used in the Bellini-Tosi system, and the main thing that strikes me on reading the paper is the number of possible causes of error liable to be introduced into the Bellini-Tosi system on account of the greater number of links in the chain between the incoming wave and the receiver—I mean the extra errors which can be introduced by the Bellini-Tosi aerials. By using rotating aerials the only correction which has to be applied is that for the quadrantal error, or, as the author calls it, the calibration error. There is one point which has not been mentioned, viz. the variation of this calibration error with the variation of draught of the ship. In the *Radio Review* for August and September 1920 the question of calibration error was examined theoretically by Commandant Réné Mesny. He treated the ship as a semi-cylinder with its axis on the water line, and he developed a formula which gave results agreeing with his observations. It would therefore appear that the calibration error is due only to that part of the ship which is above the water line. In a certain ship in which I carried out experiments, the maximum error on the bow (45° off the line of the ship) changed from 5° to 9° when the draught of the ship varied from 27 feet to 16 feet. I should like to know how this variation in error (which corresponds to the variation in the error of the fictitious loop of the author) would be allowed for in the Bellini-Tosi system. In a footnote to the table in the paper, mention is made of particulars of bad bearing-arcs in certain places in the St. Lawrence and in the English Channel. I am of the opinion that all ships experiencing definite bad errors of operation should, as a matter of routine, report them to the Mercantile Marine Department of the Board of Trade for insertion in Notices to Mariners. Finally, I should like to know if it has not been found that the bad bearings are more noticeable when the ship is close to the wireless station from which it has taken the bearing, and that these bad bearing-arcs vanish when the ship is at a great distance, say 200 miles, from the wireless station.

Professor C. L. Fortescue: With regard to the "swing" readings mentioned by the author, it appears that a "silence" zone covering 60° is very large for any reasonable degree of accuracy to be obtained. The most important point raised, however, is that which has already been touched upon by previous speakers, namely, the accuracy with which directions can be fixed by means of continuous-wave signals. Many of the difficulties to be expected from "beacon" stations would be eliminated if the continuous wave could be safely used. It has been suggested that the receiving apparatus is responsible for the observed errors, but even where the greatest care has been taken there seem still to be unexplained inaccuracies when working with continuous-wave stations.

Mr. R. Keen: Such a paper as this must of necessity be of the greatest interest to all who are concerned with direction-finding and wireless navigation at sea, and is of particular value in that the information is based on the actual experience with a hundred or more ships in which the Bellini-Tosi system has been operating under commercial conditions and with a satisfactory degree of accuracy. Some of the troubles experienced by the author in ships are common to land stations, and in the case of one coast direction-finding station that I have in mind, in which the Bellini-Tosi aerials had to be suspended from a steel jumper stay between two steel towers and over the roof of the station buildings, the re-radiation trouble was quite marked in the case of signals from ships using full power within a dozen miles or so. In such cases it was sometimes almost impossible to distinguish the minima, whilst in intervals between transmissions the more distant stations could be observed to have perfectly crisp zeros. Arising out of the addendum which the author has read this evening is a matter which seems to me to be of the greatest importance, and that is the choice of the type of transmitter to be used for direction-finding beacon stations. The continuous-wave transmitter would be infinitely more convenient, but experience shows that night variations of apparent bearing are definitely more marked on continuous waves than on spark signals. Captain H. J. Round, in his paper* read before the Wireless Section four years ago, said that he and his staff, who had been engaged upon direction-finding during the last 18 months of the war, were fully satisfied that there was more night effect in the case of continuous-wave stations than with spark stations, and whilst Admiral Sir Henry Jackson, in the discussion on the above paper, said

* *Journal I.E.E.*, 1920, vol. 58, p. 224.

that the battle of Jutland was indirectly brought about by the careful and accurate work of the direction-finding stations, it is interesting to note that the accurate work was all done on spark signals. The experience of direction-finding over sea since the war, has gone to confirm these views, and during this period we have had presented T. L. Eckersley's ingenious theory of the cause of night variations, experimental confirmations of which have also appeared in the technical Press. I should like briefly to outline this theory as it throws a good deal of light on the extraordinary variations of bearing which are often observed about the hour of sunset. The theory assumes the existence of the Heaviside layer, i.e. a horizontal layer of ionized air, the lower limit of which slowly rises, as the sun's light is withdrawn, to a height of roughly 80 to 100 km. This layer forms a reflecting and refracting medium for some of the energy radiated from a transmitting station, so that two paths exist from transmitter to receiver as in Fig. A. Now the wave which arrives at the receiver R by the direct path, and which we will call the "A" wave, must be normally polarized since any component of the wave having its lines of magnetic force vertical will be dissipated a few wave-lengths from the transmitter. A direction-finder at R will, therefore, always give a true bearing on the "A"

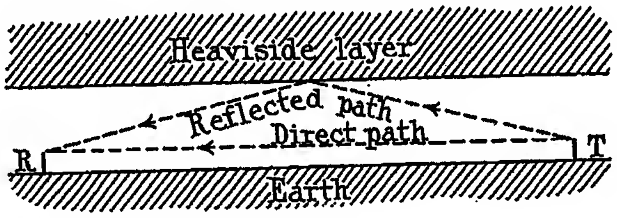

FIG. A.

wave. The reflected wave, since it is travelling in free space, may retain the degree of polarization peculiar to the transmitting aerial used, or, according to Dr. Eccles,* the polarization may be affected by the earth's magnetic field in conjunction with the ionized upper atmosphere. Eckersley now states that the reflected wave on reaching the receiver may be resolved into two components, one, which we may call the B component, being normally polarized, and the other the C component, which has its magnetic field in the vertical plane through the direction of propagation, and which is not necessarily in phase with the B component. A direction-finder at R will always give true bearings on the B component, but will always have a 90° error on the C component since a frame will have minimum linkage with the C wave magnetic flux when the plane of the frame coincides with the vertical plane of propagation between T and R, instead of when it is broadside on as in the case of a normally polarized wave. Under certain conditions of wave-length and lengths of the direct and reflected paths, the A wave and the B component of the reflected wave may be in exact phase opposition and equal in amplitude so that the only signal received is that due to the C component, with a consequent 90° error and reduction in signal strength. As the length of the reflected path increases due to the rising of the reflecting layer, the balance of the phase and amplitude of the A and B waves is destroyed, either the A or B components may preponderate, signals reach a normal night strength and the bearing is practically correct. Wright and Smith † have shown curves of bearings taken on Clifden station during the sunset period. These clearly illustrate the above phenomena and also confirm the marked fading of signal strength when the error in bearing is a maximum, although, owing to the transient nature of the factors producing the effect, it is only occasionally that the cycle is completed without some discontinuity occurring. These observations also show how the behaviour of the heart-shaped diagram of reception under the influence of night variations confirms the Eckersley theory. In the chapter on "Night Effect" in my book † I have shown a set of theoretical diagrams illustrating the effect, at a direction-finding station, of the resultant of the A, B and C component waves on the apparent bearing and signal strength, and it is interesting to note that the curves of error of bearing and signal strength and the sequence of crisp and indefinite direction-finding minima compare very closely with the observations of Wright and Smith. A further theoretical cycle of the heart-shaped diagram under similar conditions shows an equally striking similarity to the experimental results. A difference in apparent bearing of the marking and spacing wave of an arc station, which is not uncommon and may amount to 30°, is explained by the fact that whilst the condition of partial phase opposition of the A and B component waves may exist for one of the wave-lengths, allowing the C component to assert itself and produce an error, the phase conditions for the other wave may be such that the C component is entirely swamped by the normally polarized A and B components, giving the correct bearing. A number of other night-effect phenomena also fit in with the theory, and certainly no other satisfactory explanation of the facts seems forthcoming. In accepting the Eckersley theory, however, the important point is that we must also admit the probability that night effect will always be more marked on continuous-wave than on spark systems (in the existing commercial forms of direction-finding apparatus), because the latter consists of a broad spectrum of frequencies each section of which at any instant is at a different part of the above cycle, and only rarely will there be a large error with a crisp direction-finding minimum. Experience of direction-finding work over sea has shown that whilst crisp distorted bearings do occur on spark stations, particularly near the time of sunset, they are more common on continuous-wave signals, and the direction-finding operator using a spark beacon has the double advantage that the bearings will in general be more accurate at night and that when night effect is experienced there will be far more chance of the warning sign of the indefinite minimum. Up to distances of 80 miles and with a wave-length as high as 1 000 m it may be found that the night errors are not great, but I think that the evidence is quite convincing that the use of continuous waves for

* *Journal I.E.E.*, 1920, vol. 59, p. 77.

* *Radio Review*, 1921, vol. 2, p. 394.
† "Direction and Position Finding by Wireless."

beacons is very dangerous and should not be adopted until extensive trials have been carried out over sea. The adoption of spark beacons might cause interference with broadcast reception, but surely the interest of shipping and the safety of life must take precedence.

Dr. R. L. Smith-Rose: To one who has had considerable experience of all the practical systems of direction-finding, the first portion of the paper rather confirms the impression that the Bellini-Tosi system is complicated—far more complicated than any system using a simple loop or crossed-frame coil. The chief advantage that I have always appreciated in the Bellini-Tosi system was the fact that larger aerials were used than in the case of the single-loop system. I notice, however, that the aerials used on ships are as small as 70 sq. ft., and I think that with such small loops the frame coil can compete quite easily with the Bellini-Tosi system. With the use of a frame coil 4 ft. square, which would be quite good enough for ranges up to 50 or even 100 miles, four of the six errors mentioned in the paper would disappear immediately. The calibration error, which is inherent in the ship, would be of the same order and could either be read from a curve or compensated as in aircraft. The loop and plain tuning errors would disappear, and since there would be no goniometer the electrostatic and capacity errors would be eliminated. The lack-of-symmetry error could also be considerably reduced or even eliminated by the use of suitable screens. Thus a good case could be made out for the advantages of the frame coil as against the Bellini-Tosi system, and I believe that in the American ships the frame coil is used entirely for direction-finding. A point raised by Prof. Fortescue had reference to the angle of inaudibility, which, according to the author, ranged from 20° to 60°. In view of the fact that the author speaks of ranges of transmission to 50 miles, this has surprised me. This angle of inaudibility seems large, and with a swing of 60° it must be difficult to observe to the accuracy of 1°. Personally I do not like to take

TABLE A.

Table showing Results obtained in Observations on Spark and Continuous-wave Transmissions from Karlsborg.

Transmitting station	Receiving station	Type of transmission	Wave-length	Day observations			Night observations		
				Number	Total variation	Error of mean	Number	Total variation	Error of mean
			km		degrees	degrees		degrees	degrees

98	Spark	372	Night	12·0	Extremely variable with conditions
98	I.C.W.	189	Night	9·0	
98	C.W.	216	Night	11·0	

readings on the Bellini-Tosi system with an angle of swing greater than 5° each way. Judging from the table in the paper the author seems to have been very successful, in spite of the complicated nature of the system and of the several types of errors which he details. These various errors do seem to have been reduced to a reasonable quantity for practical working purposes. My own experience of the operation of a land direction-finding station has been that the limit of accuracy of 2° gives about 95 per cent of bearings correct when the range of transmission is from 10 to 100 miles. The next point of interest is in relation to the difference between spark and continuous-wave transmission. The statement as it appears in the paper is a very definite one, and I should like to inquire what evidence the author can produce to support it. The statement also seems definitely to ascribe the error on continuous waves essentially to a night effect. I am not sure that that is so; for early experience with continuous-wave direction-finding indicated that the errors were of an instrumental nature. Moreover, experiments have shown that very elaborate screening of the local oscillator is essential if any instrumental error is to be eliminated; but it *is* practicable to produce an oscillator which has no appreciable instrumental error and is available for use on any system of direction-finding in vogue to-day. I personally, working under the Radio Research Board, have operated 12 direction-finding stations in this country, all equipped for continuous-wave working. From the mass of data which I have obtained there does not appear to be any conclusive evidence that continuous waves are any worse than damped waves, other things being equal. Table A gives a specimen extract of these results showing the comparative errors experienced in observing on both damped and undamped wave transmission from Karlsborg. To decide finally if there is any difference, however, it is absolutely essential that the same transmitting station shall send out both the damped and the continuous waves from the same aerial on the same wave-length, and within a very short time—about 1 minute—of each other. Such test transmissions have been made from a special station set up at the National Physical Laboratory, and bearings were taken at two stations fitted with Bellini-Tosi direction-finders equipped for continuous-wave working on any wave-length from 300 metres upwards. A number of tests have been carried out in which a whole cycle of transmissions (spark, interrupted continuous-wave and continuous-wave) has been repeated every 10 minutes for 24 hours, and Table B shows the maximum errors experienced when working on a wave-length of 750 metres. Over a short distance of 12 miles nearly 100 per cent of the bearings are obtained within 1° on all types of transmission, and no difference between day and night working is observed. Over the longer distance of 98 miles, the errors are somewhat greater by night than by day, but it will be seen from the table that the errors are of the same order whichever type of transmission is employed. In view of the remarks which have been made in regard to the angle of inaudibility it may be interesting to point out the angle at which we usually work, as shown in Table B above. At a distance of 12 miles the angle of swing employed is from 1° to 2° on spark systems, from 0·4° to 2° on interrupted continuous-wave systems, and from 0·4° to 2° on continuous-wave systems. With the type of goniometer which we are now using it is extremely difficult to read the instrument with an accuracy of 0·2°. I should like to refer to one or two points which Mr. Keen has introduced into this discussion. His exposition of the Eckersley theory is good, but it leaves me entirely unconvinced. He made the statement that other observers had obtained very large errors on continuous waves, although the bearings were always perfectly sharp. My experience is to the contrary; the bearing minima frequently get blurred and appear to wander just as frequently on continuous waves as on spark. Mr. Keen also spoke of 180° rotations on continuous waves as being frequent occurrences, and that on 2 000 m an observation was made in which the bearing was thus rotated 3½ times round the compass. Out of the whole of the 140 000 readings which have been taken within our experience on wave-lengths from 450 to 9 000 metres, no error has exceeded 90°. We may have been particularly fortunate, but in view of the large number of bearings which have been taken there seems little to confirm Mr. Keen's suggestion. Another point mentioned by Mr. Keen was with regard to errors of the bearings originating from the transmitter. Some evidence has been produced by previous experimenters in this subject with regard to transmitting stations which are supposed to radiate waves with a vertical component of magnetic field as well as those with only a horizontal magnetic field. Observations which we have taken on well-known transmitting stations have shown no variation with the orientation of the direction-finder around the station, and there are also other reasons which go to prove that the transmitting aerial does not have any great effect on the errors in bearing. I should like to confirm the experience of the author as to the absence of effect from fog banks. I emphasize this point as some of the national regulations published give a warning as to the unreliability of bearings observed during foggy weather. In regard to areas of bad bearing, it would be interesting to know if the bearings taken outside the arcs which are marked "good" are always varying or whether there is merely a constant error. At one of our direction-finding stations when taking observations on another transmitter we have come upon a constant error of 3°, the station being at a distance of 16 miles, but there is never any variation in that error.

Major B. Binyon: Dr. Smith-Rose has mentioned the fact that among the advantages of using simple loops in preference to the Bellini-Tosi system is the fact that four of the errors mentioned in the paper are eliminated. He also referred to the fact that the Americans are using loops exclusively on ships. In addition, however, some British ships also employ loop reception on the Robinson system. There is a further advantage of the loop to which I should like to draw attention. The author says: "If the loops cannot be made permanent, but have to be lowered and re-hoisted frequently, there is a great likelihood of the symmetry

being destroyed in the process. This has been found to be a very real and serious cause of trouble." With the small loop this further source of error is entirely eliminated because it can always be installed in a permanent position and clear of derricks used for hoisting cargo. I must join issue with the author when he says, with regard to the position of direction-finding instruments: "As far as the mercantile marine is concerned, it is highly desirable to have the instrument in the wireless room. It should be under the charge of the telegraphist and always available for practice, and when using it he should be in his own place and not an intruder among the navigating staff." The wireless direction-finder is a navigational instrument and as such its proper place is among the other navigational appliances of a ship, either upon the bridge or in the chart room. Time and experience will show which is the best position, but the employment of small loop aerials enables the direction-finder to be installed either with the navigating instruments or in the wireless cabin. It is my opinion, however, that until masters and owners regard the directional equipment as a navigational instrument rather than a piece of wireless apparatus, its importance will not be fully appreciated, and for this reason I consider it desirable that the instrument should be placed in the navigational quarters.

Mr. M. Bennett: In the charts of error zones which the author has drawn up I suggest that at each transmitter there should be charted areas where errors occur due to the proximity of the ship to the transmitting aerial. It has been shown in some experiments carried out under the auspices of the Radio Research Board that near to an asymmetrical aerial there is a permanent error which is approximately equal to the angle subtended by the transmitting aerial at the direction-finder. There is therefore a liability of getting an error when broadside on to the transmitting aerial, the extent of which will depend on the distance of the direction-finder from the transmitter. Many ships coming into port will enter the region where this permanent error exists. But it is a perfectly definite error and a correction can therefore be easily applied to any particular case.

Mr. G. H. Nash: I have been impressed by the accuracy of the direction-finding results expressed in the paper, and am aware that amongst those who are interested in the safety of navigation at sea there is a growing demand that a system of wireless direction-finding should be given full support by the Board of Trade in order that their influence may be brought to bear on the actual adaptation of a system such as the one described by the author: and I have listened with interest to the opinion expressed by Admiral Jackson that this system should be adopted, but I feel that possibly the time is not yet ripe for the final determination of which system. It will be remembered that when the war broke out very little was known on the subject, and what little was known was naturally very much confined to the hands of those actually operating direction-finding apparatus during the war period. The system of operation at Admiralty stations during this period was not such as to encourage the most accurate work, because the various direction-finding stations only reported the bearings they obtained, and in the case of ships at sea it was left for another department of the Admiralty to determine the position after obtaining bearings from two or more stations. Further, as it was the position of an enemy ship that was involved, it was nearly impossible to check accurately the results obtained. There is no doubt that all non-wireless officers had very great belief in wireless direction-finding during the war, and it was on this belief that very definite statements regarding the position of enemy ships at various positions was made. It was not until after the war that light began to be thrown on the actual accuracy of direction-finding. It is stated on page 230 of vol. 58 (1920) of the *Journal* that the direction of Salonica would sometimes change by 90°, and that of Horsea by 30°. On page 238 it is suggested that a false confidence was gained by the "beautiful intersections" and it was only when shocks were received, such as when the wireless located the German fleet well inland, that any doubt was felt. Again, the immediate post-war literature shows other evidences of unreliability. In the *Radio Review* (1919–20, vol. 1, p. 381) it is stated that discrepancies up to 90° are observed. Again, in an article by Dr. Bellini in the *Electrician* (1921, vol. 86, p. 220) it is stated that the errors may vary as much as 50°, 60° or even 90°. Most of the writers at this period sought to attribute the varying accuracy of direction-finding to the uneven reflecting surface of the "Heaviside layer." Even here one is again in difficulty because in the *Electrician* (1922, vol. 89, p. 148) there is an article which goes to suggest that the Heaviside layer does not exist, but to-night one speaker has given us a most interesting exposition of the action of the Heaviside layer and why it causes direction-finding to be more accurate on spark than on continuous-wave stations, and a further speaker has revealed that there is a difference of opinion as to which system gives the most accurate determination of direction. Again, the paper and the discussion thereon have shown a marked difference of opinion as to whether the locating of ships at sea should be by means of direction-finding equipment on board the ship or on the shore. From what I have said it will be apparent that there is controversy on so many phases of the subject as in my opinion to justify the belief that it is too early to say that any system of direction-finding for the purposes of navigation has arrived at the stage where it may be regarded as being sufficiently reliable.

Major H. P. T. Lefroy: It will be a great disadvantage if continuous-wave transmission must finally be accepted as unsuitable to employ for signals whose bearing is to be taken. The difference between the reception of this and other systems lies in the use normally of a local oscillator, which is, I believe, frequently the cause of the error in the apparent bearing. I am inclined to think that the "ticker" method, properly applied, would be more suitable than a local oscillator, in that it would make for a greater degree of accuracy in practical work when taking continuous-wave bearings, though the strength of signals received would be less.

Major A. G. Lee: I am in fair agreement with the author in regard to the figures which he puts forward in connection with radio beacons, but in view of what we have heard from Mr. Keen on the one hand and from Dr. Smith-Rose on the other, it seems to me that the suggestion that the spark system is definitely better than the continuous-wave system is by no means fully proved, and before we as a country commit ourselves to radio beacon stations on the spark system (which will be without doubt a nuisance to broadcasting, amongst other interests) this question of the relative advantages of the two systems should be more thoroughly thrashed out than it has been up to the present time. The Radio Research Board have done a considerable amount of work on this subject, and are of opinion that the continuous-wave system is as good as the spark system. It would be very useful if the Marine Wireless Companies interested in the subject could take advantage of the information accumulated by the Radio Research Board and could combine with that Board with a view to arriving at some definite conclusion.

Mr. E. H. Shaughnessy: The author says that he is dealing with bearings taken from the ship. That is very interesting, because the area that he shows in one instance to my knowledge corresponds almost exactly to what we know to be the correct range from the direction-finding station. There is another point on which I think we should be quite clear. I was particularly impressed with the percentage of accurate bearings given in the table on page 549. I should like to know, however, whether this 91 or 95 per cent of accurate bearings are the bearings obtained within the known "safe" area of taking bearings. If that is the case, then we have to realize that it puts a very strict limitation on the utility of direction-finding. With the compass we do not have to mark off areas all over the globe in which there are very limited angles only within which the reading can be relied upon. We know that if there is a station well inland, and the directions are taken from an angle of almost 90° with the coast line, we are likely to get reasonably consistent results perhaps 95 or 98 per cent correct within 2°. But what happens when we work along the coast line? There is the danger area, so that in talking of direction-finding being 98 per cent correct within 2°, and almost as accurate as the compass, it is necessary to place a limitation on such statements, which limitation we do not have to place on the ordinary use of the compass. I do not quite understand the author's suggestion with regard to a new Department of Direction-Finding Control. He means, I suppose, some department for examining all direction-finding installations that are put on ships. I do not quite know what control any new department or existing department could exercise in any such respect.

Commander J. A. Slee (*in reply*): In reply to Mr. Bainbridge-Bell, so far as experience of the Bellini-Tosi system goes, a change of calibration error due to change of draught has only been reported once and an investigation of this case showed that the system was improperly earthed. When this was rectified the change disappeared, and it can be stated that no change of calibration is found necessary with changes of draught.

With reference to the bad-bearing areas, it is highly desirable that some official department should deal with this matter, though it appears that the whole subject is as yet too young and the number of ships fitted too small to expect any Government Department to undertake the work at this stage. The arcs of bad bearing shown on the lantern slides have been completed with a view to guiding the seaman and to warn him against relying on bearings taken from positions where they are likely to be indifferent. They do not represent a scientific examination of the exact boundary line. Experience shows that within distances of great importance for navigation—that is to say, up to 100 miles—the straight lines shown on the slides give a very fairly accurate representation of the facts.

Referring to Prof. Fortescue's remarks, the width of the silent arc is of no real importance provided that the cut-off is sharp so that the vanishing points can be determined with certainty. Provided that these points are clearly fixed, obviously it cannot matter whether they are 60° or 60 minutes apart. Bearings only become doubtful when the position of the vanishing point becomes difficult to determine.

It is pointed out that when a direction-finder is mounted on board an iron ship its environment is such as to make possible a large number of errors which are probably due to changes in conductivity, etc., in the whole structure of the vessel, and the object of the paper has been to explain how these difficulties have been overcome and what results can be obtained under these conditions. The methods now in use have been selected as the result of a great many trials.

Many of the points raised by Dr. Smith-Rose are dealt with in my reply to the remarks of Prof. Fortescue. Dr. Smith-Rose speaks of loops as small as 70 sq. ft. in area. In the paper it is stated that the size of loops ranges up to about 400 sq. ft.; loops as small as 70 sq. ft. are only used in special cases in very small vessels such as trawlers. Furthermore, it is stated in the paper that small loops are unsatisfactory in large vessels. The common size of loop is about 240 sq. ft. The lack-of-symmetry error can be and, in some cases, is reduced by the use of screens, but such a construction is in many cases perfectly impossible under merchant-ship conditions. This paper does not profess to be a comparison between the Bellini-Tosi system of direction-finding and systems employing moving frames, and I do not think that any useful purpose will be served by entering into such a comparison.

There are about 120 British merchant ships fitted with the Bellini-Tosi system of direction-finding, and the reports from 99 of these are constantly under review. From these reports the figures quoted have been obtained and there is no reason to suppose that the results obtained in the other ships are any worse. The total number of American merchant ships fitted with direction-finders is 41 and, although definite reports as to their performances are not available, it is believed that the degree of accuracy which they obtain is lower than that quoted in the paper. The distribution of direction-finders in the merchant vessels of the chief nations is approximately as shown in the following table. No

figures are to hand for German, Swedish or Japanese vessels.

	Bellini-Tosi	Frame
Great Britain	121	?
United States	—	41
Germany	?	?
Sweden	?	?
Japan	?	?
Norway	9	—
Belgium	3	—
Spain	22	—
Portugal	1	—
Italy	52	—
France	—	32
Holland	6	—

With regard to the latter part of Dr. Smith-Rose's remarks, the small amount of experience available on the subject indicates that from a fixed position the error due to "land effect" is constant, but the matter has not been explored as it is clear that the error varies considerably with slight alterations of position. It is certain that a badly arranged local oscillator will cause errors in bearings, but it is doubtful if this cause will account for variations in a bearing which ought to remain constant. No difficulty has been found in arranging a local oscillator so that it makes no difference at all (except breaking up the note) to the steadiness or accuracy of spark bearings.

With reference to Major Binyon's remarks on the subject of the position of direction-finders in ships, it may be of interest to know that so far only three Bellini-Tosi direction-finders have been erected (at the request of the shipowners) for working on the bridge. One of these has been removed to the wireless office, also at the request of the shipowners.

In reply to Mr. Bennett, it does not seem really necessary to record on sketches the error to which he alludes, as no sea-going ship is ever likely to get close enough to a wireless station for this error to be noticeable.

In reply to Mr. Nash, it appears that the state of affairs to which he refers can be cleared up as follows:—Results which are reliable from a navigational point of view can be obtained by the Bellini-Tosi direction-finders from spark transmitters. This does not state that reliable bearings cannot be obtained from other types of transmitters. A great deal of past experience shows that bearings taken at night by direction-finders of continuous-wave transmitters are not reliable. On the other hand Dr. Smith-Rose states that reliable bearings can be obtained under such conditions.

There is no doubt that it would be to the general advantage if further experiments were to show that reliable navigational bearings can be obtained from continuous-wave transmitters, and experiments to settle whether the continuous-wave system is or is not a suitable form of transmission for navigational purposes are now in progress, bearing in mind the adverse conditions under which a direction-finder is used on board ship. The use of the interrupted continuous-wave system may prove to be the best solution.

With reference to the remarks of Major Lefroy, it is possible that the use of a chopper may be found advantageous.

In reply to Mr. Shaughnessy, the "arcs of good bearing" indicated on the lantern slides apply only to bearings taken by ships of the land station. The last two columns of the table have been made up after the bearings outside the "good bearing" areas had been rejected. Previous to May 1923 all bearings were lumped together.

There are a few patches of fairly shoal water where the sea bed appears to be of an ironstone nature, in which the compass is likely to become inaccurate, but this comparison between the reliability of the compass and that of a direction-finder does not seem to be quite fair. It is more just to lay the blame for "arcs of bad bearing" on the positions of the coast stations, and to mark the "arc of good bearings" in the same way that all lighthouses erected on land have a definite arc of visibility, outside of which they cannot be used, indicated on the chart. Arc of bad bearings are entirely a matter of the intervention of land between the ship and the transmitting station; they have nothing to do with the general conditions of the locality, such as the nature of the sea bed.

The author does not suggest a new Department of Direction-Finding Control. He only expresses the hope that in the future, when a large number of vessels are fitted, some Government Department will undertake the duty of publishing official documents indicating "arcs of good and bad bearings."

INSTITUTION NOTES.

Council's Nominations for Election to the Council.

The following have been nominated by the Council for the vacancies which will occur in the offices of President, Vice-Presidents, Honorary Treasurer, and Ordinary Members of Council on the 30th September next:

President. *(One Vacancy.)*

W. B. Woodhouse.

Vice-Presidents. *(Two Vacancies.)*

S. Evershed. A. Page.

Honorary Treasurer. *(One Vacancy.)*

P. D. Tuckett.

Ordinary Members of Council.

Members. *(Four Vacancies.)*

W. E. Highfield. B. Longbottom.
H. W. Jones. E. H. Shaughnessy, O.B.E.

Associate. *(One Vacancy.)*

The Viscount Falmouth.

Informal Meetings.

The Informal Meetings Committee will consider, in the course of the next three months, the programme for the session 1924–25, and will be glad if members will indicate to the Secretary subjects which they suggest for discussion.

Members willing to open discussions are invited to submit, for consideration by the Committee, the subjects on which they wish to speak; a written paper is not necessary.

Associate Membership Examination Results: April 1924.

Passed.

Ashford, D. G. (Bristol).
Baker, E. W. (London).
Bannatyne, A.M.(London).
Baxter, J.MacG.(Croydon).
Bennett, E. H. (Bromley, Kent).
Bent, F. (Bolton).
Cantelo, H. R. (Southampton).
Cawson, W. F. (Hull).
Chase, J. J. (Norwich).
Chorlton, H. C. (Newcastle-on-Tyne).

THE DESIGN OF APPARATUS FOR THE PROTECTION OF ALTERNATING-CURRENT CIRCUITS.

By A. S. FITZGERALD, Associate Member.

(*Paper first received* 14*th September*, 1923, *and in final form* 10*th January*, 1924; *read before* THE INSTITUTION 28*th February*, *before the* NORTH-EASTERN CENTRE 25*th February*, *before the* NORTH MIDLAND CENTRE 26*th February*, *before the* NORTH-WESTERN CENTRE 4*th March*, *before the* SCOTTISH CENTRE 11*th March*, *before the* SHEFFIELD SUB-CENTRE 19*th March*, *before the* WESTERN CENTRE 7*th April*, *and before the* SOUTH MIDLAND CENTRE 30*th April*, 1924.)

SUMMARY.

The paper deals with differential protective systems, particularly those suitable for use where there is a neutral earthing resistance.

The operating conditions, and their influence on methods of design and construction, are discussed, and improved means of practically applying the various protective circuits are described.

The superiority of biased systems, in principle, is accepted as having been established, but the objections to a more complicated relay are recognized. The author advocates the use of simple relays only, in order to restrict to a minimum the employment of moving parts associated with small amounts of power.

The necessary functions peculiar to biased and certain other protective systems have led to the use of balanced beam, dynamometer, and other special forms of relay. The paper describes how these features may be achieved with a simple relay and a static device called a "biasing transformer."

Current transformers and simple types of relay are briefly dealt with, and a further static device called a "phantom auxiliary switch" is described.

The application of the foregoing apparatus to actual protective circuits is described in the second portion of the paper, and attention is drawn to the advantages of dealing with earth faults and line faults independently.

TABLE OF CONTENTS.

INTRODUCTION.

Several papers dealing with this subject have been read and discussed before the Institution, and much helpful expression of opinion and useful experience have been made public.

In the present paper the author describes certain methods and devices whereby the ideals and objects aimed at and expressed may more nearly be approached.

No new principles or fundamentally novel circuits will be found in the paper, but the author endeavours to indicate how existing methods may be made simpler and more reliable by the use of apparatus operating on well-known principles and presenting no new features of construction, but which has not in the past been associated with protective gear.

It is proposed to restrict the paper to a description of differential systems of protection only, and to the class of protective gear operative on flow of current, rather than to arrangements of a preventive nature.

The systems described will be those considered specially suitable for supply systems operating with a neutral earthing resistance.

General agreement with the principle of instantaneously clearing earth faults of reasonably small value is assumed, as is also the necessity for protective relays being of the simplest design as well as of robust construction.

Section 1.

GENERAL FEATURES OF DESIGN.

The nature of the requirements associated with protective gear presents more stringent conditions to be met, and demands greater precision and reliability of operation, than is the case in almost any other class of electrical apparatus.

The principal features of difference between the more

common forms of electrical circuits, instruments, etc., and the devices comprising a protective system, may be considered under the following headings :—

Reliability.—Occasional failure, whilst admittedly undesirable, may be commercially permissible, in most ordinary classes of apparatus, to an extent depending on considerations of maintenance.

Moreover, such failures will be readily brought to light in the ordinary course of duty.

The primary function of protective gear is to function with absolute certainty on the occurrence of trouble, and any shortcomings in this connection may not be discovered until an actual fault has occurred.

Conditions of service.—The requirement of reliability, to the maximum extent commercially obtainable, is common to all devices created by the engineer, but only in a very limited range of apparatus, which includes protective gear, is it an essential feature of the working conditions that the operation shall only be effected on very infrequent occasions.

In the general case it must be admitted that constant use is one of the circumstances whereby the operating mechanism is maintained in a state of efficiency.

Range of operation.—Neither machines, instruments, nor control circuits are expected in the ordinary way to perform the function for which they are designed, over a range exceeding to any great extent a ratio of 10 to 1, either of current or voltage.

A protective system, on the other hand, whose function is to discriminate between the flow of current due to local or remote faults, must carry out this operation with precision when subjected to currents the magnitude of which may vary from that of an earth fault current, of the order of 50 amperes, to that associated with the short-circuit current which may flow due to a breakdown between lines on a large network. Such fault currents have been known to exceed 20 000 amperes.

Responsibility.—In a protective circuit will be found certain items of apparatus consisting of current transformers, relays, etc., variously arranged and connected, and involving wiring and contacts, the whole, as a rule, being energized to the extent of a few volt-amperes and being correspondingly proportioned.

Directly dependent, however, on the small operating forces and light moving parts necessarily associated with the limited energy available, there may be not only generating plant, mains, etc., representing an appreciable percentage of the total capital involved, but also, in an industrial area, means of production of which the output may be computed in hundreds of pounds per minute.

It will be seen, therefore, that such electrical apparatus, which is in itself trivial and insignificant when compared with the majority of the machines or devices met with in an electrical power station, is rarely so applied that unsatisfactory performance of the gear itself is likely to give rise to results more unfortunate financially or of greater extent.

Limitations of protective circuits.—It would seem that a very good case might be made out for a direction of development closely following that which has proved successful when applied to control devices and circuits. Present practice in this sphere favours the use of mechanical principles and ample operating forces rather than numerous electrical components, especially those involving small contacts. Methods of discrimination, therefore, which involve selective contacts in series, cannot be considered as a line of development likely to lead to the standard of reliability essential to the success of a protective system.

Similarly, every effort should be made to provide operating forces as large as possible, but it is precisely in regard to this feature that the protective circuit is at a disadvantage.

Much better results will attend the employment of transformers capable of increased output, rather than endeavour directed to the design of sensitive relays, but there are definite limits to such a line of development.

Owing to the desirability of clearing an earth fault at an early stage in its development, the energy available for operating relays under such conditions can scarcely exceed a few volt-amperes.

For this reason, therefore, the above argument in favour of employing mechanical principles does not seem equally applicable to protective apparatus.

Stability.—Immunity from incorrect operation due to " through " currents is of equal importance to certainty of operation on the occurrence of a fault. It is notably in this respect that existing methods of protection have not always been found adequate.

The magnitude of the disturbances which may be met with on large systems is now realized to exceed the range within which uniform performance of ordinary current transformers may be relied upon.

Only where air-gap transformers are used can balance be properly obtained under short-circuit conditions, but this practice leads to the necessity for very sensitive relays if limited earth faults are to be dealt with.

It is to be noted that these difficulties are definitely associated with the employment of a system depending for its operation on the direct difference between the effects concerned. Much more satisfactory results have attended the efforts which have been made to arrive at a solution along other lines.

Biased systems.—This reference is intended to cover those systems of protection in which the value of the difference current necessary to effect operation of the relays is not a fixed quantity as in the case of a relay connected in a differential circuit and having a given current setting, but one in which the amount of the difference current required is augmented as the load current, transmitted by the circuit protected, is increased. In order to give effect to this principle, existing methods have employed what is referred to as a biased relay, this term denoting a relay having a variable electrical bias in addition to, and distinct from, the constant mechanical bias due to gravity, a spring, or other controlling force.

The construction of a relay of this type will necessarily be less simple than that of a plain relay having but one electromagnetic element. It is well known that difficulty is met with in designing biased relays in forms sufficiently sensitive to be operated by the limited energy available, on account of the considerable forces which they must withstand without operating.

A perusal of the published expressions with regard to the principle involved, indicates clearly that the principle of biasing is accorded general support. The employment of forms of relay departing from the simplicity of the single element, however, is deprecated and much difference of opinion exists as to whether this objection is outweighed by the advantages associated with the use of biased relays. The author, however, feels justified in assuming general agreement with the biasing principle as applied to a protective circuit, provided that the objections above referred to are avoided and the advantages retained.

Static Method of Providing Bias.

It is required, therefore, to provide a means of restraining a relay from operation, as well as actuating it, without the necessity of introducing into the relay additional forces and components.

In making comparison between the relays incidental to biased systems of protection and arrangements which do not present this feature, the protection of a single circuit was implied. Where the protection of parallel circuits as such is concerned, however, the employment of balanced-beam or similar forms of relay is usual, whether the fault setting varies with the through current or not.

A further field of application is therefore seen to present itself to a method of carrying into effect, by more simple means, the function hitherto performed by differential or biased relays.

A very simple method of restraining the relay from operation is provided if, instead of introducing additional forces in opposition to the operating effect, a reduction in the magnitude of the latter be brought about.

It would seem, therefore, that there is required some form of intermediate device connecting the operating effect with the relay and capable of transmitting to the latter such proportion of the available energy as may be appropriate to the circumstances under which the apparatus is functioning.

To meet this requirement the author has employed a device which, whilst its use in connection with certain special systems of control is on record, has not, to his knowledge, undergone extensive development, nor has it hitherto entered the sphere of practical engineering. In its simplest form it consists of a transformer of special design and possessing the following novel features. Whilst it has, in common with other forms of transformer, a secondary winding and a primary or operating winding, it is provided with a further winding, described as a restraining winding, in order to indicate its function. This latter winding is not inductively related to the operating or secondary windings, but it excites a magnetic circuit a portion of which is common to that with which the other windings are linked.

Such an arrangement might consist of a pair of ring cores as in Fig. 1 (*a*), each provided with similar operating and secondary windings connected in series; a third coil present on each core but in one case reversed in relation to the other windings will, if excited, have the following effect. Such E.M.F.'s as may be induced in each secondary by this third coil will not appear in the complete secondary circuit as they will be in opposition; nevertheless the magnetic circuits of both transformers will be excited. If such proportions be chosen that currents flowing in the restraining winding give rise to saturation of the iron, this will clearly affect the secondary current corresponding to any given operating excitation, since the secondary ampere-turns will roughly be equal to the difference between the primary and magnetizing

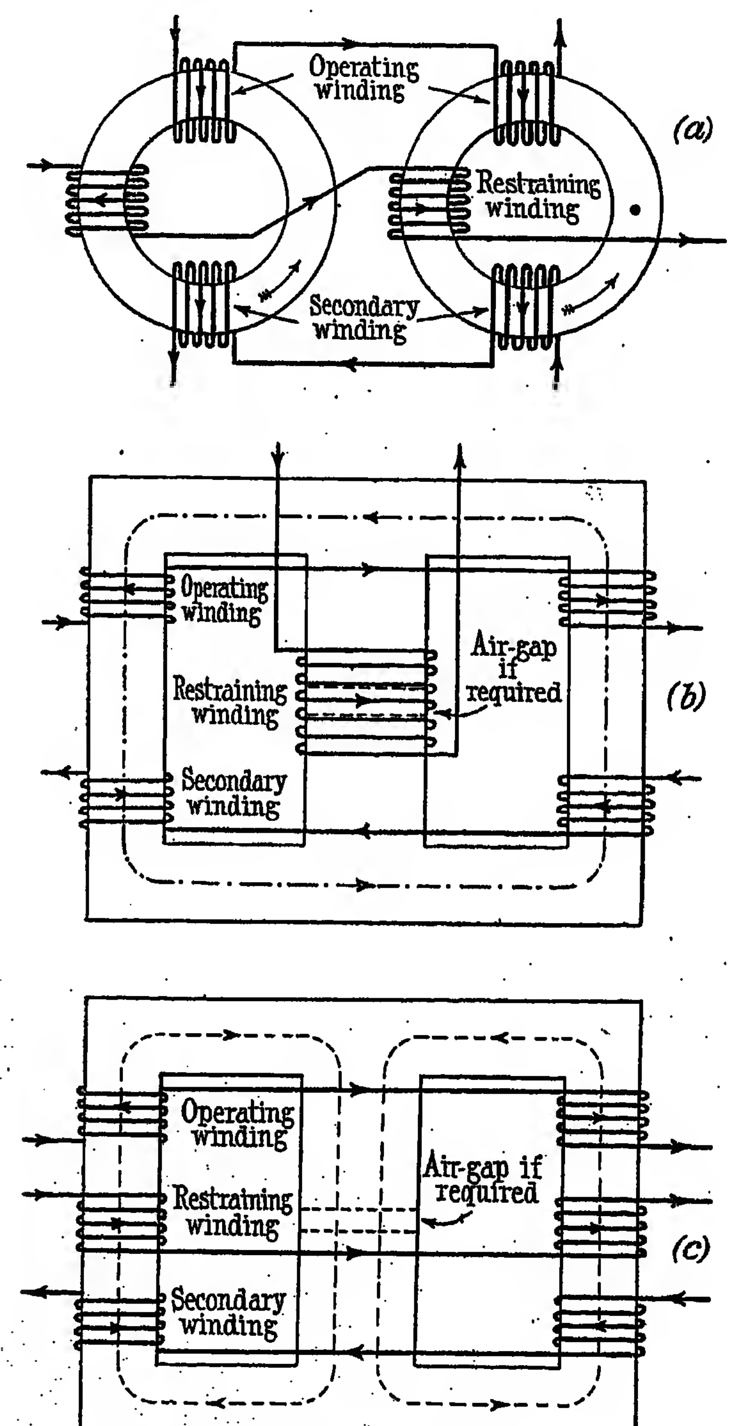

Fig. 1.—Forms of biasing transformer.

ampere-turns. Excitation of the restraining winding is capable of increasing the reluctance of the magnetic circuit to such an extent as will necessitate a very much greater operating current in order to deliver the required secondary energy. If, therefore, the operating winding be connected in place of the protective relay, this being connected to the secondary, the desired effect is obtained.

Whilst the above scheme is one of the most efficient

forms of restraining winding, the author employs a somewhat different method presenting peculiar advantages. In lieu of the pair of cores described, a single core, having three limbs, of the form shown in Fig. 1 (*b*), is used. This shape enables two magnetic circuits to exist in the one core, each of which has a common portion as specified, and coils may be arranged in various ways to have inductive relation with either of the magnetic circuits.

Windings appropriate to the excitation of one or other of these magnetic circuits may, however, themselves be mutually non-inductive. The restraining winding, for instance, may consist of a single coil situated on the central limb, as in Fig. 1 (*b*).

Divided operating and secondary windings will then be employed, consisting of two coils having equal numbers of turns, each being on one of the external legs of the core. This sets up a flux as indicated by the chain-dotted lines. A more efficient restraint, however, is given if divided restraining windings are employed,

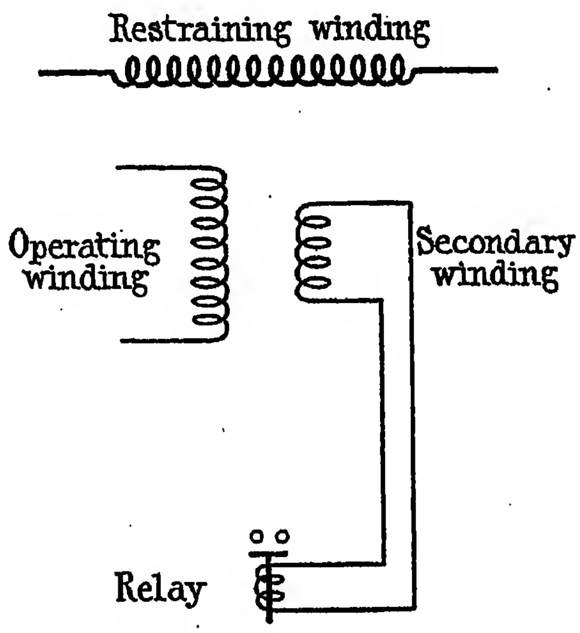

FIG. 2.—Method of indicating windings of biasing transformer.

as shown in Fig. 1 (*c*). In either case the restraining winding gives rise to a saturating flux passing through the centre, as shown by the dotted lines in Fig. 1 (*c*).

This form of construction is obviously superior to the ring arrangement, since former-wound coils may be used in which laminations, conventionally jointed, may be assembled. It will be seen that the core is laminated in one plane only. A further advantage, however, is that an air-gap may be provided in the restraining magnetic circuit without reducing the unrestrained permeability of that associated with the other windings. This enables very useful restraining characteristics to be achieved, as will be more readily comprehended in relation to the various methods of applying this device to protective circuits. These characteristics will be more fully explained later in the paper.

It might perhaps be thought that the employment of this device would be inclined to lead to internal balancing difficulties peculiar to its construction. It is to be pointed out, however, that it is clearly less difficult to procure uniformity between two halves of the same set of laminations than where separate cores are involved. Even where, due to careless assembly of the core, a lack of symmetry is produced, the author's experience is that unless cores of a much larger size than those which he employs are used, the out-of-balance current in the relay when the heaviest restraining current is flowing cannot be detected by any instrument of such range as might be used to indicate the tripping current of the relay.

In order to carry out the various requirements in connection with the different schemes to be considered, it is often necessary to employ more than one transformer element, and in such cases these will be connected in cascade, i.e. the secondary winding of one transformer will be connected to the operating winding of another, and so forth, the relay being excited by the final secondary.

In order to avoid complication in diagrams of protective circuits of this nature, a simple form of representation of the various windings, as shown in Fig. 2, has been adopted in all the diagrams which follow. In every case, therefore, the restraining winding will

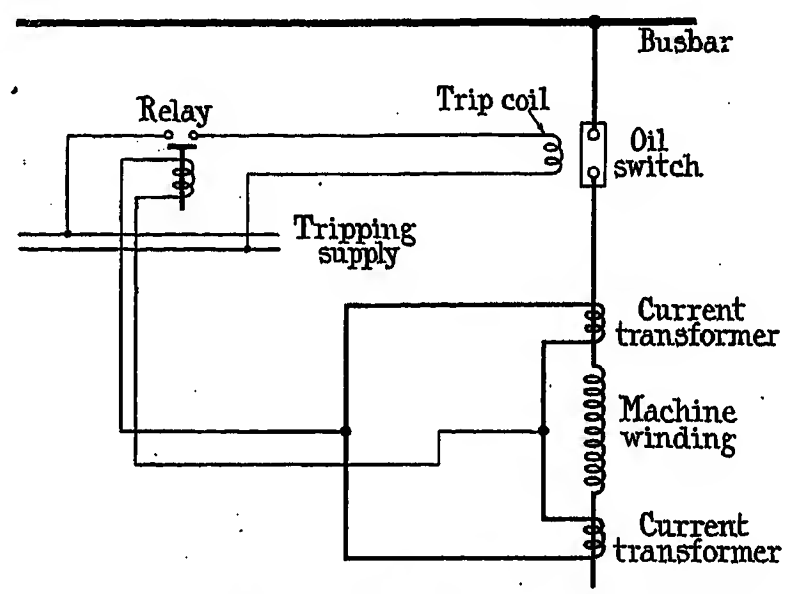

FIG. 3.—Simple circulating-current protective circuit.

be shown horizontally and the operating and secondary windings the longer and shorter respectively of the two vertical indications.

A combination, therefore, of biasing transformers and simple electromagnetic relays may discharge the functions usually performed by balanced-beam relays, differential induction relays, or dynamometer relays in applications of the foregoing to balanced-current protection, reverse-power apparatus, and differential forms of the latter.

The principal functions of the biasing transformers applied to systems of protection are as follows:—

(1) Overload restraint.
(2) Discriminating restraint.
(3) Directional discrimination.
(4) Auxiliary restraint.

(1) *Overload restraint.*—In order to apply the feature of overload restraint the operating winding will be connected so as to receive the difference current, and the restraining winding will be connected in a suitable portion of the protective secondary circuit carrying current proportional to the load on the unit protected.

In the majority of differential protective circuits this will be known as the "circulating current" circuit.

Fig. 3 shows what is probably the simplest form of protective circuit, viz. the protection of a single winding or conductor on the circulating-current system. It will be seen that the two current transformers are connected so that current normally circulates between them when their primaries are carrying equivalent currents, but that in the event of a fault on the winding protected—to the effect that the entering and leaving currents are no longer of equal magnitude—there will appear a difference current in the relay, this being connected between equipotential points on the circulating-current circuit.

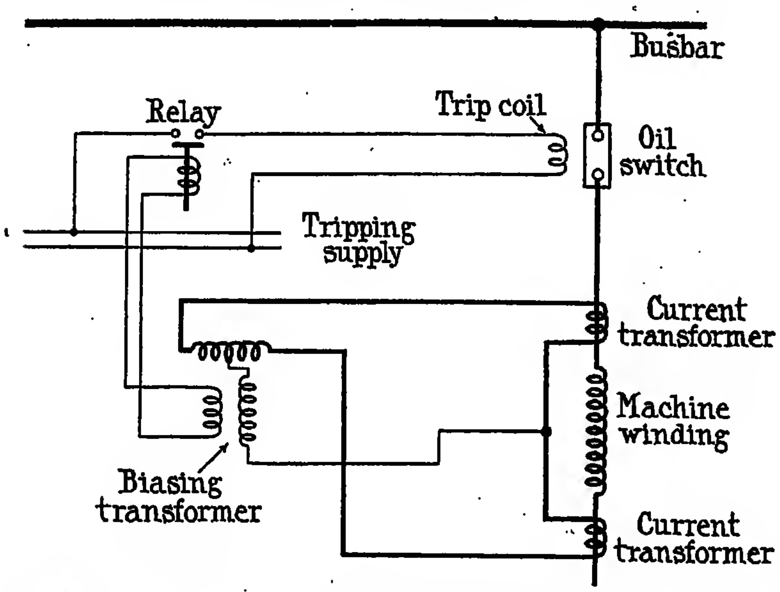

FIG. 4.—Application of biasing transformer to circulating-current circuit.

This relay will be of simple design, having no differential feature. It will therefore operate at a given value of difference or fault current irrespective of the "through currents" which may traverse the protected circuit. This arrangement is well known and has been widely used. It has given entire satisfaction within its sphere of utility, which is limited to cases where no great sensitivity is aimed at and where it is possible to provide accurate balance between the current transformers, or where, alternatively, the protected plant will not be subjected to the effects of heavy external faults.

There is scope for improvement in performance in many instances and, by the employment of the biasing transformer, this may be achieved with freedom from additional complication.

An equivalent protective circuit is outlined in Fig. 4. A relay similar to that embodied in the scheme shown in Fig. 3 may be utilized in this circuit. In accordance with the principles indicated above, the operating winding of the biasing transformer is connected in Fig. 4 where the relay was shown in Fig. 3. The relay is excited from the biasing transformer secondary, whilst the restraining winding is included in the circulating-current connections. In order that the operating winding shall continue to receive the true difference current, the restraining winding must clearly be symmetrically disposed with regard to it, and accordingly one end of the former will be taken to a mid-point on the restraining winding. This modification endows the protective circuit with the characteristics shown in Fig. 5, which gives the relation between the current in the restraining winding (that is to say, the transmitted load or "through current"), and the operating excitation. In other words it shows the difference or fault current necessary to cause the relay to trip.

Fig. 5 shows the magnitude of restraint that can be achieved under these conditions. The actual value attained will depend, of course, on the number of turns on the restraining coil, and a restraining action of the full extent indicated may not, in every instance, be necessary or desirable.

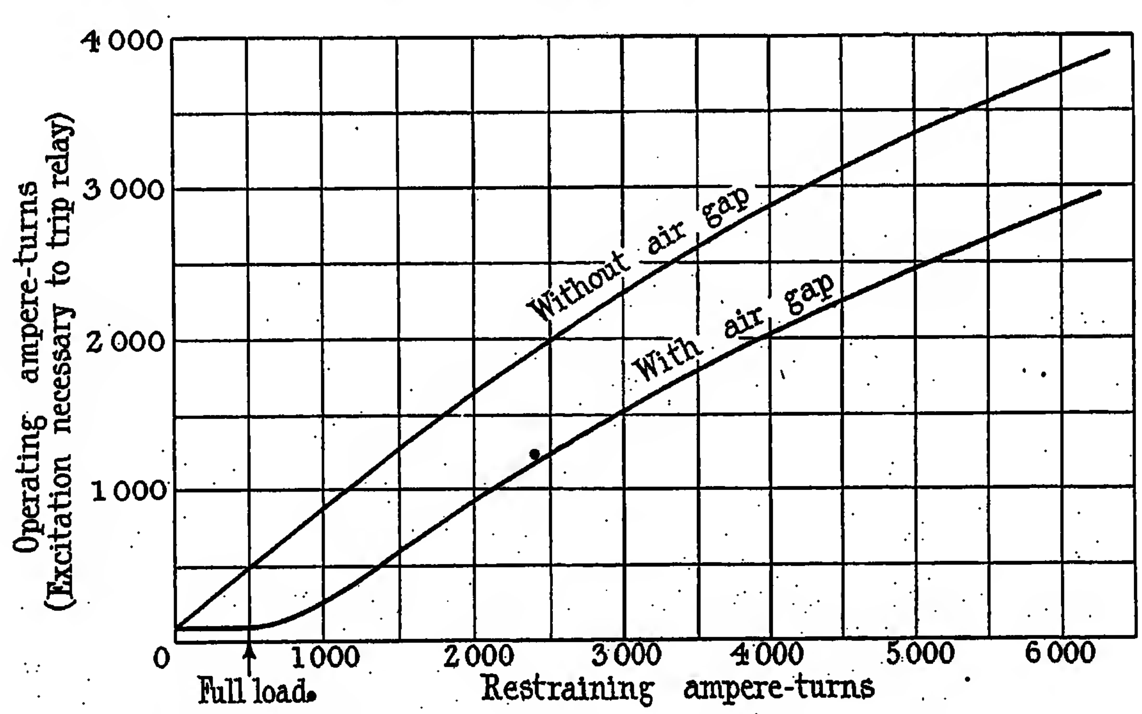

FIG. 5.—Characteristic curve of biasing transformer; overload restraint.

The use of the biasing transformer, however, renders possible the provision of a further advantageous feature not usually inherent in systems employing biased relays.

In any scheme in which restraint is derived from current proportional to the transmitted load, there is likely to be present at normal load a corresponding fraction of the restraint provided under overload conditions, and, unless the latter be of moderate extent only, the full-load sensitivity will be appreciably less than the maximum of which the protective circuit is capable.

In this connection there will be seen the utility of the central air-gap to which reference has previously been made. Under normal circumstances when the transmitted load and, accordingly, the restraining current, is of no very great magnitude, the presence of the air-gap will materially reduce the restraining effect, causing as it does a very marked increase in the reluctance of the magnetic circuit carrying the restraining flux. When, however, due to remote faults or overloads, the restraining excitation is of the order of magnitude capable of saturating the core of the biasing transformer, the effect of the air-gap will be very much less, in fact almost inappreciable, since the permeability of the core itself in this state will more nearly approximate to that of an air path. The upper curve in Fig. 5 indicates the characteristic of a biasing transformer in which the central member is not furnished with an air-gap, whilst the lower curve corresponds to the provision of a suitably designed magnetic circuit in which one is present.

Thus it is possible to arrange that the inherent sensitivity of the protective circuit shall not be impaired by the presence of the restraining effect until the transmitted load or fault current considerably exceeds the rated load of the unit protected. It is not until currents of this order of magnitude are attained that the difficulties associated with current-transformer balance, etc., which postulate the provision of a biased protective system, become in evidence.

On the occurrence of a fault within the area embraced by the protective circuit, however, the difference current flowing in the operating winding is able, under conditions of maximum efficiency, to effect the isolation of the defective plant through the actuation of the relay.

Consideration of another aspect of the design of protective apparatus will disclose an additional benefit incidental to the use of this device. The provision of very sensitive fault settings has been restricted in the past by considerations of immunity from incorrect operation, having regard to the question of balance, and accordingly there has been no extensive use of relays capable of operating at small values of energy except where, due to the type of protective transformer provided, the available volt-amperes are of an extremely low order, in which case the use of such relays has not given rise to notably advantageous sensitivity.

The extreme range of current values over which it is necessary for protective gear to operate has already been indicated, and it will be immediately apparent that improvement in the sensitivity of a protective system has the effect of extending the limits within which accurate and correct performance must be achieved.

Reduction in the fault setting may be arrived at in two ways. First, relays of a highly sensitive design may be used; and secondly, a more efficient protective circuit may be evolved, i.e. an arrangement of transformers and connections capable of delivering to the protective relays, for any given fault effect, an increased amount of energy.

The immediate effect of the latter method of improvement will be to give rise to mechanical forces of augmented magnitude exerted on the movable portions of the relays when a heavy fault occurs. If at the same time additional improvement be sought in the direction of more sensitive relays, it is evident that difficulty will be met with, the forces accompanying a short-circuit on the plant protected becoming of destructive magnitude if this line of attack be indefinitely pursued.

As the biasing transformer will have a magnetic circuit of restricted cross-section, this will become saturated by operating current alone when it exceeds, to any great extent, the value necessary to effect tripping of the relay, even though the restraining winding is not energized. The secondary output will therefore be correspondingly limited, as will also the maximum force which may be developed in any relay operated by the biasing transformer, no matter to what magnitude the fault current may increase.

In applying the biasing transformer to differential circuits with a view to the provision of overload restraint, one essential characteristic of this class of apparatus must be borne in mind, viz. the relation which will exist between the extent of the restraining effect and the phase displacement of the restraining current with regard to that flowing in the operating winding. As may be anticipated, the restraint will be a maximum when the phase angle is zero and will be a minimum when the two effects are in quadrature. It is to be noted, however, that the restraining action is by no means non-existent even in the latter case. In the case of overload restraint it will further be obvious that the actual value of the restraint is not essentially of any great importance provided that it is sufficient for its purpose under the least favourable circumstances, and that when operating and restraining currents are coincident in phase the decrease in sensitivity is not appreciable under conditions of normal loading.

No difficulty has been encountered in meeting these requirements, and the author has carried out a very large number of tests of an exhaustive nature in this connection, "turn errors" and other discrepancies having been introduced into the current transformers employed. As a result it has been demonstrated that, in the matter of current-transformer balance, ample restraint may be applied without more than a small fraction of the maximum possible effect being brought into use. In one instance samples of a proprietary steel from entirely different mills were supplied by the manufacturers. Transformers built from different batches were tested together in a simple protective circuit and it was found that the relay tripped with through currents of less than 10 000 amperes. When, however a biasing transformer was employed, a low-impedance instrument connected in series with the relay and giving a half-scale deflection with the current at which the relay was set to trip, gave no perceptible reading when the maximum obtainable current (considerably in excess of 10 000 amperes) was applied.

There will, of course, be a certain loss of secondary tripping current due to the additional transformation, but the sensitivity is unimpaired if the relay setting be reduced by 20 per cent. In unbiased systems, however, the question of stability will determine the setting of the relay rather than the question of the minimum volt-amperes at which the relay is capable of operating. The employment of the biasing transformer, in fact, renders possible the use of a very much more sensitive relay should this be desired.

(2) *Discriminating restraint.*—In the foregoing it has been shown how a biasing transformer may advantageously be applied to a simple differential protective circuit, i.e. one in which it is desired to effect operation of a single relay on the occurrence of a difference between two currents which are normally equal.

In many well-known systems, notably those concerned with the protection of parallel circuits, a more extended function is required. In such instances the protective apparatus will, as before, be called upon to compare normally equivalent currents, and to operate in the event of inequality. There will, however, be more than one relay, each associated with a particular circuit, and it will be necessary to give rise to tripping of one particular relay, usually that carrying the greatest current. It will be of corresponding importance in such applications that relays other than the one specified shall be immune from operation.

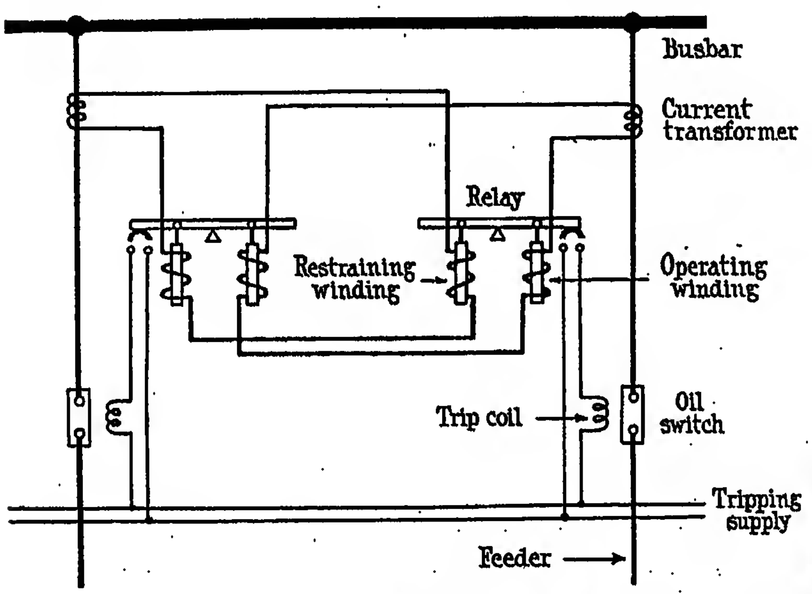

Fig. 6.—Discriminating balanced-beam relays.

It is apparent, therefore, that systems of this nature are necessarily those referred to previously in the paper, when it was pointed out that the employment of balanced, biased or differential relays was inevitable in circuits of this form.

The simplest case is that of direct balance between two feeders, when, as in Fig. 6, two simple mechanically balanced relays of the beam type might be used. Each of these relays is arranged, as shown, to trip out the line from which it derives the current exciting the coil which tends to close the contacts. The restraining coils are each connected in series with the operating coil of the opposite relay and current transformer. Assuming equal turn ratios, etc., both relays will be balanced when the load or other currents are carried to the same extent by both lines. If one of the feeders carries an excessive current, due perhaps to a fault, the corresponding relay will be subjected to an augmented force, in excess of its restraining effort, tending to actuate it. This relay will accordingly operate, whereas on the other there will be increased restraint and the sound line will remain in service.

Fig. 7 shows an analogous scheme in which ordinary relays and biasing transformers are substituted for the balanced relays, no other change being made in the connections. With such an arrangement a similar performance may be obtained. This will be more clearly understood by reference to further characteristic curves of the biasing transformer. As shown by the curve in Fig. 5, referring to a biasing transformer having a closed restraining magnetic circuit, the ratio of operating to restraining ampere-turns giving tripping current in the relay remains fairly constant over a wide range. From this it is clear that any ratio of operating to restraining excitation greater than that indicated by the slope of

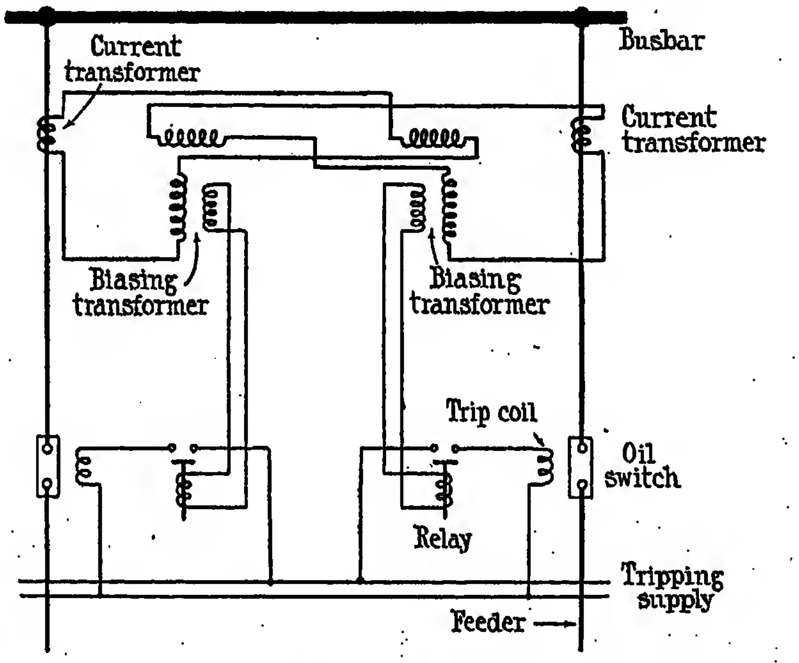

Fig. 7.—Discriminating circuit with biasing transformers.

this curve will provide a current in the secondary circuit more than sufficient to trip the relay, whilst any ratio less than that shown will not cause the relay to operate at all.

In Fig. 8, therefore, are shown curves connecting relay current with operating current, a restraining current having direct proportional relation to the operating current being simultaneously present. Each curve refers to a different ratio between operating and restraining excitation.

If the value of current at which the relay is set to trip is that indicated by the dotted line, the curve of secondary current due to a ratio as in Fig. 5 would, except in the neighbourhood of zero excitation, lie along this line. It was pointed out, however, in regard to Fig. 6 that when the two circuits are carrying equivalent currents the operating and restraining currents in the coils of each relay are likewise of similar magnitude; the same state of affairs exists in connection with the operating and restraining windings of the biasing transformers in Fig. 7.

Evidently, therefore, it is possible to provide biasing transformers having such operating and restraining turns that, when excited in series, there will be set up in the secondary winding and relay, a current as indicated by curve (*a*) in Fig. 8, which shows the actual characteristic obtainable.

It was further seen in connection with Fig. 6, and present in the appropriate relay. In the previous case it will be recalled that under circumstances when the operation of a relay would be incorrect the only operating current would be that due to imperfections of balance.

The connections in Fig. 7 indicate that this requirement is met by the arrangement shown, since under all possible fault conditions there will be present in

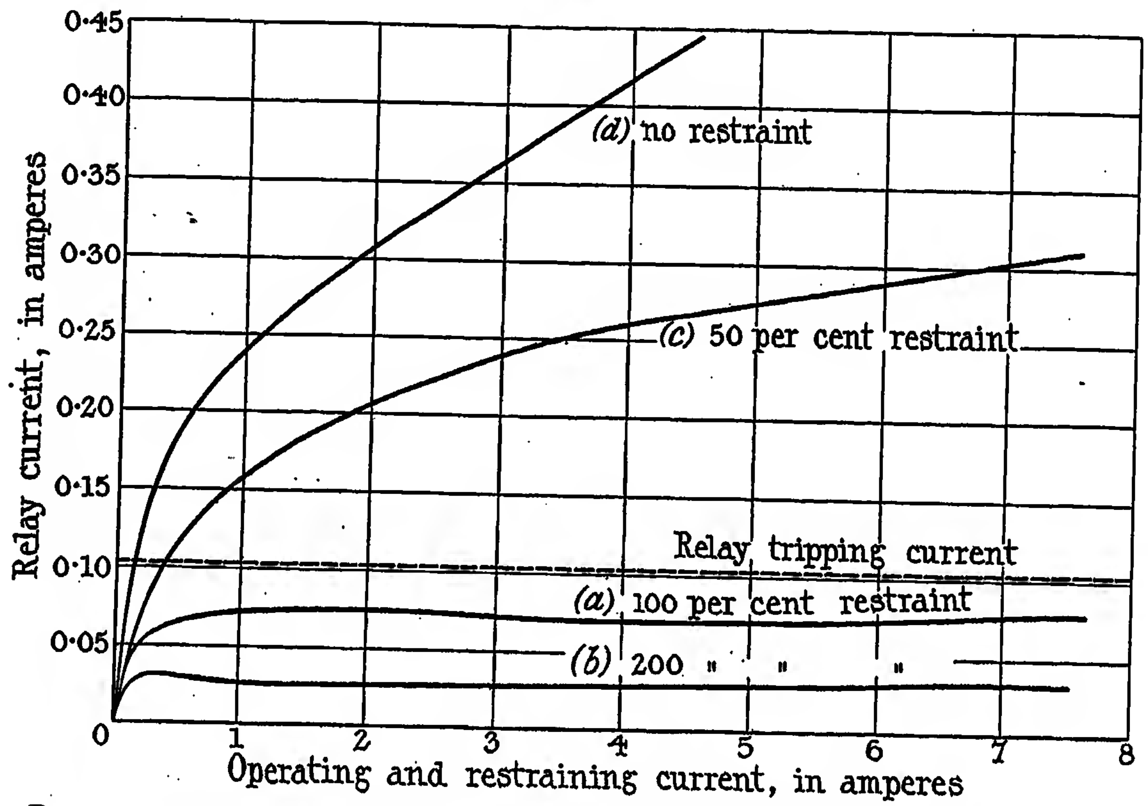

FIG. 8.—Characteristic curve of biasing transformer; discriminating restraint.

accordingly it applies to Fig. 7, that on the occurrence of a fault on one of the circuits there will be an operating current exceeding its restraining current in the biasing transformer associated with the defective line, whilst on the sound feeder the restraining current will be greater than the operating current. In Fig. 8 the latter circumstances are illustrated by curve (*b*) and the former by curve (*c*).

In the extreme case of a severe fault on one circuit with no current flowing in the other, there would of course be no current in the relay which trips the latter, whereas in the other relay there would be a secondary current in accordance with curve (*d*) in Fig. 8, which is simply that of unrestrained transformation. As indicated in the previous section, however, the relay would receive only a limited current no matter how severe the fault current might be, being thereby protected from mechanical or electrical damage under such circumstances.

In connection with the provision of overload restraint, the effect of a phase difference between the operating and restraining excitation has been referred to, when it was pointed out that the magnitude of the restraining effect was not always of great importance provided that it was sufficient to serve its purpose. In the present instance it is essential that where it is necessary for a relay associated with a sound circuit to be restrained from operating under fault conditions, this restraint shall be of a definite nature, since an operating current due to that carried by the sound line will be the defective circuit a resultant current containing a component equal to, and in phase with, that in the sound line.

Fig. 6, however, does not represent the most advantageous method of protection on these lines, as such an

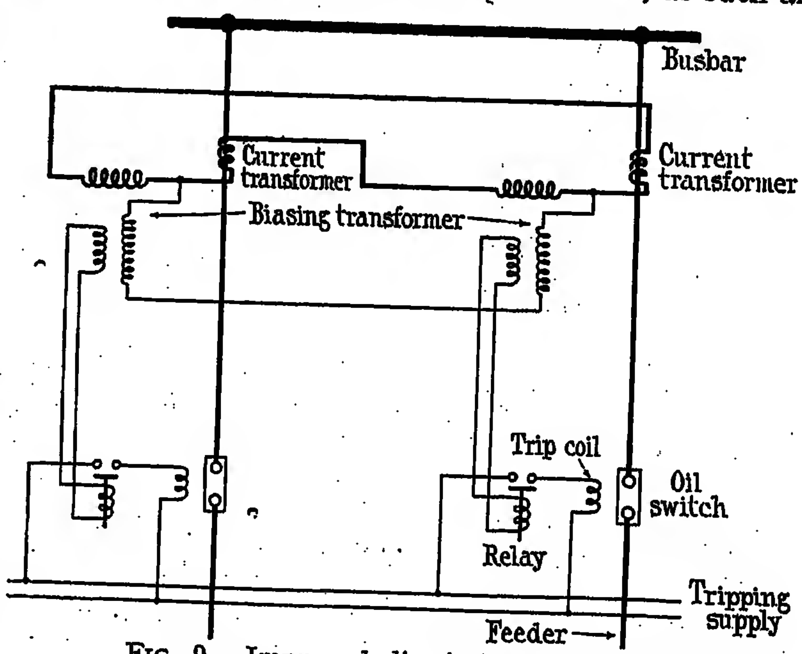

FIG. 9.—Improved discriminating circuit.

arrangement operates on a constant difference current. The superior merits of a system operating on a value of difference current increasing in accordance with the transmitted current or through load have previously been pointed out.

In order to endow the scheme shown in Fig. 6 with such properties it is only necessary to provide a restraining effort exceeding, for equal exciting current, the operating force. This may be arranged by providing an increased number of turns on the restraining coil, or by slightly adding to the length of the relay beam between the fulcrum and the point of attachment of the restraining plunger. The author has found that the latter gives a more extended range of truly proportional bias, as this effect is likely, in the former instance, to be restricted by saturation of the plungers. This arrangement, it is believed, constitutes the first known example of a biased system of protection and is due to Mr. Wedmore.

Instead of a scheme on the lines of Fig. 7, the author employs the arrangement shown in Fig. 9, which gives both discriminating and overload restraint. The current transformers and restraining windings are connected so as to form a circulating-current circuit having equipotential points across which the two operating windings are connected in series. The restraining windings, it will be noted, are cross-connected.

Unlike the arrangement shown in Fig. 7, the connections indicated in Fig. 9 ensure that no current will appear in the operating windings when both circuits are sound, except such as may be due to lack of balance on the part of the current transformers or the primary circuits themselves. On the occasion, however, of a short-circuit on some other part of the system being fed through the circuits protected, and due to which unbalancing may be in evidence, correspondingly heavy currents will be set up in the restraining windings. The property of overload restraint is thus seen to be present.

The properties of discrimination of this scheme are, however, very similar to those provided by the connections shown in Fig. 7; on the occurrence of a fault on one of the protected lines a corresponding difference current will appear in both operating windings. It is clear that the presence of a heavy short-circuit on the one line, there being no current in the sound primary circuit, represents the most severe condition for discrimination, and under these circumstances the difference or operating current is equal in magnitude to that in the restraining winding on the biasing transformer controlling the relay on the sound line.

Relations similar to those described in connection with Fig. 7 are employed between the operating and restraining windings, and accordingly Fig. 8 will also be applicable to this circuit. The biasing transformers associated with the sound line, therefore, have equivalent operating and restraining currents and will in consequence, in accordance with curve (*a*) in Fig. 8, remain inoperative. The transformer controlling the other relay, whilst receiving the same operating current, will be unrestrained and will therefore trip, thus disconnecting the defective circuit from the system.

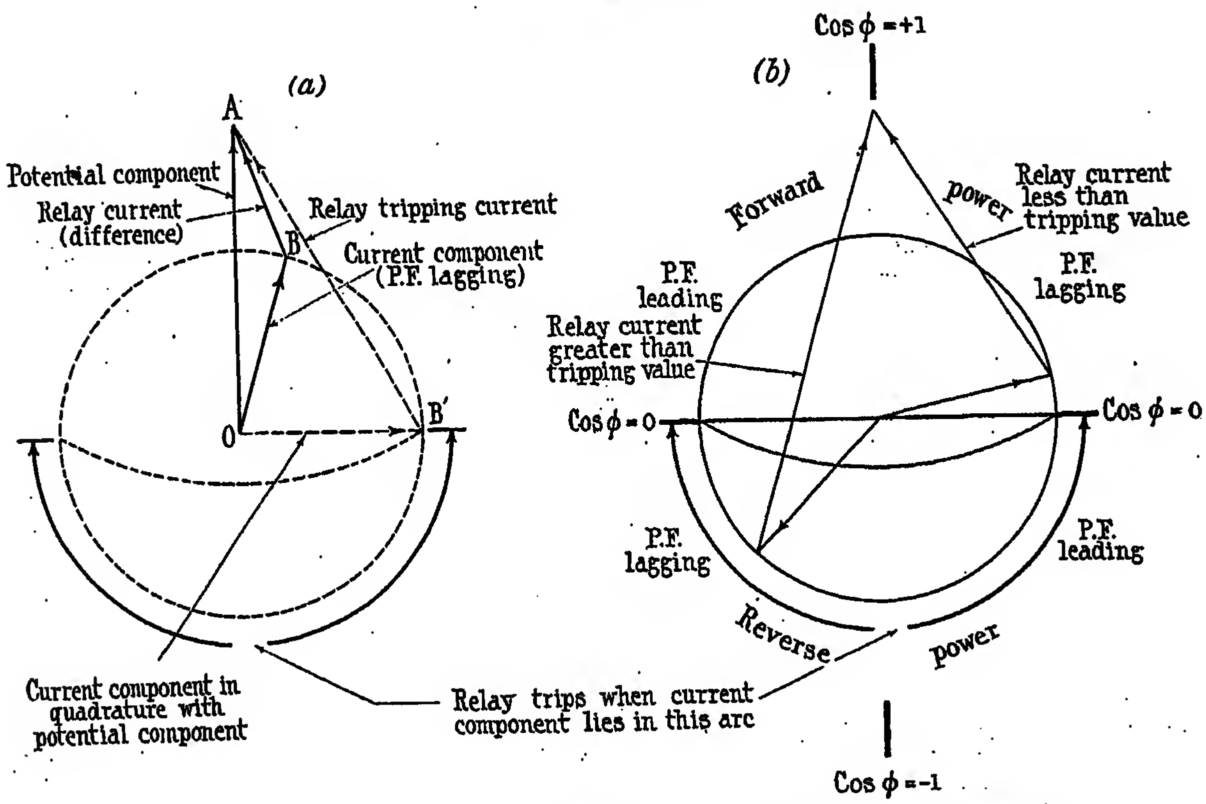

FIG. 10.—Vector and polar diagrams illustrating directional operation.

Attention is directed to the fact that in any biasing transformer protecting a healthy line, the operating current appears in its restraining winding when a fault occurs. Hence the restraining excitation is in phase with the operating ampere-turns.

Circulating-current circuits operating on the above principle may be arranged for protecting any number of parallel circuits.

In the arrangements described in regard to the protection of double circuits it is evident that if one of the lines trips out, no measure of discriminating protection may be applied to the remaining circuit. In practice, means of automatically rendering the protective gear inoperative if either switch be open would be arranged.

In schemes involving more than two lines it will be

necessary to provide auxiliary switches which, in the event of one line coming out of service, will so modify the circulating-current circuit that it remains effective for the protection of the reduced number of lines.

(3) *Directional discrimination.*—Existing methods of directional discrimination usually make use of one of two operating principles. The former of these, in which the relay is actuated by the reaction set up between two windings, one of which is excited by current and the other by potential, necessarily employs relays of appropriate type, usually of dynamometer form. The other principle involves the vectorial addition or subtraction of electrical effects set up respectively by current and potential excitation, some means being devised for arranging that neither current nor potential alone can effect operation of the relay.

The latter principle has been applied by the use of balanced-beam relays, and, as may be anticipated—following the use of the biasing transformer in lieu of this type of relay for other purposes—it is possible to employ a biasing transformer, controlling a simple relay in an analogous manner.

Whilst this principle is not capable of quite the degree of precision attainable with the dynamometer type, it is thought to possess some sphere of usefulness.

If it be supposed, for the purpose of explanation, that the voltage and current concerned be of constant magnitude, a means of arranging directional discrimination, within the specified limitations, by means of a simple relay having current and potential windings, is immediately apparent. It might be carried out, for example, on the lines indicated in Fig. 10, in which OA represents the vector value of the potential excitation, which it is convenient to consider as being of fixed position, and, by hypothesis, is of constant length. OB represents the current vector, also of fixed magnitude but having a varying phase relation to OA, according to the conditions of power. The excitation of the relay, being the resultant of OA and OB, will vary between the limits of the arithmetical sum and difference of these two quantities, and is represented by the vector AB.

This arrangement will possess directional properties if the relay be set to trip at a value equal to that of AB′ when the current and potential are in quadrature, under which circumstances AB′ will form the hypotenuse. If the connection be made so that addition occurs when the direction of power is negative or reverse, the relay tripping current will be reached whenever there exists a negative component in the current. In practice, however, we are concerned with both potential and current of varying magnitudes, and the above scheme is clearly inapplicable; it could only be employed were some means available of obtaining an excitation related to the current or pressure in direction but not in magnitude.

The possibility of this is suggested by the form of curve (*a*) in Fig. 8, and it has in fact been found possible, by a suitable design of windings and magnetic circuit, to provide a biasing transformer which, with series-connected operating and restraining windings, will maintain in the relay a current approximating very closely indeed to the mean value, this being maintained over a current range extending from a small fraction of full load to the maximum possible overload.

If the assumption be made that the potential will always be of constant value, only the current excitation need be provided through the medium of a biasing transformer. The relay would then be furnished with a separate winding, energized in series with a resistance large in comparison with the reactance of the winding, with a view to the provision of a current in phase with the potential. Advantages accrue, however, if the potential excitation be also provided by means of a biasing transformer, a simple relay being employed having one winding only, connected as shown in Fig. 11.

In this figure it will be noticed that the relay is excited in series with the secondaries of two biasing transformers, one of which receives the secondary current of the current transformer whilst the other

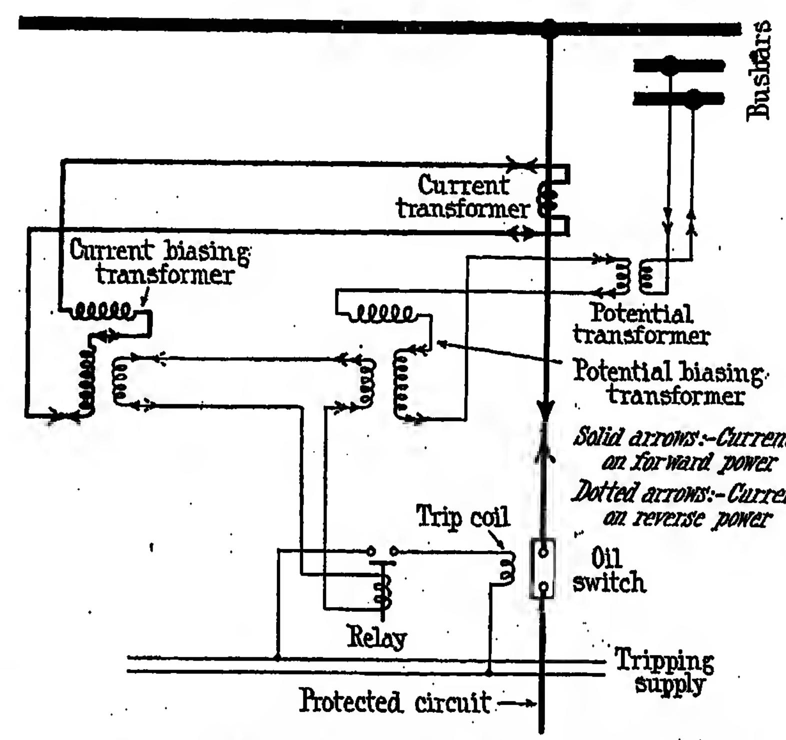

FIG. 11.—Directionally operating circuit with biasing transformers.

derives its energy from the secondary of a potential transformer. The relay will accordingly trip when the resultant secondary current of the biasing transformers reaches the appropriate value in the manner described in reference to Fig. 10.

If the arrangement be excited from the current transformer only, the relay current would be in accordance with curve (*a*) in Fig. 12, which is seen to be similar to curve (*a*) in Fig. 8, except that in this instance it may be desirable to provide as flat a characteristic as possible.

The relation between the relay current and the potential may now be considered, it being supposed for the moment that no energy is derived from the current transformer. Apparatus of this nature will essentially be more commonly associated with polyphase circuits than with others, and the present example is intended to be applied to an ordinary three-phase system.

In directionally functioning apparatus it is now the accepted practice to excite the potential windings from phases adjacent to those in which the corresponding current elements are connected, in order to overcome

difficulties due to vectorial distortion of the potential under short-circuit conditions, which difficulties are known to occur if this principle is not adopted. It will be seen that the present arrangement is peculiarly suitable for carrying out this requirement, for the following reasons.

Where the above practice is carried out it is clearly necessary to arrange that the potential relay current shall be in quadrature with the voltage producing it, in order that at unity power factor there shall be coincidence of phase relation between the current and voltage effects. Where dynamometer relays are used, the pressure coils are sometimes excited in series with condensers for this reason.

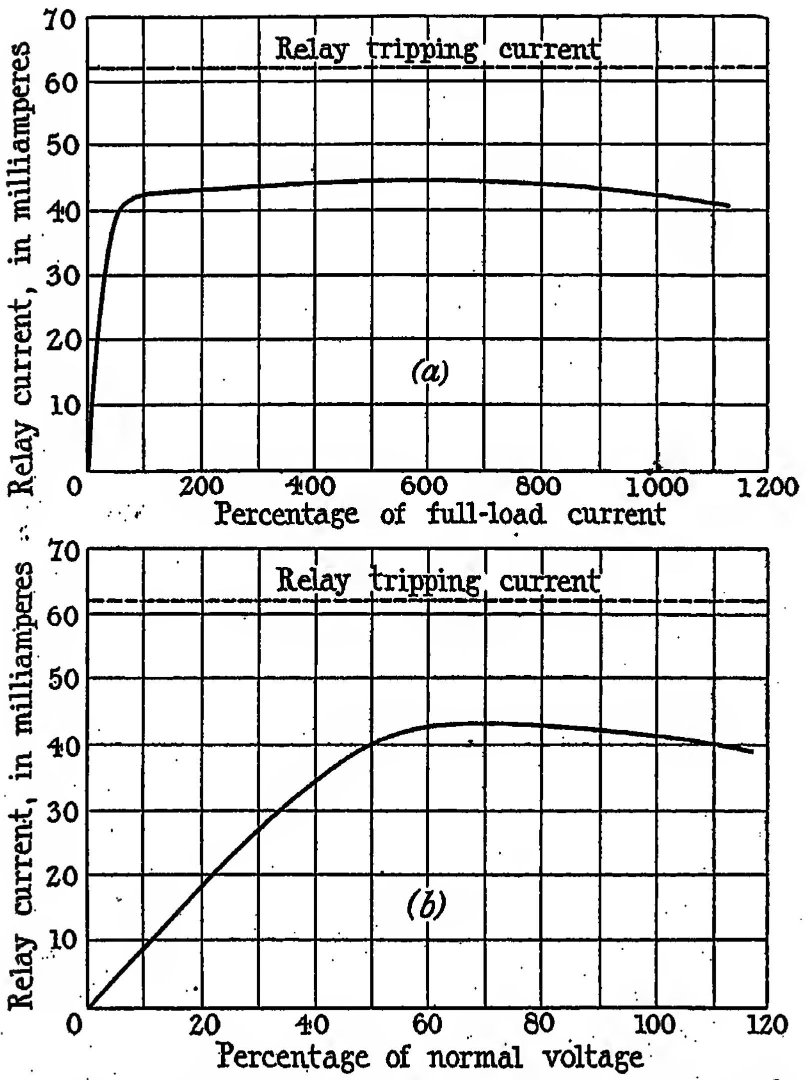

FIG. 12.—Characteristic curves of biasing transformer; directional operation.

In Fig. 11 it will be observed that the potential biasing transformer, as well as that excited by the current transformer, has operating and restraining coils connected in series. Since the restraining winding has more turns than the operating winding, and, moreover, since it is of a more highly reactive nature, due to the absence of any associated secondary winding, its impedance will very greatly exceed that of the latter, with which, it is to be noted, it has no inductive relation. The phase relation of the current in the operating winding to the potential from which it is derived, will accordingly approximate very closely to quadrature. If, therefore, the above method of potential connection be adopted, the proper conditions are accordingly obtained.

Whilst the characteristics of the potential biasing transformer may be arranged to be similar to curve (*a*) in Fig. 12, it may be preferable to arrange them after the pattern of curve (*b*), for the reasons explained below.

It will be seen that the effect of the flat characteristic will be such that if any point on the curve be chosen to represent normal pressure, a reduction in voltage due, for instance, to a fault on the system, will not cause a proportional decrease in the relay current, only that current derived from the potential being considered for the present. The shape of curve (*b*) in Fig. 12 will enable more sensitive operation to be obtained on reduced pressure, whilst the falling-off of current on over-voltage is likely to have a favourable effect on the performance of the apparatus when subjected to surge effects giving rise to transient pressure-rises.

Whilst it is theoretically possible to provide unlimited compensation for extinction of voltage, in practice this will be limited by the capacity of the apparatus to withstand the heating effect of the current which is normally carried. To obtain adequate operating current at very small fractions of rated voltage, therefore, it is necessary to provide correspondingly increased ampere-turns under normal conditions. Similarly, it is possible

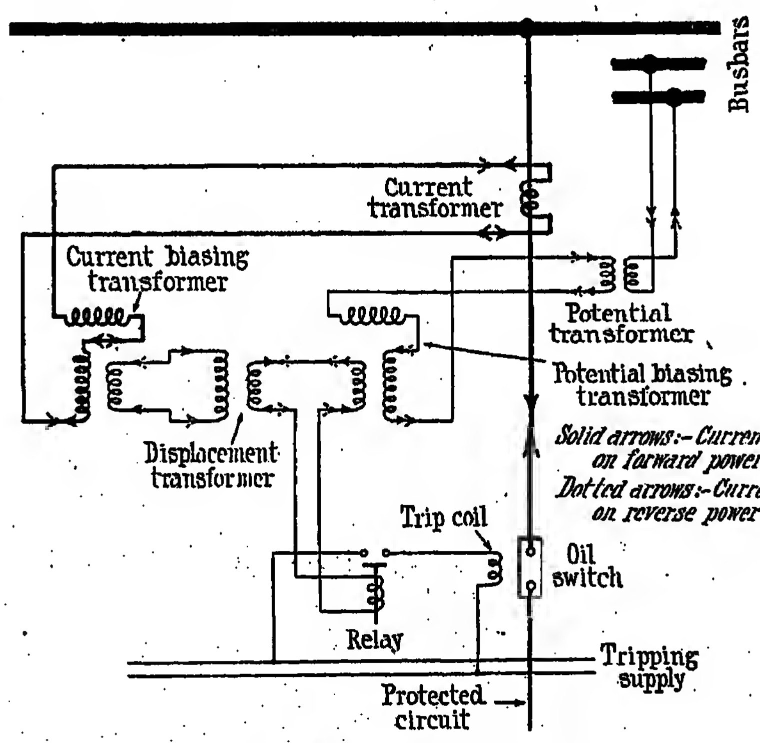

FIG. 13.—Improved directionally operating circuit.

to design the current element so that it will only be operative on currents not exceeding the rupturing capacity of any given circuit breaker. Alternatively, it may be designed to trip without potential on a sufficiently heavy short-circuit. Such an arrangement, therefore, will operate in accordance with the vector diagram shown in Fig. 10 (*a*), and its tripping characteristics may be more clearly exhibited by a polar diagram as in Fig. 10 (*b*). Here the full extent of angular relation between current and pressure and the respective portions of both, over which the relay is restrained and operated, are indicated.

The arrangement shown in Fig. 11 would probably possess a slight error due to internal losses in the poten-

tial biasing transformer, which would deflect the polar diagram slightly in a counter-clockwise direction, due to the fact that the potential current would lag behind the potential by an angle slightly less than 90°. This could be compensated for by connecting a resistance, taking a small fraction of the normal current, in parallel with the operating winding. This would cause the operating current to lag slightly behind the total potential current, thereby introducing the necessary correction.

A preferable arrangement, however, is illustrated in Fig. 13, in which an additional transformer is introduced between the biasing transformer excited by the current transformer and the relay. For reasons which will be more fully discussed in connection with the complete scheme of differential protection to be described in a subsequent section of the paper, this second transformation will usually be present in the form of a further these circumstances consists in the arrangement of the potential connections so that a phase displacement of the potential excitation in a direction favouring tripping on a reactive fault is effected. One method of carrying out this idea is the connection of the potential windings between line and earth instead of between phases, a scheme which introduces a displacement of 30°. This is not entirely effective, since on the occurrence of a single-phase fault very little difference in phase may actually exist between either arrangement; moreover, the presence of this phase-shift under normal conditions is of no advantage and might conceivably be detrimental in the event of any considerable leading current being found in the circuit protected.

In the scheme outlined in Fig. 13, however, the following phenomena occur, and give rise to a feature of utility. It has been explained how the presence of a second

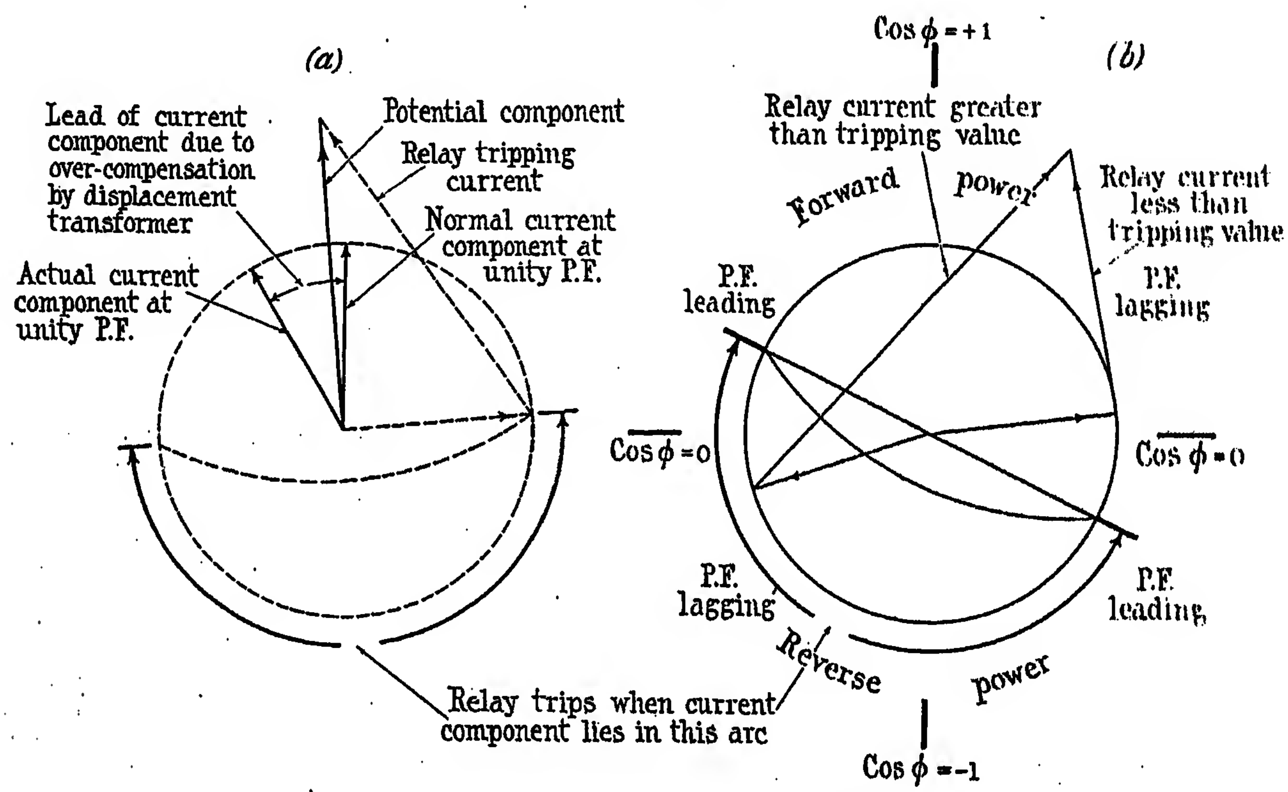

FIG. 14.—Vector and polar diagrams of improved directional circuit.

restraining effect, in directionally operative circuits of which the present simple diagram may form a portion. In Fig. 13, however, this is indicated as a simple transformation possessing no restraining feature. Under conditions of normal load this arrangement can be designed to have symmetrical tripping characteristics in accordance with diagram (*b*) in Fig. 10, without any additional resistance.

An additional feature of utility will now be discussed. It is well known that the majority of the more severe fault effects necessarily give rise to heavy lagging currents of low power factor, and in all forms of directionally discriminating apparatus this has been a source of difficulty, as such devices are necessarily not operating to best advantage under these conditions. Even more unfavourable to the present device are these conditions, since it is dependent for its property of acting directionally on a purely quantitative principle of operation.

A method of obtaining improved operation under transformation causes a corrective phase displacement giving correct tripping limits, as in diagram (*b*) in Fig. 10. It is found that on the occurrence of fault effects giving rise to heavy currents this effect becomes augmented in accordance with the magnitude of the current, so that under such conditions the tripping characteristics are as shown in the polar diagram (Fig. 14) rather than in Fig. 10. This gives the required feature in that under heavy-current conditions a current lagging by exactly 90° will give a greater relay current than one leading by precisely the same angle. In this instance the combined effect of both current and potential excitation is, of course, referred to.

This property, therefore, enables more definite discrimination to be achieved under the more difficult circumstances accompanying fault currents of low power factor and large amplitude, at the same time preserving accurate phase relation on currents of smaller magnitude, e.g. faults to earth on a system employing earthing

resistances. It will be perceived that with this arrangement it is not possible to vary the sensitivity of the apparatus by adjusting the relay setting, as it is upon this latter factor that the system depends for its discriminating features, and due to this inherent condition the precision of its operation will depend largely on the nature of the performance of the relay itself. Where it is required to provide variation in the value of the current necessary to operate the gear, a simple form of adjustable reactive shunt may be employed, or tappings may be provided in the operating windings. As previously indicated, it is realized that this device cannot be considered as a substitute for dynamometer relays in general; nevertheless there are often conditions where, due to lack of skilled maintenance or other local conditions, very simple apparatus may be preferred. Apparatus functioning on these lines might, for instance, be devised directly to trip the switch. In the more special systems of directional protection, shortly to be described, a simple relay operating on the above principle may always be employed. Alternatively, by using similar biasing transformers, and retaining all the special features to which they give rise, the simplest form of dynamometer relay or its equivalent may be used, should it be preferred. Each coil of the relay will be excited from the biasing transformer secondaries, which in the above case are connected in series.

(4) *Auxiliary restraint.*—In the circuits and applications described above, there has always been used in the restraining windings an alternating current of the same frequency as the operating excitation, the restraint depending for its magnitude on considerations associated with the conditions obtaining in the primary circuit, as, for instance, in the simplest case described, on the load carried by the apparatus or circuit protected.

A restraint of equivalent effect, not in fact dependent upon any questions of phase relation, might evidently be obtained by exciting the restraining winding from a source of direct current. In this manner a number of functions might be carried out on lines already familiar to switchboard and control engineers, e.g. practical requirements in connection with interlocking, signalling and similar schemes. Under any circumstances where the employment of a biasing transformer renders possible the use of a reduced number of contacts, the author suggests that its application is at least worthy of consideration. As an example, conditions sometimes arise when it is desirable simultaneously to put out of action for a brief period, or perhaps to render less sensitive, a considerable number of relays. To do this by ordinary methods might quite conceivably require as many contacts as there are relays, yet, if a device of the nature described be incorporated, all the restraining windings might be connected in series and energized from a single switch or relay contact. It might be possible in schemes of this nature, in which it is necessary to make dispositions in accordance with the closing or opening of circuit breakers, to utilize existing lamp-signal circuits. Many similar adaptations and devices will suggest themselves to those familiar with work of this kind. The object aimed at by the author in every case is the replacement, by static devices, of moving parts not associated with considerable amounts of power. In circuits where relays and biasing transformers are already employed for purposes of protection in accordance with the requirements previously described, the addition of controlling means on the above lines may clearly be carried out with facility, a further transformation being added to the existing circuit. It should be noted particularly that the loss in efficiency due to the second restraint is not so great as might be expected, the primary current necessary to trip a relay directly, with one transformation and again with double transformation being, in one practical case used by the author, in the ratio of 100, 120 and 140, respectively.

By controlling the value of the d.c. restraining excitation by means of a rheostat or other convenient apparatus, the tripping current might be remotely adjusted, and in stations where it is not possible to provide attendance of a very skilled order, adjustments of this nature might be preferably carried out in this manner, if they are frequently necessary, rather than interfere with the actual relay mechanisms. A simple example of direct-current restraint is illustrated in Fig. 22.

Construction of the Biasing Transformer.

The biasing transformer is built up in an entirely conventional manner exactly like any other type of small transformer suitable for outputs of the same order, that is to say, apparatus used in connection with instruments, etc., rather than with the supply of power.

In the majority of cases the core is made of punchings, assembled in the usual way, in former-wound coils. Where there is more than one winding situated on one limb of the core these are made up into one coil, suitable insulation being provided between the respective circuits. It is recommended that all coils be subjected to appropriate vacuum and impregnating treatments which, besides improving their insulating properties, render them less likely to break down due to mechanical causes, the process having the effect of solidifying them. It will be realized that in a complete scheme of protection a number of such elements may be employed. It is usual for all the elements necessary for a three-phase circuit to be assembled in a metal tank or other suitable receptacle, leads being brought out to conveniently situated terminals. The whole is then filled with compound. As this portion of the protective gear is under no circumstances energized by pressures exceeding that of the secondary of a potential transformer, and is more commonly associated with current-transformer connections at voltages, under normal circumstances, even smaller than the above, it would certainly appear that the section of the protective system which has discriminative properties could scarcely be provided in a form less likely to suffer deterioration of function from any cause whatever.

It is to be noted that since the biasing transformer is connected only in secondary circuits, it does not receive the full extent of any excessive primary currents, due to short-circuits, etc. It has been found possible to design the windings so that they may be

subjected, for testing purposes, to effects of equal magnitude to those arising in practice, without suffering damage. The tests may be made as often as required. This feature is very desirable in view of the importance of carrying out comprehensive and searching tests on protective gear.

Design of Protective Current Transformers.

The author does not propose to refer at any great length to this section of the protective circuit, as there would not appear to be any great conflict of opinion as to the objects which should be aimed at. The following brief notes, therefore, should suffice.

The most essential requirement in the design of apparatus to be installed as part of a protective system is that there must not be any feature likely to contribute towards risk of breakdown. Clearly, if the presence of any component of the protective gear introduces into the main circuit any hazard not otherwise present, the object of the apparatus is abrogated. Throughout the design of a protective transformer, therefore, both in regard to its insulation and to all other constructional considerations it is recommended that a more liberal factor of safety than that appropriate to lines of current transformers designed purely for energizing meters, etc., should be worked to. In the event of a destructive accident on a transmission system, the protective gear should obviously be the last portion of the plant to cease functioning. The use, for instance, of wound-primary current transformers for protective purposes is to be avoided, as this type is inherently more liable to damage on heavy short-circuits, both in regard to mechanical forces and destructive heating.

In every case, therefore, transformers of the bar-primary pattern are to be preferred. A straight primary conductor through opposite bushings is more desirable than the form associated with tank type transformers in which, although only one conductor may be employed, this is brought into the case through top bushings. With such a form of construction a partial loop in the primary circuit is unavoidable.

Within reasonable limits of dimensions and cost, an augmented secondary output, desirable for the reasons already given, should be sought rather by increase in the size of the iron core than by adding to the number of turns.

The reactive component of the primary impedance varies, at normal frequency, as the square of the primary turns and directly as the permeability of the magnetic circuit. A current transient of steep wave-front encountering such a transformer will, however, set up across its terminals a local pressure-rise not necessarily in accordance with the above relation. Under such conditions one would expect the flux set up in air paths by disturbances of this nature to bear a larger ratio to the total induction than would be the case at working frequency. If these aspects be considered, the advantages of a large core and single conductor as compared with an arrangement capable of equivalent sensitivity (so far as protection is concerned), and having less iron and more turns, will be self-evident.

Protective Relays.

General.—In the protective schemes dealt with, which only require a relay of simple type, any desired form of relay may be employed. The attracted-armature relay is one of the most suitable, chiefly because, for given excitation, it can develop an operating force considerably greater than any other type of a.c. relay. Moreover, a relay of this form employs the minimum amount of movement and consequently is less likely to be affected by frictional effects than types involving greater displacement of the moving parts. It is possible, indeed, to design a relay on these lines without pivots, since the movement of the armature is confined to a few degrees of arc.

Anti-surge device.—In most instances it is a decided advantage that the speed of operation of the attracted-armature relay is probably greater than that of any other type. It is, however, sometimes desirable to render such a relay immune from operation due to

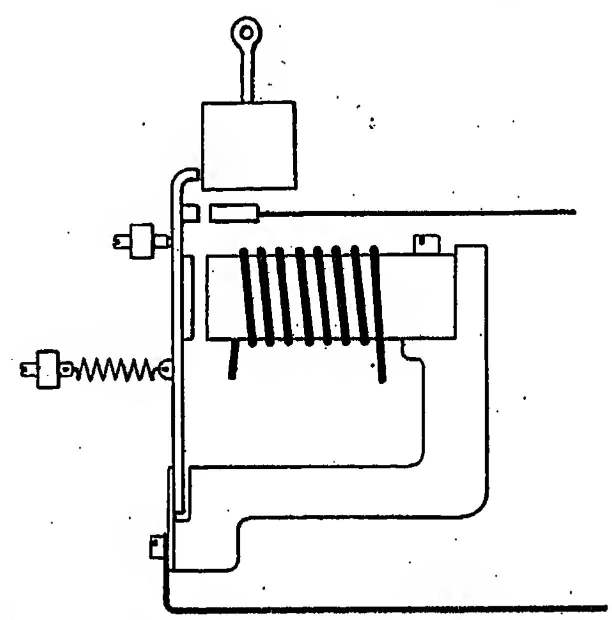

Fig. 15.—Attracted-armature relay with anti-surge device.

sudden impulses not sustained for more than two or three periods. Loading the armature delays the tripping of the relay but does not prevent it operating on a transient, as the moving system acts like a ballistic pendulum and stores up the energy due to the sudden impulse.

Instead of increasing the mass of the armature a suspended weight may be added, as shown in Fig. 15. This weight hangs free of the armature but is displaced when the latter operates.

Only an operating current sustained for something of the order of 0·1 sec. will then trip the relay. If the impulse is of shorter duration the armature will be observed to strike the weight a sharp blow and to make no further movement. The energy due to the transient is transmitted to the weight, the movement of which may be seen to persist after the operating current has ceased.

Augmented contact pressure.—In relays of a sensitive nature it is usual to employ some means of augmenting the contact pressure when the trip circuit has closed. This generally leads to a certain amount of complication in the construction of the relay, but the desired

feature may be simply contrived on the lines indicated in Fig. 16.

The magnetic circuit associated with the operating winding, it will be perceived, resides entirely in the upper section of the core and armature, as indicated by the chain-dotted lines. The contacting winding is wound up with the operating coils, but is connected in a different manner so that each limb of the core is excited in the same sense. This will result in a flux being set up by this winding, existing not only in the upper part of the core but also in the lower portion. This flux is shown by the broken lines. It will thus be seen that the provision of the contacting winding does not entail any further mechanical complication. It should be noted that the a.c. and d.c. windings must be mutually non-inductive, or the relay may vibrate synchronously.

Resonant protective relay.—Compared with d.c. protective relays it is particularly to be noted that the a.c. relay is at a disadvantage on account of its low power factor. In the d.c. relay the exciting ampere-turns are only limited by the available winding space.

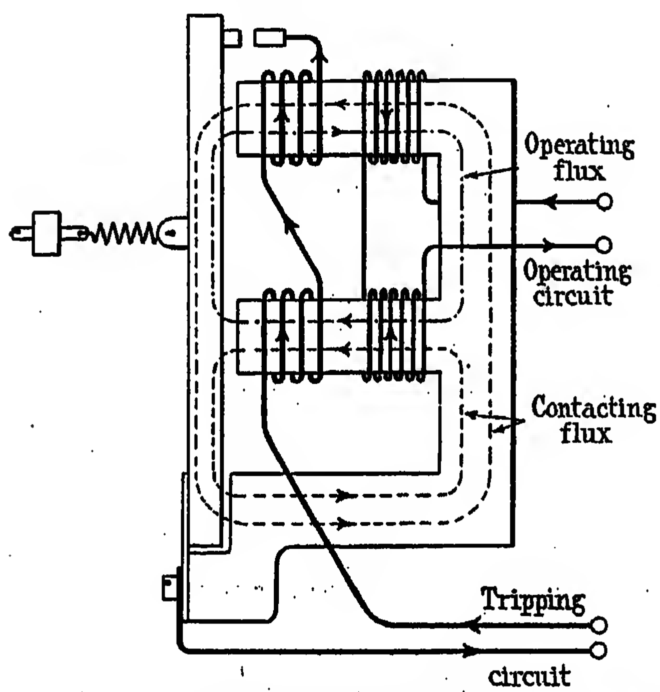

Fig. 16.—Simple attracted-armature relay with augmented contact pressure.

On the other hand, the a.c. relay is subject to the limitation imposed by the reactance of its windings. If any given relay be operated with alternating current and again with direct current, the volt-amperes being the same, the relay in the latter case will receive excitation several hundred per cent in excess of that possible where alternating current is used. Thus the force exerted by the relay when energized by direct current is correspondingly greater.

This point of view suggests that it may be possible to bring about an increase in the operating force of an a.c. relay if means be provided to increase the power factor. This may be done by utilizing a resonating capacity connected across the relay terminals. Such a condenser, however, if suitable for a current-operated relay might be expected to be of very considerable dimensions, and a preferable arrangement is illustrated in Fig. 17, in which a secondary winding is provided, directly connected to the condenser, on the relay. The number of turns on this winding may be chosen so that a condenser of small bulk will fulfil the requisite conditions. If this condenser be built into the relay assembly no complications will be introduced so far as the installation of the gear is concerned, and, provided that the secondary pressure cannot exceed, say, 50 to 100 volts, there is no reason why such an arrangement, which is only concerned with a few volt-amperes, should not prove reliable.

Whilst it is realized that the addition of the extra complication might not be welcomed were the object the achievement of specially small fault settings, it is suggested that the possibility of the use, for any given sensitivity, of a larger and heavier relay and increased operating force may be worthy of consideration. It is found that without what may be described as "close tuning," such that the operation might be affected to a serious extent by normal frequency variations, a reduction of 60 per cent or more may be achieved in the volt-amperes necessary to cause operation of a relay.

For a given primary current, the protective transformer is capable of providing a definite maximum output in volt-amperes. The latter is not affected by the power factor of the relay forming the secondary load.

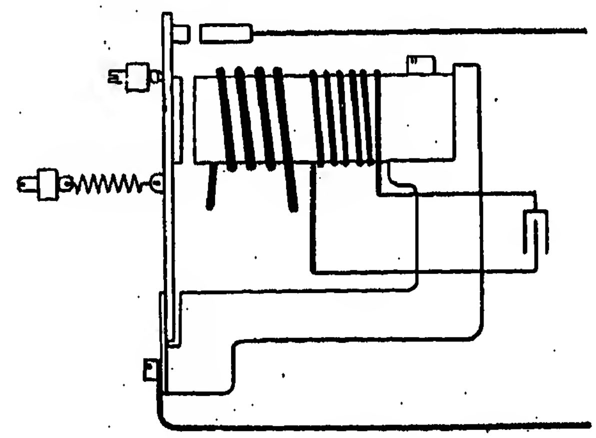

Fig. 17.—Resonant relay.

On the relay being called upon to clear a fault of such severity as may cause a considerable drop in the speed of the generating plant, ample tripping energy will be available even though the relay operate at the current value at which it would trip were it not resonated. Such a relay would also be less affected by any transient effects of the nature associated with steep wave-fronts or abnormal frequencies.

Other Components of a Protective Circuit.

The author has dealt at varying length, according to their novelty, with the relays, current transformers and biasing transformers comprising the apparatus present in protective circuits of the nature embraced by the present paper, and, as will be seen, very little further apparatus is required. There will, however, in certain instances be a few further items, of a general nature, but installed for purposes purely associated with the protective gear. The considerations relevant

to the design of protective transformers, relays, etc., discussed above, should evidently apply to an equivalent extent to such miscellaneous components as are required to complete or assist the operation of the protective gear.

Obviously it is useless to expend great care on the design and installation of a protective system if there is the remotest possibility that the circuit breaker will fail to open when the tripping circuit is properly completed by the relay, due to such causes as failure of the supply of tripping energy. Moreover, in some systems it is essential that certain auxiliary switches should be provided on the circuit breakers, and in such cases the proper operation of the protective gear is just as much dependent on these as on the relays. Accordingly they should be in no way less reliable. It does not follow, for instance, that an auxiliary switch designed for operating a signal lamp is equally suitable for incorporating in a protective circuit.

Apart from questions of reliability and general robustness of design, it is usually necessary for auxiliary switches operating in protective circuits to open or close their contacts at a more definite instant in the stroke of the switch than is required of apparatus having a more general application. Where there is present, in a protective circuit in which provision is made for any form of core balance or leakage protection, a three-phase auxiliary switch, the simultaneous operation of all phases will be a point requiring atten-

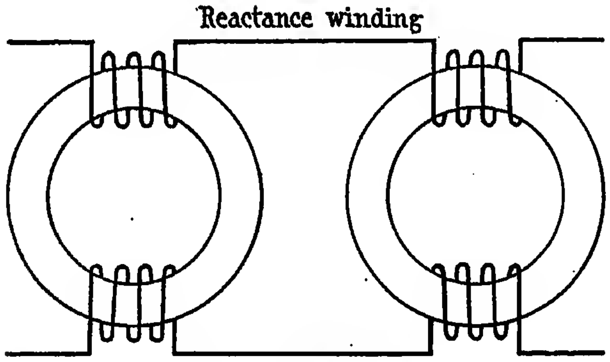

FIG. 18.—Phantom auxiliary switch.

tion, lest it be possible for transient leakage effects to be set up due to one contact being made before another, no real leakage component being present.

Whilst it will no doubt be agreed that systems of protection not requiring auxiliary switching are to be preferred to schemes necessarily involving this feature, there are unquestionably certain occasions when, due to cost or to the impossibility of applying the preferred arrangement, such devices must be adopted.

For these reasons it must be admitted, therefore, that the employment of automatic switching means, other than the conventional and necessary arrangements concerned with the operation of the circuit breakers, must constitute a definite addition to the attention necessary to maintain such a system in a state of efficiency.

A further objection to the installation of such devices is often encountered in the presence, on the oil switches concerned, of auxiliary switches associated with other requirements, e.g. interlocking or signalling. Under such circumstances the provision of further contacts may be impossible or at any rate difficult and undesirable. These restrictions have led the author to consider whether, where no alternative to the installation of additional auxiliary contacts appears to present itself, some means may not be devised for reducing the number required or for simplifying the arrangement by applying the principles utilized for reducing the complication of the protective apparatus itself. Where the requirement to be met is simply to ensure that certain relays shall be inoperative in the event of corresponding switches being open, this may be achieved by an auxiliary direct-current restraint, operative from existing signal or other contacts. This would involve only the addition of extra elements in the biasing transformer, and two extra terminals. As all three relays in a three-phase arrangement would be controlled by the one d.c. circuit, some simplification would result.

This, however, will not meet every case, because it is sometimes essential that, on the opening of an oil

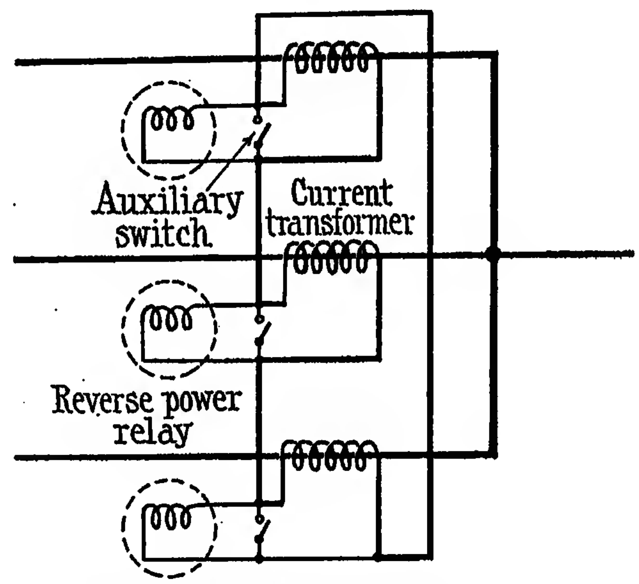

FIG. 19.—Typical protective circuit.

switch, appropriate modification shall be made to the a.c. secondary circuit, idle current transformers and windings having to be short-circuited in order that they may not interfere with other portions of a circulating-current circuit. For such a purpose it would certainly appear that an actual switch contact forms the only possible solution. The author has, however, carried out experiments with a device intended to perform this function, and this has given very favourable results.

Phantom auxiliary switch.—The particular line of attack is suggested by considering a switch as an impedance capable of being varied, theoretically, between zero and infinity, and in practice over a suitable range. Investigation shows that in a secondary circuit excited by current transformers of conventional design, the correct relation of the equipotential points in a circulating circuit may be maintained, on a portion of the circuit becoming inoperative, if a device capable of

undergoing, at will, a change in impedance in the ratio of about 1 : 250, is substituted for an actual auxiliary switch contact.

As the permeability of magnetic steel is variable between limits of this order, according to the flux density at which it is operated, use may be made of this material in a reactance.

If the secondary winding be omitted from the pair of ring cores shown in Fig. 1 (*a*), an arrangement as outlined in Fig. 18 results, the operating winding having an impedance varying with the induction in the core. The reactance curve of any ring core shows an increase of reactance with exciting current up to a certain sharply defined maximum, after which it becomes reduced, rapidly at first, but more slowly with further increase in current.

previous maximum value, so that only negligible currents can flow through the parallel circuit.

It is to be noted that here, as in the previously described scheme, all three phases may be controlled by one d.c. contact, which may possibly be necessary for other purposes. In this case no additional auxiliary switch will be called for. This arrangement ensures simultaneous operation on all phases, thus avoiding the effects in leakage circuits to which reference has been made. The control of a direct current of the necessary magnitude, not usually exceeding 1 ampere, may quite possibly entail less severe service on the control contact than on a similar one liable on occasion to carry secondary currents corresponding to primary overloads or short-circuits.

Again, the "phantom switch" device may be built

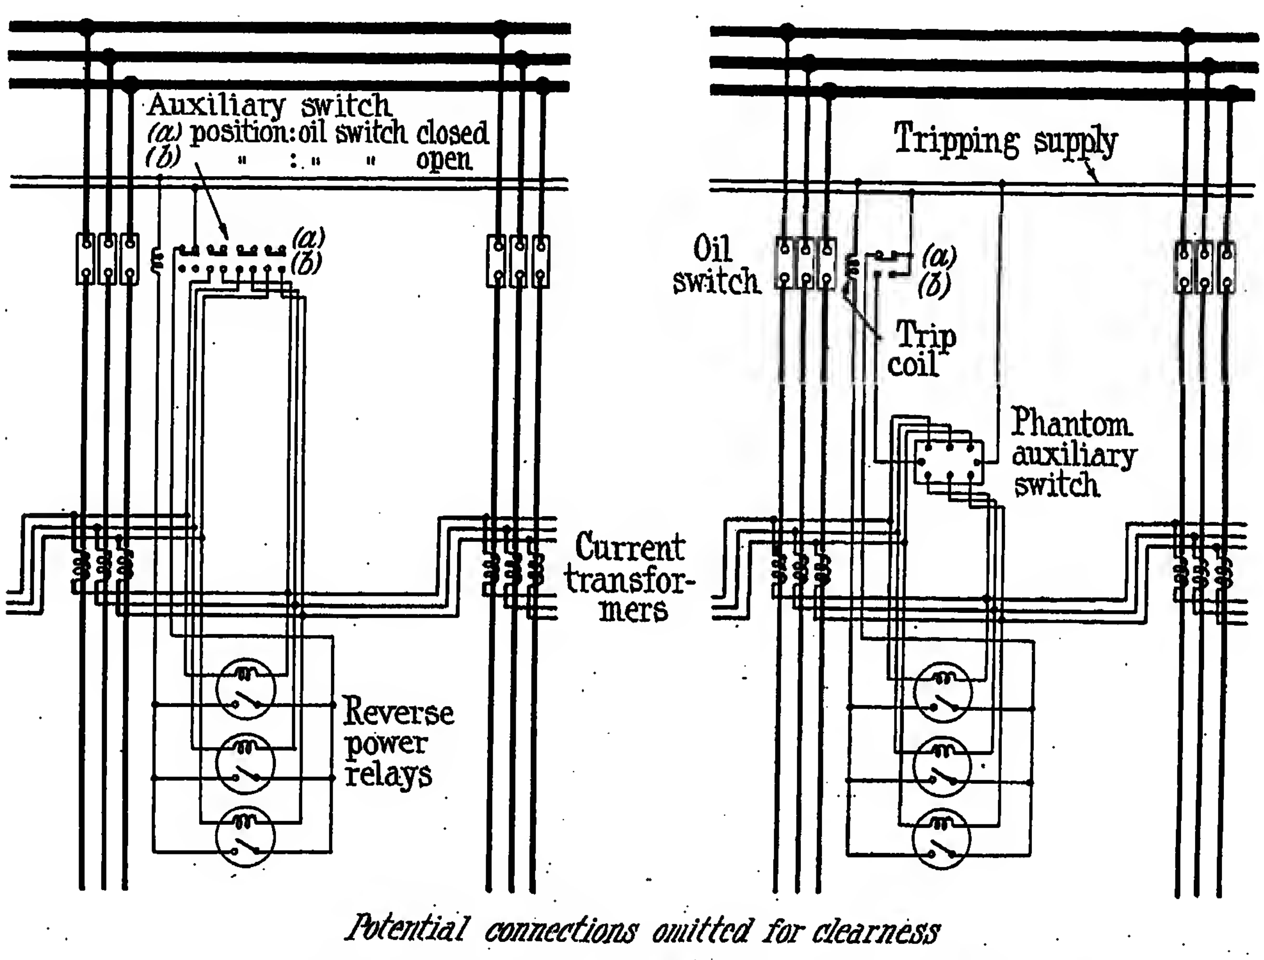

FIG. 20.—Application of phantom auxiliary switch to protective circuit.

The winding above referred to, which may more correctly be called the reactance winding, is placed in circuit in lieu of the switch contacts. If the turns and cross-section are so selected that under the maximum voltage to which it can be subjected its reactance is still on the rising portion of the curve, and if the reactance is correctly apportioned in relation to the circuits with which it is connected in parallel, it passes only an inappreciable current. The winding referred to in Fig. 1 as the restraining winding, which, it will be recalled, is not inductively related to the other winding, is capable of saturating both cores. In the event of its being necessary, in effect, to "close" the switch contact represented by the reactance winding, the saturating or control winding is excited by direct current. The impedance of the short-circuiting winding will immediately be reduced to about 1/300th of its

into the biasing transformer case, and similarly compound-filled if desired. This results in a distinct simplification of the actual wiring.

Complete protective systems or circuits in which the application of the biasing transformer is shown are given in Section 2, but the practical result of the use of this device may be illustrated in connection with another typical protective circuit.*

Fig. 19 shows a single-line schematic diagram of a method of parallel-feeder protection using differentially connected reverse-current relays. For the sake of clearness in this and the succeeding diagram, potential connections are not shown, the current transformer secondary connections only being relevant to the matter under discussion.

The actual wiring diagram involved on any one of

* See *Journal I.E.E.*, 1920, vol. 58, p. 395.

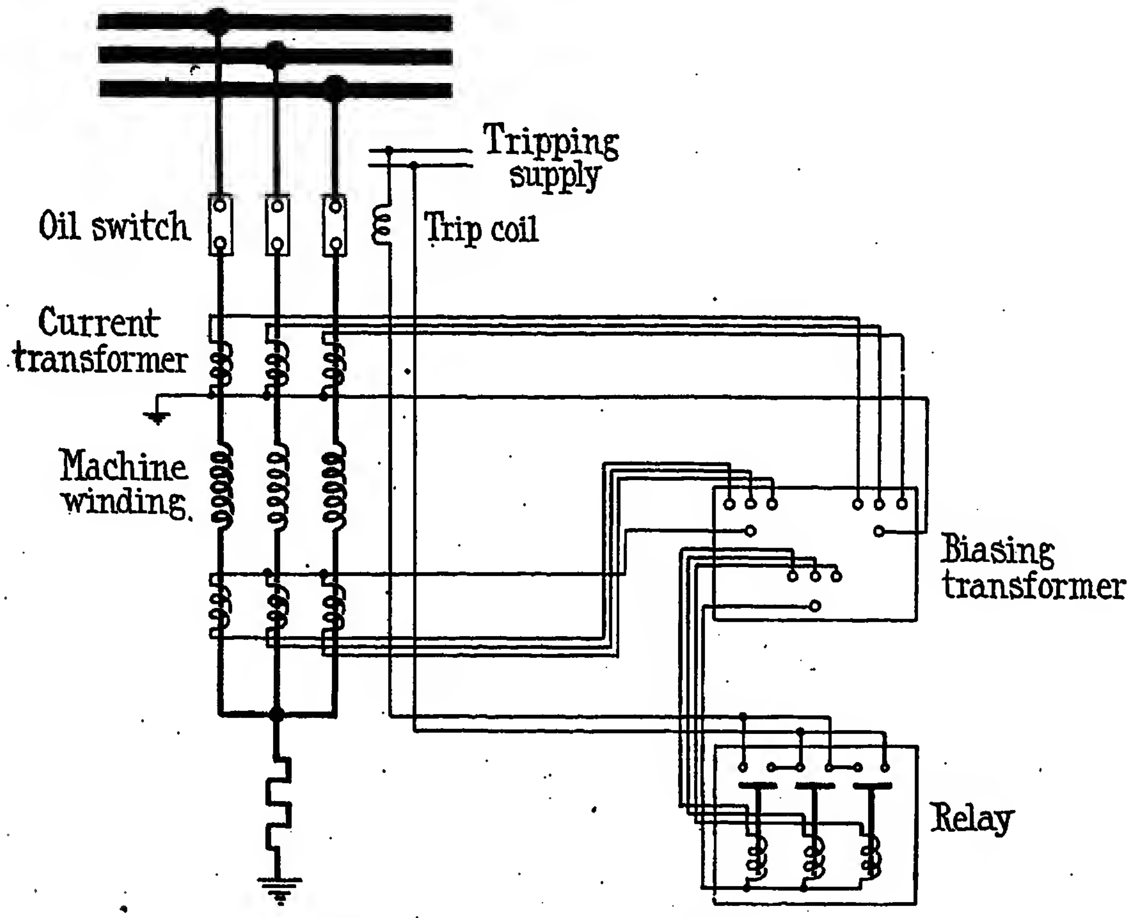

FIG. 21.—Generator protection.

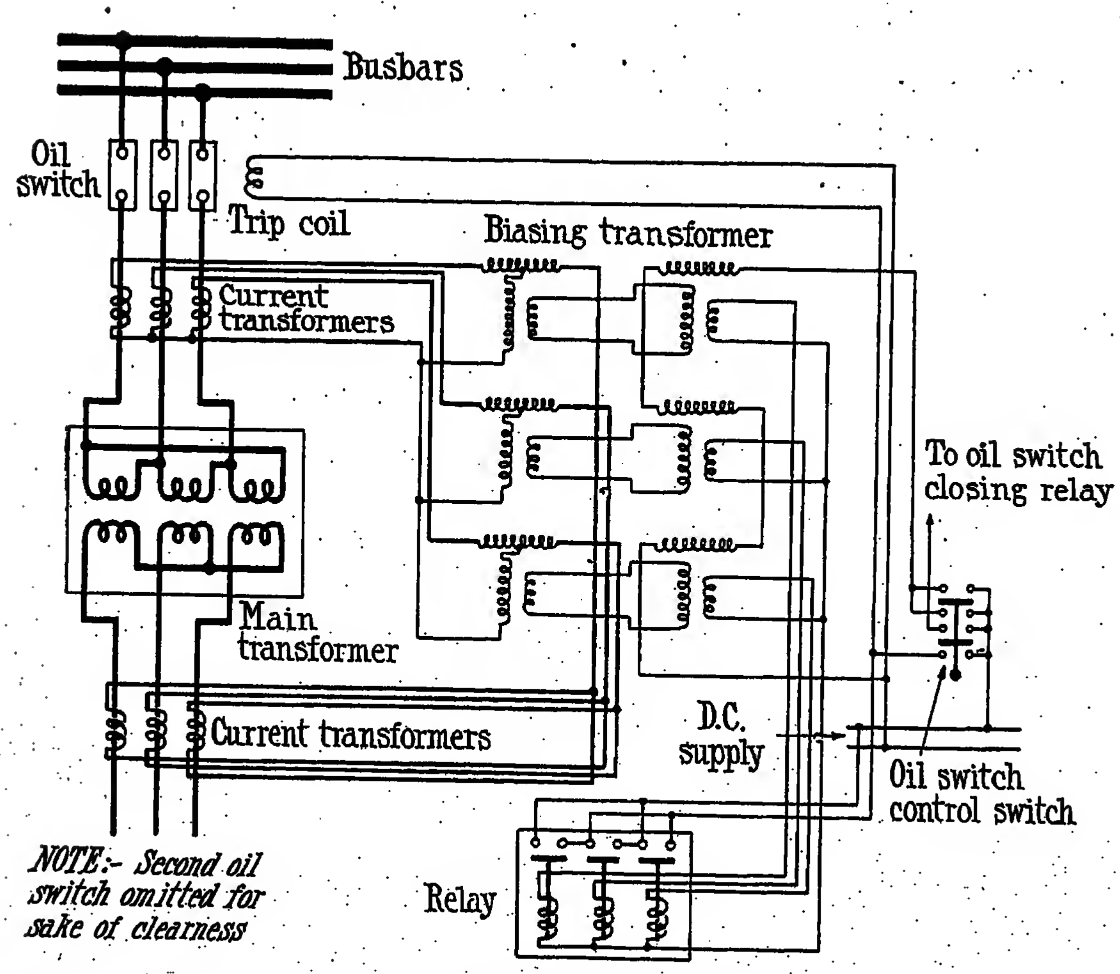

FIG. 22.—Transformer protection.

the above feeders might be expected more or less to resemble that shown in Fig. 20, in which both the use of ordinary auxiliary contacts and the corresponding arrangement with the alternative device are illustrated.

Apart from the fewer contacts involved, it is possible in installations of considerable extent that the cost of the static device may be more than compensated by the saving in cable. Where a number of lines are concerned, common control connections are evidently possible, according to the usual practice in regard to trip circuits, etc.

Section 2.

Protective Systems.

General.—It is now proposed to describe in greater detail the application to various protective circuits of the apparatus dealt with in Section 1.

In the case of each individual piece of apparatus, stress has been laid on the desirability of maintaining the utmost simplicity in construction. Clearly the same considerations apply to an enhanced extent to the complete protective circuit.

In the systems to be described the author has more particularly had in mind the simplification of the installation and maintenance of the gear. All connections involving phase relation and polarity are permanently made, as far as possible, in the biasing transformer itself. The complete assembly of all the units required for the various functions of a three-phase circuit is referred to by the latter term.

Typical practical wiring diagrams are given in certain instances, in addition to explanatory figures in order to indicate these characteristics.

Generator protection.—The method of application of a biasing transformer to the protection of a single winding has already been described with reference to Figs. 3 and 4. The protection of generator windings will therefore be carried out on similar lines and is shown in Fig. 21, which is self-explanatory.

Transformer protection.—The protection of transformers on the circulating-current system is carried out on very similar lines to the protection of a generator. The effect of the magnetizing current, however, has to be reckoned with, more particularly at the instant of switching on, when, as is well known, a transient of considerable amplitude usually occurs.

A very simple method of rendering the apparatus less sensitive during the switching period may be provided by the use of an auxiliary d.c. restraining feature as described in Section 1.

Instead of a biasing transformer containing three cores as in Fig. 21, one having six units, as in Fig. 22, may be used. Under normal conditions the additional biasing cores, which are connected between the relay and the secondaries of the overload restraining units, act as a simple transformer, since the restraining windings are not energized. These are connected to the d.c. tripping supply through an auxiliary switch on the main circuit breaker. This switch completes the restraining circuit while the circuit breaker is operating.

In the case of remotely operated breakers an auxiliary contact on the control switch may serve the same purpose. This arrangement is shown in Fig. 22.

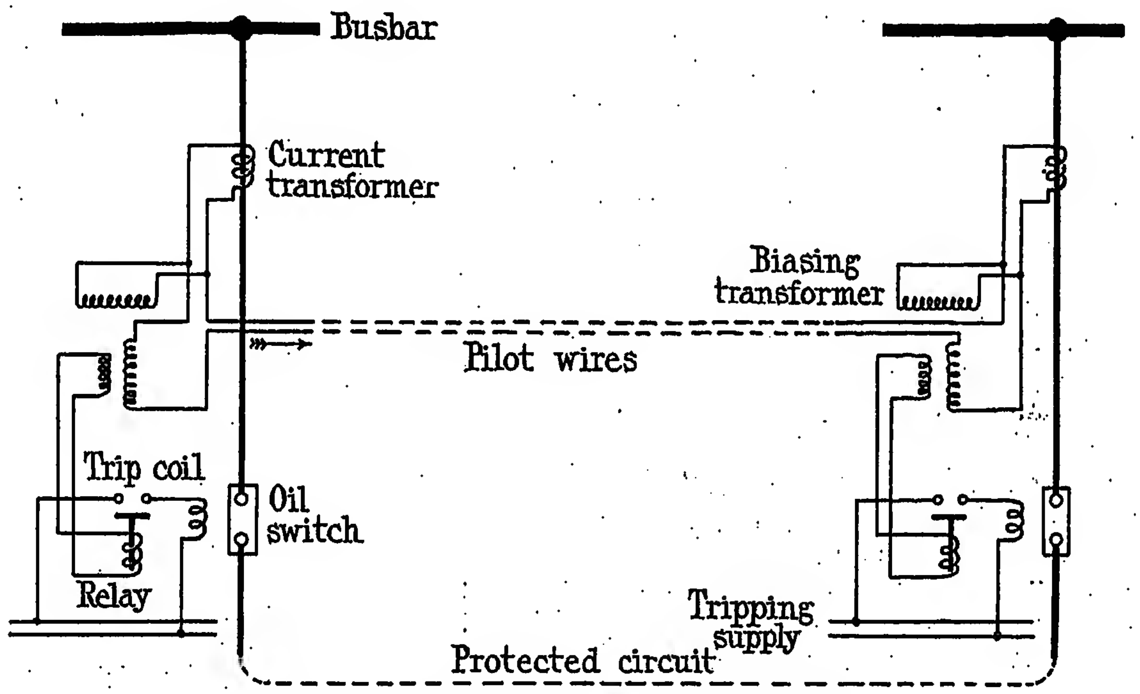

Fig. 23.—Opposed-voltage feeder protection.

Protective Systems for Single Feeders.

The opposed-voltage system.—This system of feeder protection has probably been more widely employed for the protection of single feeders, as such, than any other scheme. It has given excellent results within its sphere of utility, but difficulty is encountered in maintaining small fault settings on systems of large plant capacity, both in regard to accurate balancing and to pilot-wire capacity.

In order to avoid saturation of the transformers by normal load currents, and with a view to overcoming balancing troubles due to differences in the iron, air-gap transformers have been found necessary. Early types employing simple gaps gave rise to difficulties of

balance due to stray field effects, and ironclad designs having distributed gaps have been the most successful. Only when very great care in design is directed towards perfect and permanent balancing may satisfactory results be obtained.

The air-gap transformer, due to its inherently poor efficiency, is notably at a disadvantage in regard to sensitive fault settings, and very sensitive relays must be employed where this type of transformer is used. The capacity-current difficulty may be almost entirely overcome at some considerable expense by the well-known Beard-Hunter screening sheath.

The biasing transformer may be applied to an opposed-voltage circuit as in Fig. 23. Neither out-of-balance currents nor capacity currents are in evidence except under overload conditions when the restraining effect may also be arranged to be active. If sufficient restraint be provided to take charge of the maximum capacity current no very special accuracy of balance need be sought, as the former effect is likely to exceed the latter.

Discrimination between earth faults and line faults.—Better results may, however, be achieved by improved arrangements, on the lines suggested by Mr. Wedmore, who has pointed out that the demand for sensitive fault settings is necessarily associated with the isolation of earth faults. As fault currents to earth are usually limited in magnitude by an earthing resistance, it is rather in regard to faults between lines that difficulties are encountered in securing immunity from operation on "through" currents. Mr. Wedmore, therefore, has proposed the use of a protective circuit responsive to earth faults and line faults separately.

Such a scheme would provide sensitive earth-fault settings, which are only affected by "through" earth faults limited by the earthing resistance, and for line faults less sensitive settings, which may be insufficiently sensitive to trip on "through" faults. No useful purpose is served by sensitive line-fault settings, because faults of this nature necessarily involve heavy currents.

Mr. Wedmore's proposed arrangement is shown in Fig. 24, and it will be seen that the protective transformer consists of two portions—a closed ring embracing all three primary conductors, and inside the ring a star-shaped member.

Primary line currents will not cause saturation of the ring core. By the term "line currents" it is intended to convey that the vector resultant of the currents in all the phases is zero, i.e. no leakage component is present.

On the occurrence of an earth fault fed through a single transformer of this nature, there will immediately be a vector resultant other than zero, due to which the ring core will become magnetized. The star-shaped member, on the other hand, will become magnetized by line currents. As has been pointed out, no particular purpose is served by the provision of particularly sensitive line-fault settings, and, accordingly, the Y-shaped core is built of such a size that air-gaps are presented between its extremities and the surrounding ring. The ring core, therefore, will not become saturated under normal-load conditions. The arrangement will afford a measure of protection comparable, so far as line faults are concerned, with the earlier air-gap types of opposed-voltage protective transformers. Owing to the closed ring core, however, a very much greater sensitivity in regard to protection from earth faults will be achieved without resorting to the use of a specially sensitive relay.

By the provision of similar transformers at each end of the protected cable, connections for opposition of voltage being made by a pilot cable, discriminating protection as regards the circuit embraced may be obtained. In order, however, that there shall be no increase in the conventional number of pilot conductors, Mr. Wedmore arranges windings as shown in Fig. 24. So far there are two separate protective windings, and by connecting these to a common con-

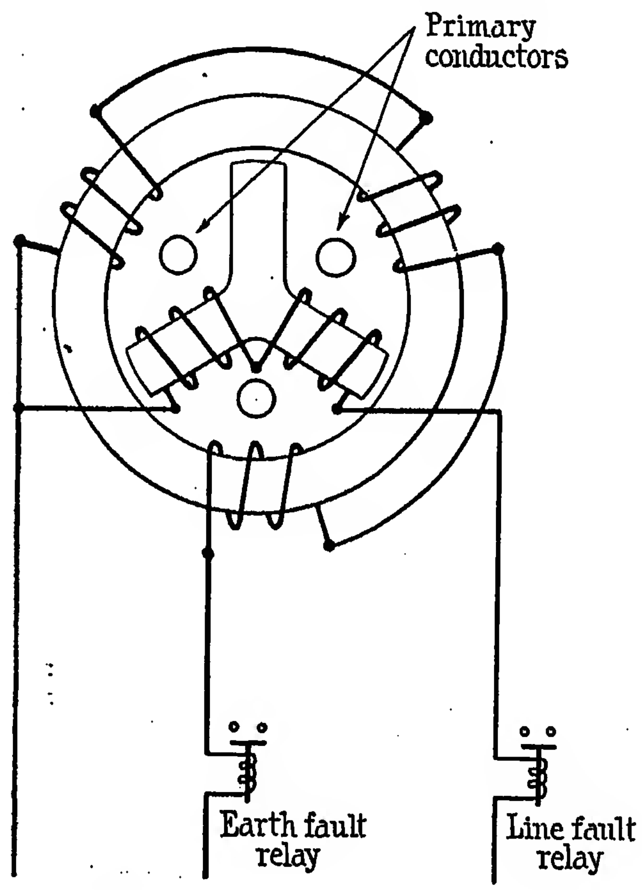

FIG. 24.—Diagram of protective transformer for line- and earth-fault protection.

ductor it is possible for the complete scheme to function when connected by a three-core pilot cable. It should be noted, however, that the line sensitivity will vary according to whether the line fault embraces both or one only of the wound limbs, this characteristic being inherent to this form of apparatus. Since, however, on the occurrence of a line fault heavy currents are immediately set up, the actual value of sensitivity is of small import. It will be seen that the earth relay in this scheme can only be affected by capacity currents flowing in the pilot cable to the extent of "through" earth faults, and these, due to the earthing resistance, will be of limited magnitude. The earth relay, however, will not receive in its operating winding any capacity currents set up by line faults. Moreover, since the ring core remains unmagnetized on the occurrence of line faults, it is clear that no very great balancing difficulty is likely to be encountered

so far as the earth relay is concerned. As regards the line relay, the question of balance is not of great importance, as only relatively high fault settings are required.

The author feels that the arrangement due to Mr. Wedmore is capable of notably better results than any by requirements connected with phase separation. It is essential in the arrangement illustrated in Fig. 24, for instance, that all phases should be brought through one special transformer. A suggestion has been made that this transformer should be situated in a special form of trifurcating box. Faults are not unknown in

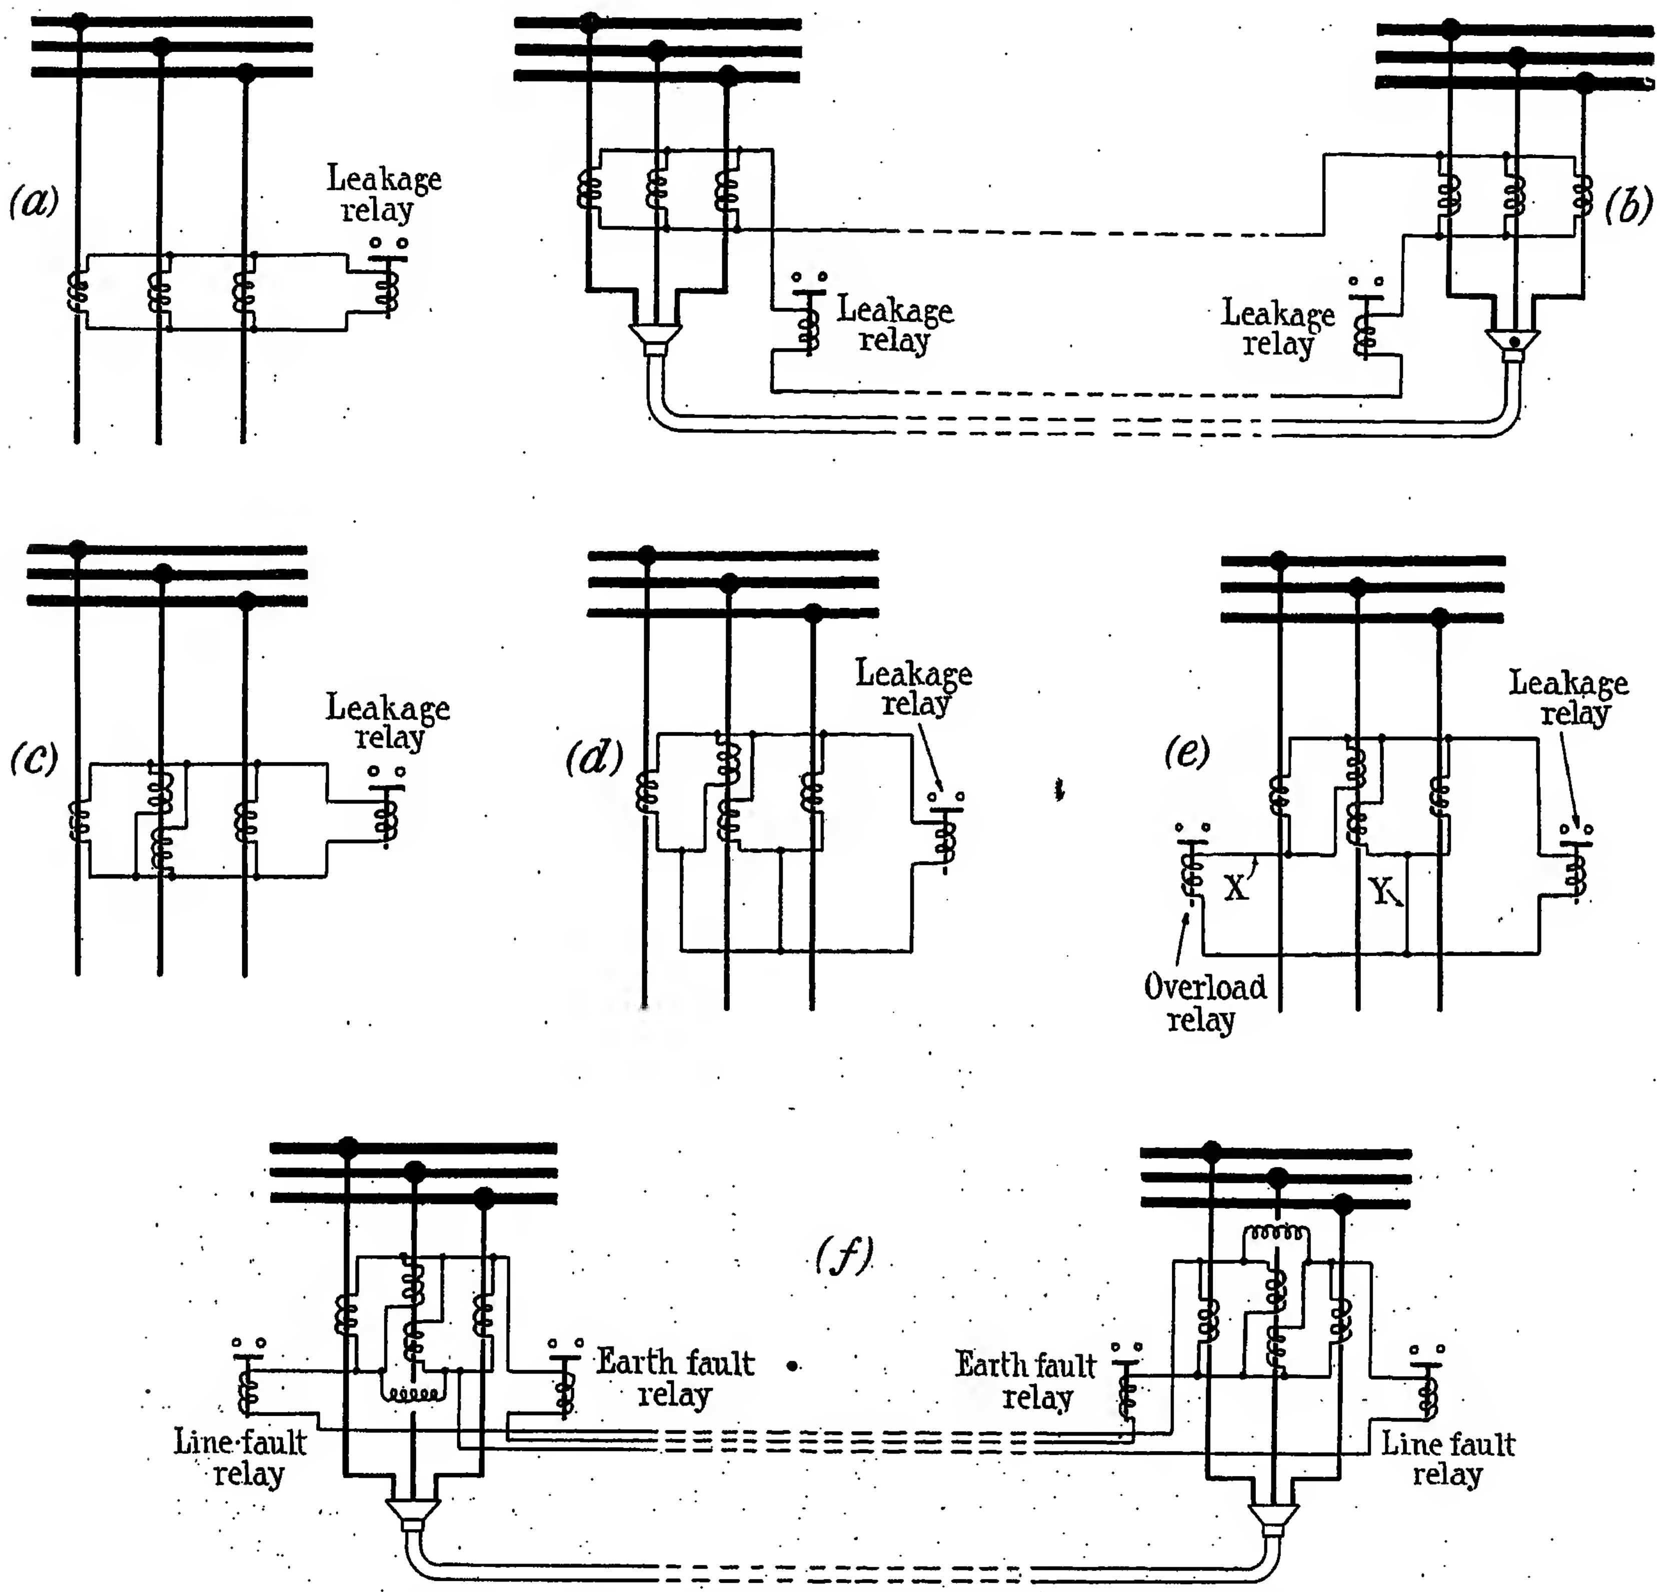

FIG. 25.—Evolution of protective circuit for line- and earth-fault protection.

previous system of opposed-voltage feeder protection, this being more particularly due to the principle enunciated by Mr. Wedmore regarding discrimination between line faults and earth faults.

In a number of the protective schemes which it is proposed to describe, use has been made of this principle. For the protection of feeders by a pilot-wire system, however, the author has been influenced joint boxes, however, and the author was directed by the British Thomson-Houston Co. to devise, if possible, means of providing the advantages inherent in Mr. Wedmore's scheme, at the same time retaining conventional construction, so that current transformers of ordinary type could be used on the system. The evolution of this circuit through various stages is shown in Fig. 25.

Figs. 25 (*a*) and 25 (*b*) are self-explanatory. In Fig. 25 (*c*) two transformers having double the ratio are substituted for the middle transformer in Fig. 25 (*a*). This gives rise to no change in the operating characteristics, nor does the slight alteration indicative of the evolution of the scheme shown in Fig. 25 (*d*).

In Fig. 25 (*e*) a further relay, which carries a current proportional to the load, is added. Under all conditions, not involving leakage, the secondary currents in leads X and Y will be equivalent.

The other relay, as before, is responsive to leakage currents only.

The final step is shown in Fig. 25 (*f*), which represents a discriminating opposed-voltage circuit based on Fig. 25 (*e*). The points X and Y are now joined by a small resistance or reactance. If this were zero the conditions would revert to those of Fig. 25 (*b*) and the line-fault relay would be inoperative. An impedance, however, sufficient to provide a line-fault setting of a few hundred amperes is such as to allow under normal present characteristics similar to those of a symmetrical network of condensers, as shown in the diagram, except that the capacity will be distributed.

It is found that under all load- or line-current effects, irrespective of whether the currents in the three phases are symmetrical, there will be set up at each end of the pilot cable a voltage between the outer pilot conductors, the centre line being at an equivalent potential displacement from each of the outer lines. The middle conductor, in effect, forms a mid-point, and only when leakage currents flow is this condition upset. Consideration of the capacity network will show that capacity currents due to "through" line faults will not be set up in the pilot conductor in which the earth-fault relay is connected. These capacity currents are confined to the outer conductors. Capacity currents in the earth relays can only be caused by "through" earth faults, which in general are of limited magnitude.

So far as construction is concerned, the apparatus presents features exactly in accordance with con-

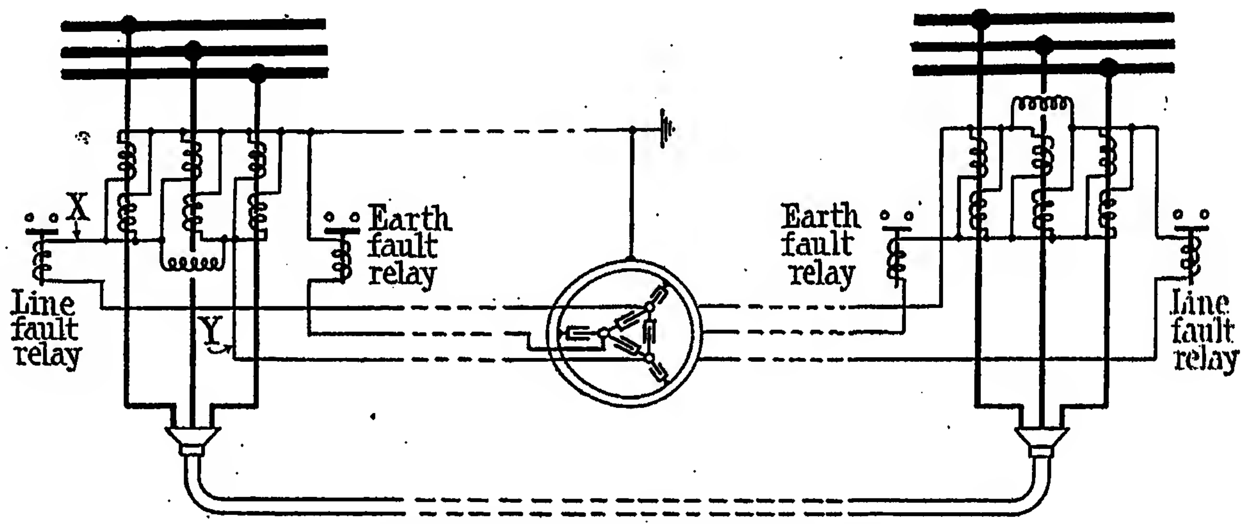

Fig. 26.—Effect of pilot-line capacity.

load conditions a free circulation of current between the current transformers. Thus saturation due to load currents does not occur and transformers having closed iron magnetic circuits may be used. Earth-fault currents, however, directly magnetize the transformer on the phase affected. Thus the arrangement is closely analogous to Mr. Wedmore's scheme, so far as operation in regard to faults is concerned. It is capable of providing separate line-fault and earth-fault trips, the latter being more sensitive than the former.

Due to the possibility of using ring-type transformers, it is not necessary, as in other opposed-voltage systems, to employ exceptionally sensitive relays in order to get good fault settings. Moreover, it is not essential that dissimilar types of transformer, as shown in the explanatory diagrams, should be used.

Three transformers, all exactly like the middle one, might be used without detriment to the results obtained. The windings would be put in parallel if they were installed on the outer phases.

This arrangement is shown in Fig. 26, which refers to the effects of capacity currents under "through" fault conditions. The pilot cable will be expected to ventional current-transformer design, the two cores being assembled together on a single porcelain insulator, and only differing from an ordinary current transformer in appearance, due to the fact that there are four secondary terminals instead of two. Only one type of transformer will now be required, and a replacement may be made on any phase, the secondary connection being arranged accordingly.

If this latter circuit be compared with Mr. Wedmore's arrangement, it will be seen to possess almost identical characteristics, at the same time permitting ordinary constructional methods to be employed; such transformers, moreover, if installed according to ordinary cellular methods of power house design, will embrace trifurcating boxes and all conductors right up to the actual oil switch, near to which it is usual to place a protective transformer.

This system will be inferior to the arrangement shown in Fig. 24 in one respect only, namely the question of current-transformer balance. This, however, may easily be overcome by the use of biasing transformers applied to the circuit, according to Fig. 23. The line-fault relay may on a "through" short-circuit

carry current due to out-of-balance and to capacity. It should therefore be subject to overload restraint under these conditions. The earth-fault relay may suffer from bad balancing under the same circumstances and should receive a similar restraint. It will also receive capacity current on a "through" earth fault, and accordingly should be restrained against such conditions.

The reactance shown in Fig. 25 (*f*) carries a current proportional to the "through" line current, and may therefore be replaced by the line-fault restraining windings. No P.D. will exist between the mid-point of the above restraining windings and the middle pilot conductor under any condition of "through" line current. A winding connected between this mid-point

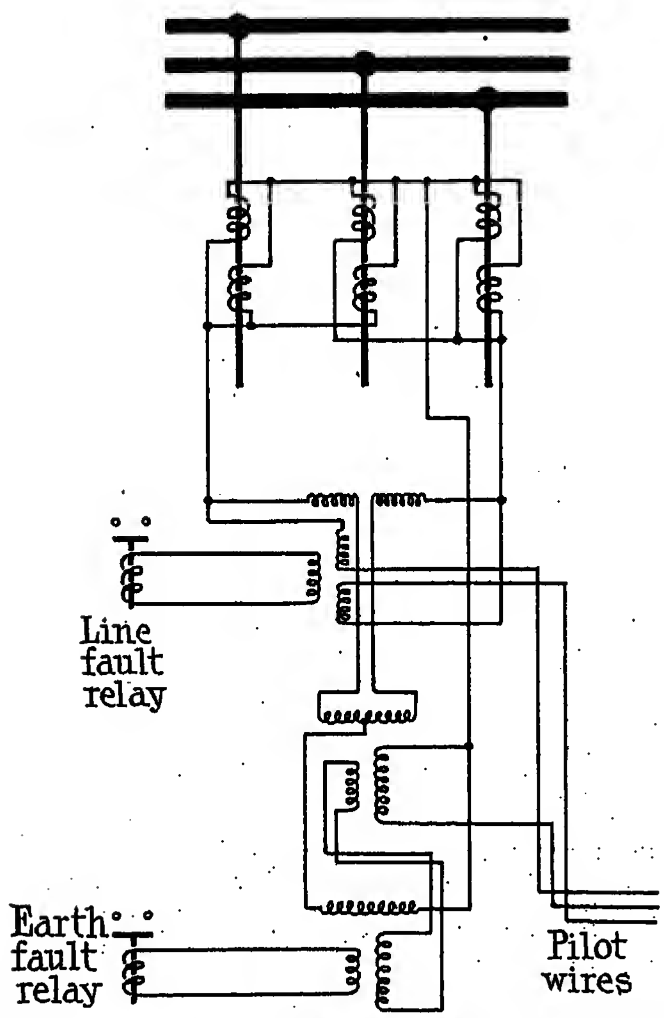

FIG. 27.—Diagram of opposed-voltage circuit with biasing transformers.

and the pilot conductor will receive current only when an earth-fault current is present in the primary circuit. The restraining winding on the earth-fault relay which is to be operative on "through" earth faults should evidently be thus connected.

In the complete scheme, therefore, which is illustrated in Fig. 27, the earth-fault restraining winding is connected between the neutral pilot conductor and the mid-point of the line-fault restraining windings, which are accordingly arranged so as to permit this. Both the line-fault restraining windings will have air-gap characteristics, as their effect is required only under heavy-current conditions. The restraint applied to the earth relay on the occasion of a "through" earth fault may, if desired, be arranged to become effective on small "through" earth faults, since the existence of the same is an abnormality. In the case of cables operating at pressures greater than about 11 000 volts the following effect may be of importance. The normal charging current of a cable, being the difference between input and output current, appears in the protective circuit as a fault current, and will not affect the earth relay, as it will contain no earth or leakage component. This capacity current in the primary conductors must not, however, be overlooked in regard to earth faults. If the cable protected be of considerable length there may be a charging current appearing as an earth fault due to the disturbance

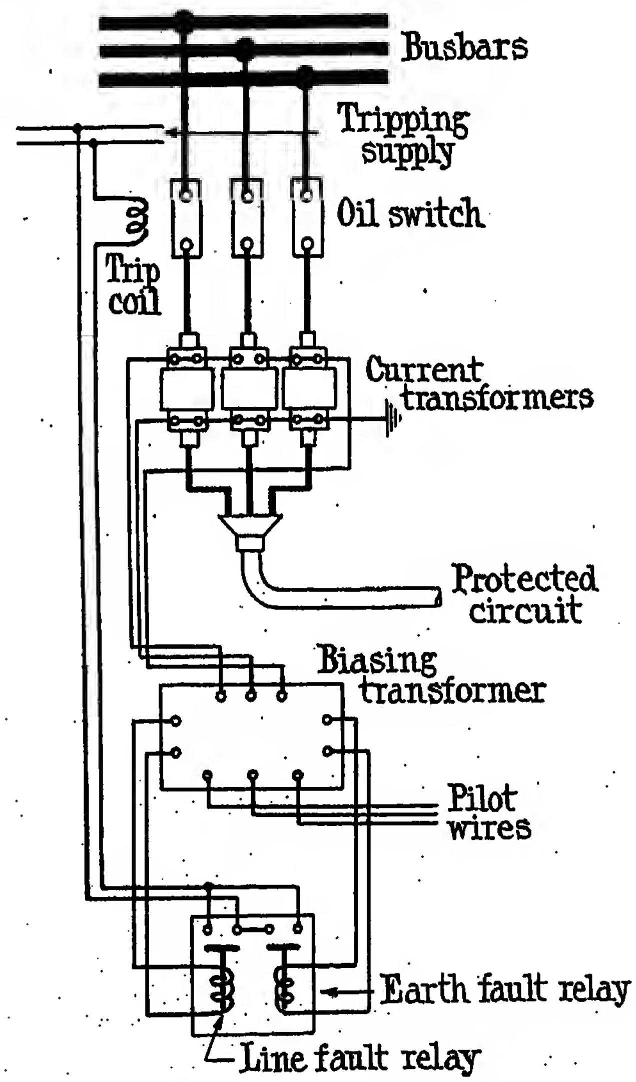

FIG. 28.—Wiring diagram of opposed-voltage circuit.

of pressure distribution on the power system. The wiring diagram is shown in Fig. 28.

As indicated above, the system described is specially adapted to give advantageous operation on power systems in which the maximum possible current that may flow to earth is definitely limited, and where the design is carried out with this application in view it is found possible, using bar-primary current transformers, to provide fault settings of between 25 and 50 amperes on faults to earth, using a plain relay capable of operating at 0·5 volt-ampere.

The principle which has been adopted, namely, that of discriminating between line and earth faults, and of assuming the latter to be of limited magnitude, has

been criticized on the grounds that it is not applicable in certain instances. It may be demonstrated that in the event of two simultaneous earth faults occurring on different parts of the network, and not on the same phase, a fault between lines that is not limited by the neutral earthing resistance will result. It is not impossible for this to be fed through two different feeders in such a manner that the current will appear in each as a " through " earth fault of the magnitude actually attained by the between-phase short-circuit which, in fact, exists. Tests on the gear, however, indicate that in a large number of practical cases the fault settings given above may be maintained with satisfactory results, even if this somewhat exceptional condition be envisaged.

Circulating-current feeder protection.—This system is an extension of the methods which have been described in connection with the protection of generators and transformers on the circulating-current system. It would be needed. These, however, make the system too expensive.

The connections will, therefore, be made in accordance with Fig. 29. It will be seen that whilst the occurrence of a fault on the length of cable embraced by the protective circuit will evidently cause the relays to trip, currents of sufficient magnitude fed through the system will set up out-of-balance currents in the operating windings due to the pilot-wire resistance. To the extent, therefore, that these further effects exceed transformer unbalance they must be regarded as additional discrepancies necessitating biased characteristics, and it is due to these considerations that the present system of feeder protection has been found to be useful only where such features have been provided. The arrangement in Fig. 29 may easily be rendered immune from incorrect operation by the provision of suitably designed biasing transformers.

Whilst the above arrangement will function correctly

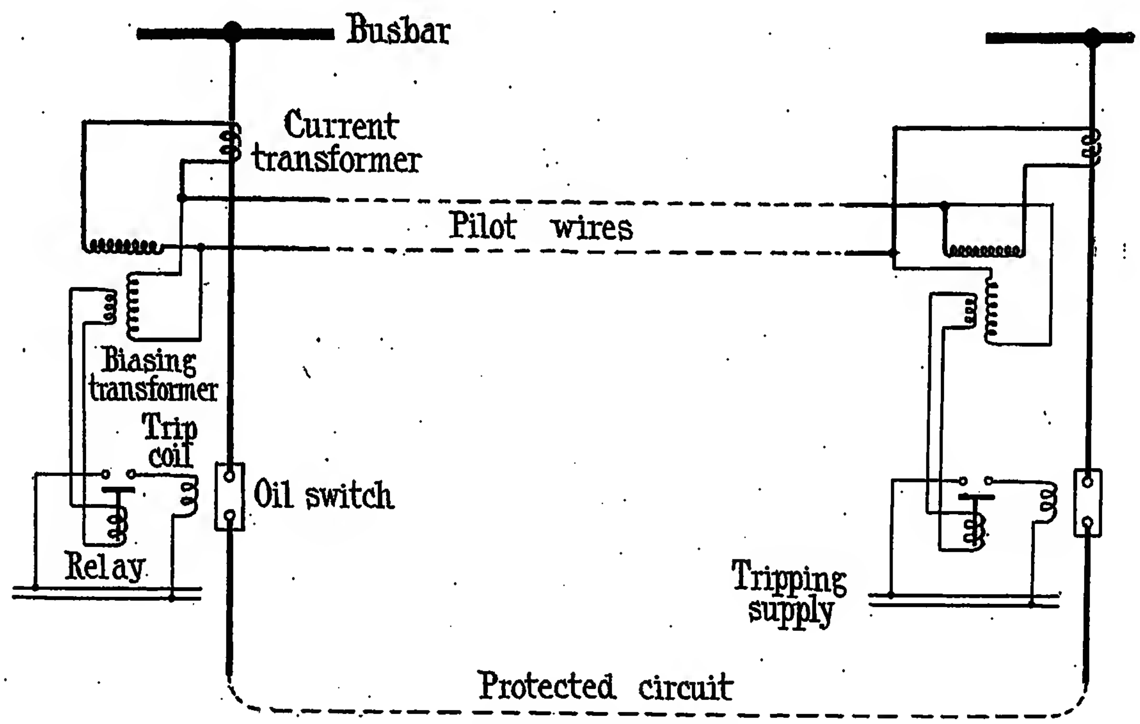

FIG. 29.—Circulating-current feeder protection.

differs from these schemes in the arrangement of its circuits, on account of the additional difficulties incidental to the greater lengths of pilot line connecting the protective transformers. These difficulties are entirely associated with the fact that a pilot cable used in conjunction with a feeder protective system may be expected to have a resistance very considerably in excess of the figure which might be met with in systems of protection having no secondary connections extending outside the station in which the protected plant is installed. Moreover, it will always be possible, in a small circulating-current circuit confined to one station, to make precisely equipotential points accessible for the connection of operating windings, etc. In the arrangement essential to a feeder protective scheme these equipotential points will be found at opposite ends of the line, and, for both operating windings to be connected between these points, additional pilot conductors under all conditions, it may be improved by a slight departure from the simple form shown. The alterations, as detailed below, will be more readily appreciated if consideration be directed toward certain conditions associated with the use of biased circuits in general.

Having, at some length, described the various ways in which a biasing action may be simply achieved, and restraining effects of very considerable magnitude provided, by the biasing transformer, the author wishes to deprecate any impression which may have been created to the effect that a complete remedy for out-of-balance effects of any extent resides in the biasing principle, and that there is no object in making any attempt to provide transformers or circuits which balance to a reasonable economical extent.

It should be noted that an out-of-balance effect due to any cause would be expected to produce in the operating

windings of any differential protective circuit, currents proportional to the transmitted load, when the feeder or plant protected is sound. If the balance be so bad that these currents reach an appreciable magnitude under normal conditions of load, it will be obvious that, should the gear be called upon to clear a fault under such circumstances, the sensitivity will be augmented or decreased according to the relative direction of the respective currents. Clearly, therefore, unlimited imperfection of balance might be very detrimental to the proper functioning of differential protective gear, even though the biasing effect may be sufficient to prevent the relays being tripped by the heaviest of "through" faults.

It will have been noticed in the arrangement shown in Fig. 29 that the unbalancing due to resistance is proportional to the transmitted load, whereas it has been pointed out that the troubles associated with

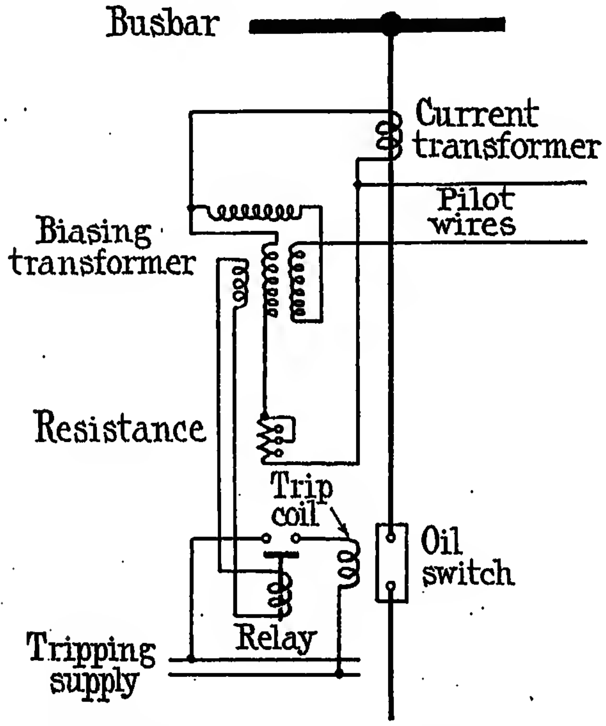

Fig. 30.—Improved form of circulating-current feeder protection.

transformers are not usually in evidence until very considerable overload currents are attained.

Whilst it is considered that the above scheme is capable of entirely satisfactory results in cases where the relation of the pilot cable resistance to that of the secondary turns, etc., is not exceptional, it is possible to utilize the arrangement shown in Fig. 30. In this the resistance effect may be balanced out, the biasing action being accordingly arranged to correspond to the usual extent of unbalancing where transformer effects only need to be taken into account.

It should be noted that it is not necessary to take any special measure to obtain exactly correct duplicate resistances. Provided that these are approximately as required, no special adjustments, after installation for instance, should be entailed. If the balancing effect of the duplicate resistance be sufficiently close to avoid, at overloads of no great magnitude, the trouble described, the biasing action will preclude any incorrect operation due to more severe "through" faults.

The circulating-current feeder system described has not yet been commercially developed, but the author believes it to be capable of very good performance.

Split-conductor protection.—The balancing difficulties

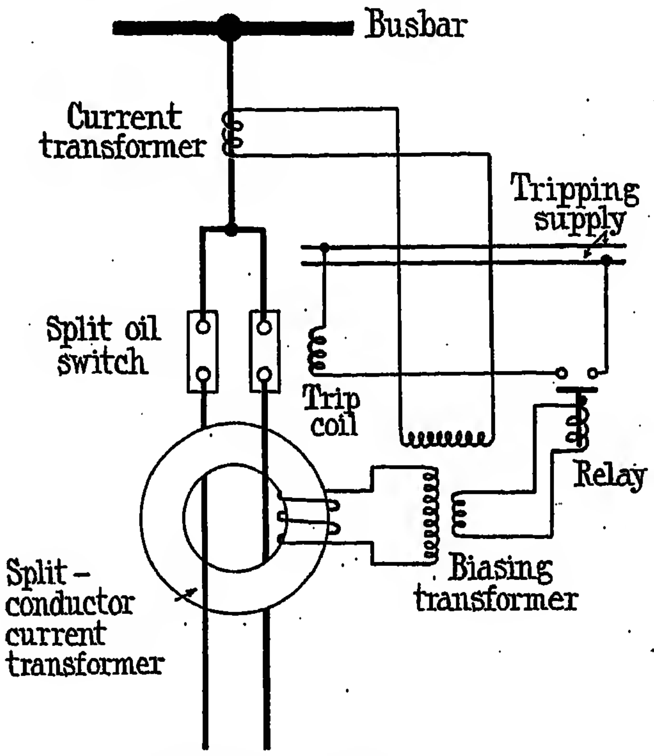

Fig. 31.—Application of biasing transformer to split-conductor circuit.

associated with this system are mainly connected with cable jointing so as to obtain exactly equal impedance in both splits. When the reactance type of protective transformer is used, exceptional balance, both of the

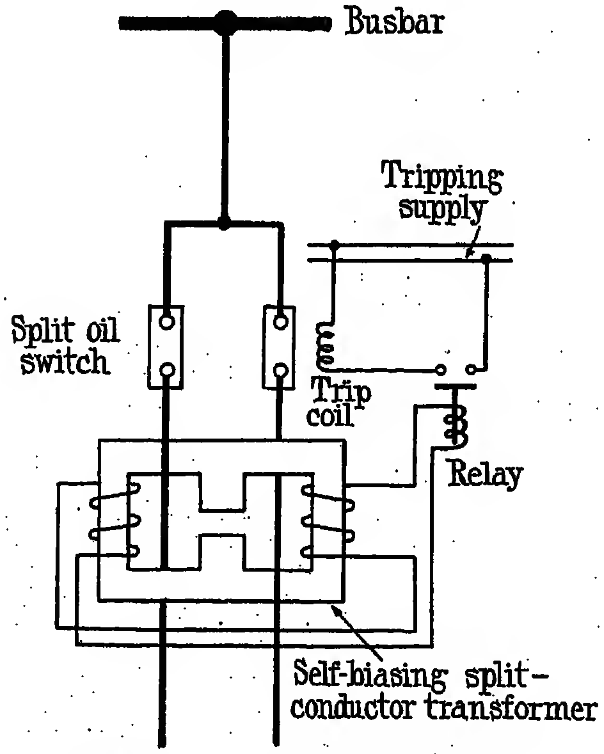

Fig. 32.—Self-biasing split-conductor transformer.

cable and of the transformer itself, is necessary. All the diagrams are applicable to both simple and reactance forms, but the former is illustrated.

An obvious method of providing a biased form of split-conductor protection is shown in Fig. 31. This

is of interest in that existing gear might be modified very simply on these lines should this be found desirable.

The biasing feature, however, may be incorporated in the split-conductor transformer as shown in Fig. 32. The external connections would then be similar to the ordinary arrangement having no biasing action (see Fig. 33).

If Fig. 32 be compared with Fig. 1 (*c*) it will be seen that equivalent currents in the two splits produce excitation corresponding to a restraining winding, whereas difference currents function as an operating winding and energize the relay.

An even better scheme, particularly suitable for e.h.t. application, is shown in Fig. 34. Ring-type cores are used throughout, as these are the kind most easily insulated for high pressures. A simple differential

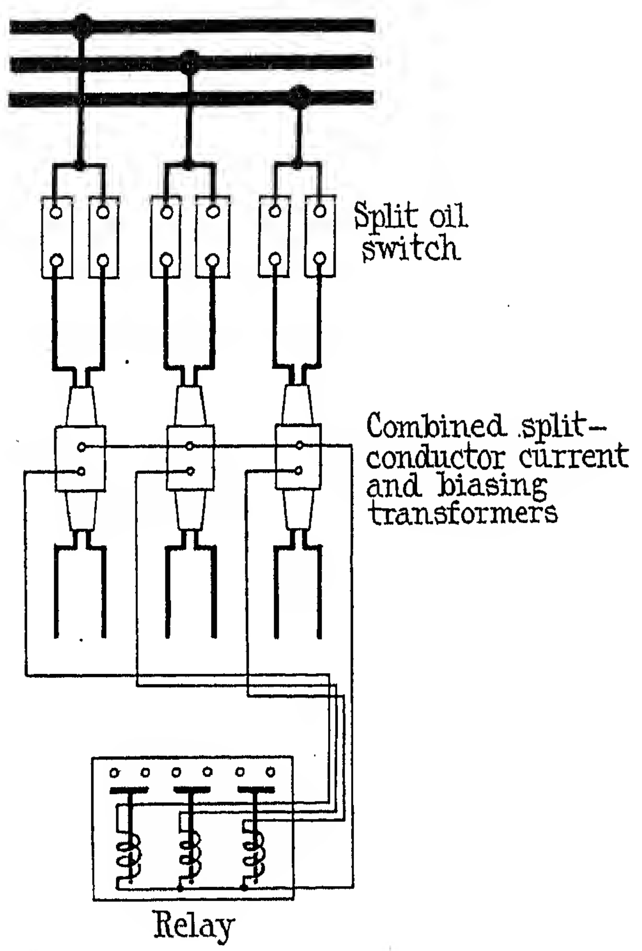

FIG. 33.—Wiring diagram of split-conductor system.

core only excited by a fault current, exactly as in the ordinary arrangement, is here used. The secondary of this core excites the relay through the medium of a biasing transformer of the type consisting of a pair of rings, as illustrated in Fig. 1 (*a*). The operating excitation sets up fluxes in the rings in opposite directions, while the primary windings passing through the biasing cores magnetize them in the same sense. Thus they have no inductive effect on the relay, and on heavy overloads they will act as restraining windings. Fig. 35 shows how such a transformer might be constructed, the biasing cores being arranged on each side of the differential core. The ring-core scheme does not lend itself to the provision of an air-gap to reduce the restraint under normal load conditions. This characteristic is hardly necessary in split-conductor work, as no very great extent of maximum restraint is required, and such proportion of this as may be present on normal load will not seriously affect the sensitivity. The air-gap effect may be obtained, however, if required, as follows: A further winding is provided on both the biasing cores, the two forming a closed circuit. This is not inductively related to the operating or secondary windings but is wound so as to receive current induced by the primary or restraining current. It may be arranged to have such a resistance as will prevent saturation of the cores at light loads but permit of this when the "through" current is of greater magnitude. This winding could be used to operate an overload relay.

PARALLEL-FEEDER PROTECTIVE SYSTEMS.

General.—Purely differential systems of parallel-feeder protection are entirely dependent for their

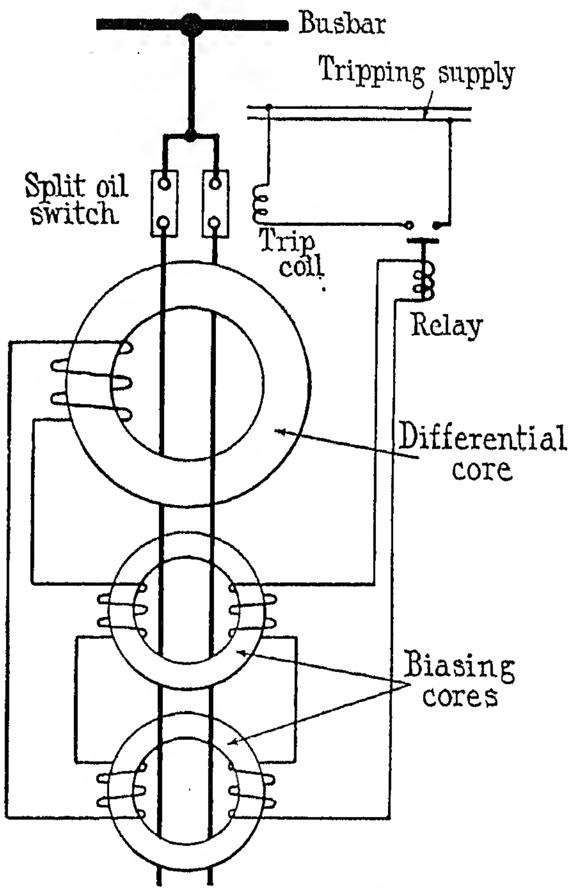

FIG. 34.—Diagram of self-biasing split-conductor transformer with ring cores.

functioning on the installation of a number of feeders operating in parallel under all circumstances.

In comparison with the split-conductor system these arrangements present the advantage that if there is a fault on one line, the supply may be maintained through the remaining feeder or feeders.

The protective relays on sound lines must be immune from disturbance due, first, to faults on other portions of the power system, and secondly, to a breakdown on one of the lines in the group protected. Overload restraint will be desirable on the former, whilst the latter condition will be met by arrangements of biasing transformers operating on the discriminating or directional principle. The particular problems met with in systems of the present form are due to the use of two separate protective circuits at each end of the lines.

These give rise to two conditions under which the apparatus must discriminate correctly: first, when both ends are completely closed up, and secondly, when one end of the faulty line has opened. In the latter instance the transmitted load will cease to be divided correctly among the parallel feeders. The circumstances are such that either end may open first, depending on the location of the fault.

these lines, however, is open at the other end and, unless this circumstance be allowed for, incorrect operation on faults and needless disturbance under healthy conditions may result.

Balanced-current system.—This system operates in accordance with the principles described in relation to Figs. 8 and 9, and in its simplest form would consist of a three-phase circuit, as shown in these figures.

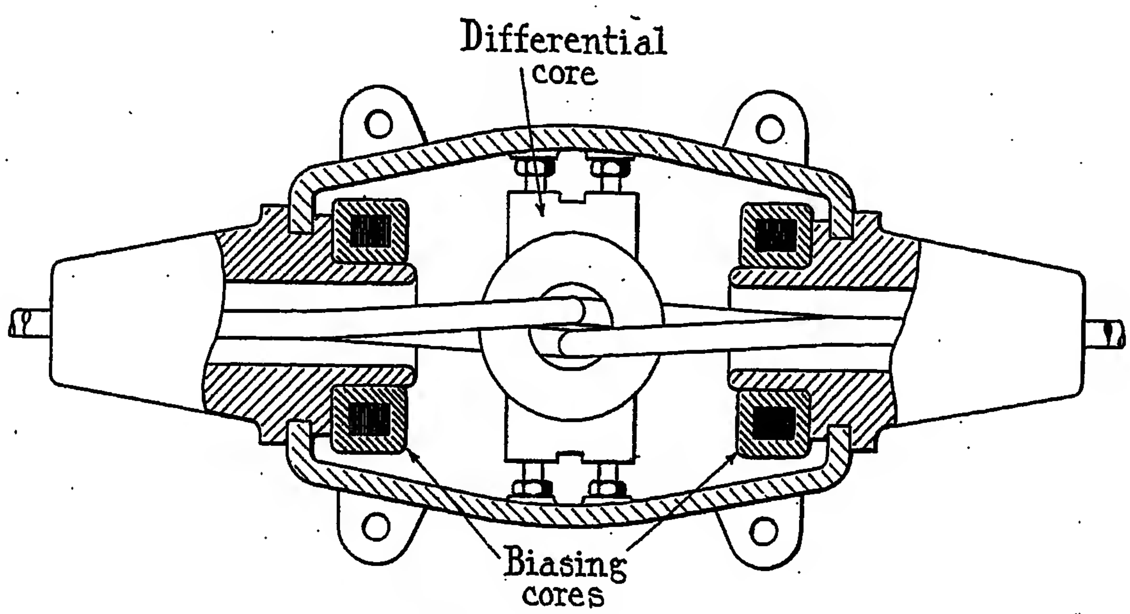

FIG. 35.—Construction of self-biasing ring-core split-conductor transformer.

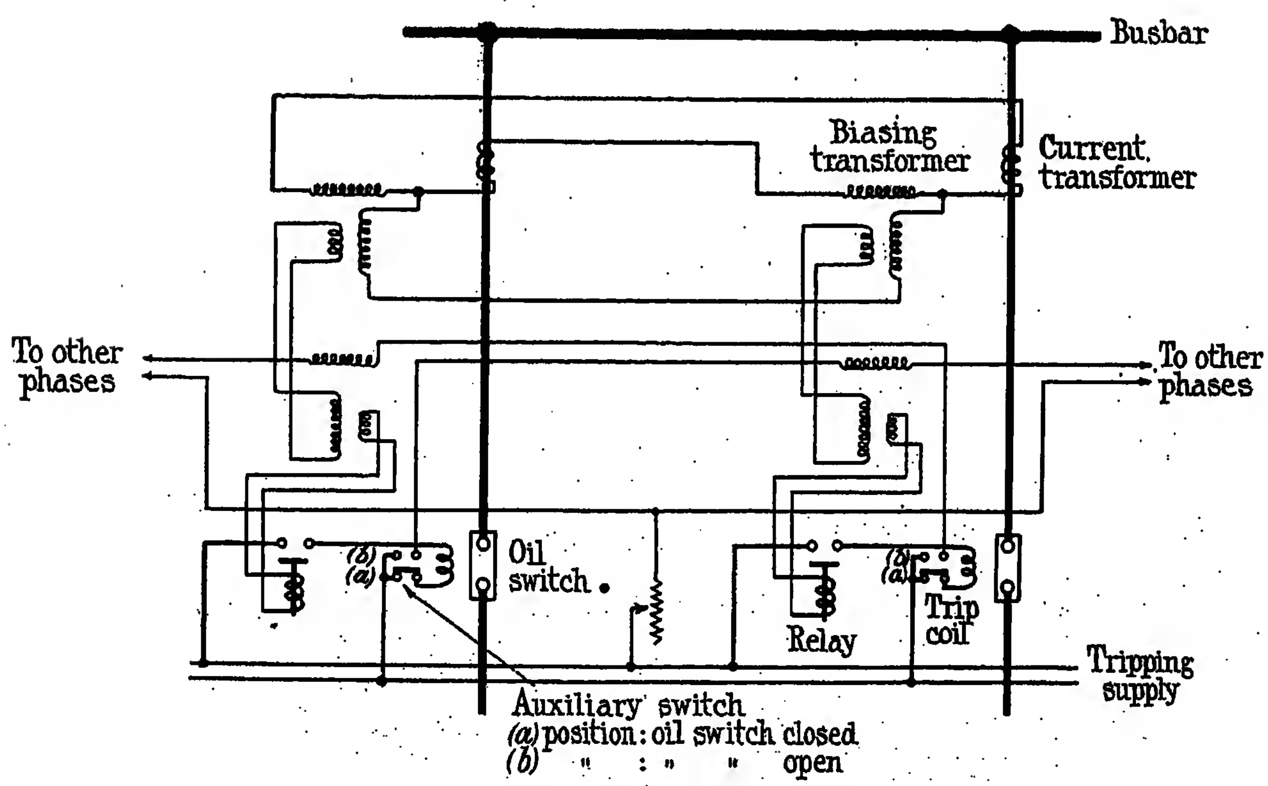

FIG. 36.—Balanced-current protective circuit.

It is evident that the protective circuit may be automatically modified by auxiliary switches at the end where the line is not closed up. It is the conditions obtaining at the remote end which must be examined if such protective gear is to be immune from disturbance due to switching operations involved by the normal functioning of the supply system. Here the protective circuit will be completely disposed for discriminating between parallel lines completely closed up. One of

If a fault causes one feeder switch to open, the complete apparatus appropriate to both lines is automatically rendered inoperative. Clearly no discriminating function can be provided when only one cable remains in circuit, and if no change be made to the protective circuit when one line is open, the second line will trip when the current carried by it is equivalent to the fault setting of the protective gear. Various methods are available by which this end may be attained, an

obvious solution involving triple-pole auxiliary switches adapted to short-circuit the operating windings.

Two preferable arrangements will now be described. If it is desired to cut out entirely the discriminating gear, and to rely on such stand-by overload or other apparatus as may exist, then both relays may be subject to a direct-current restraint if one feeder is tripped. This necessitates only a single-pole auxiliary switch for each three-phase line. The extent of this restraint would be such that no possible value of current could effect tripping.

In certain instances, however, no additional protective means may be present, and it may be an added advantage to provide for a measure of protection transformer circuits or in relay connections, with the exception of the conventional practice of opening the tripping circuit on the circuit breaker instead of at the relay contacts.

The simple three-phase circuit hitherto described, whilst it is capable of entirely satisfactory and correct operation within its sphere of application, is subject to certain restrictions. If these be now indicated the advantages of the improved arrangement will be more clearly understood.

Operating conditions of balanced-current gear.—It has been shown that if one feeder be opened there will be a tendency for the remaining line to be automatically tripped unless means of the nature described be applied

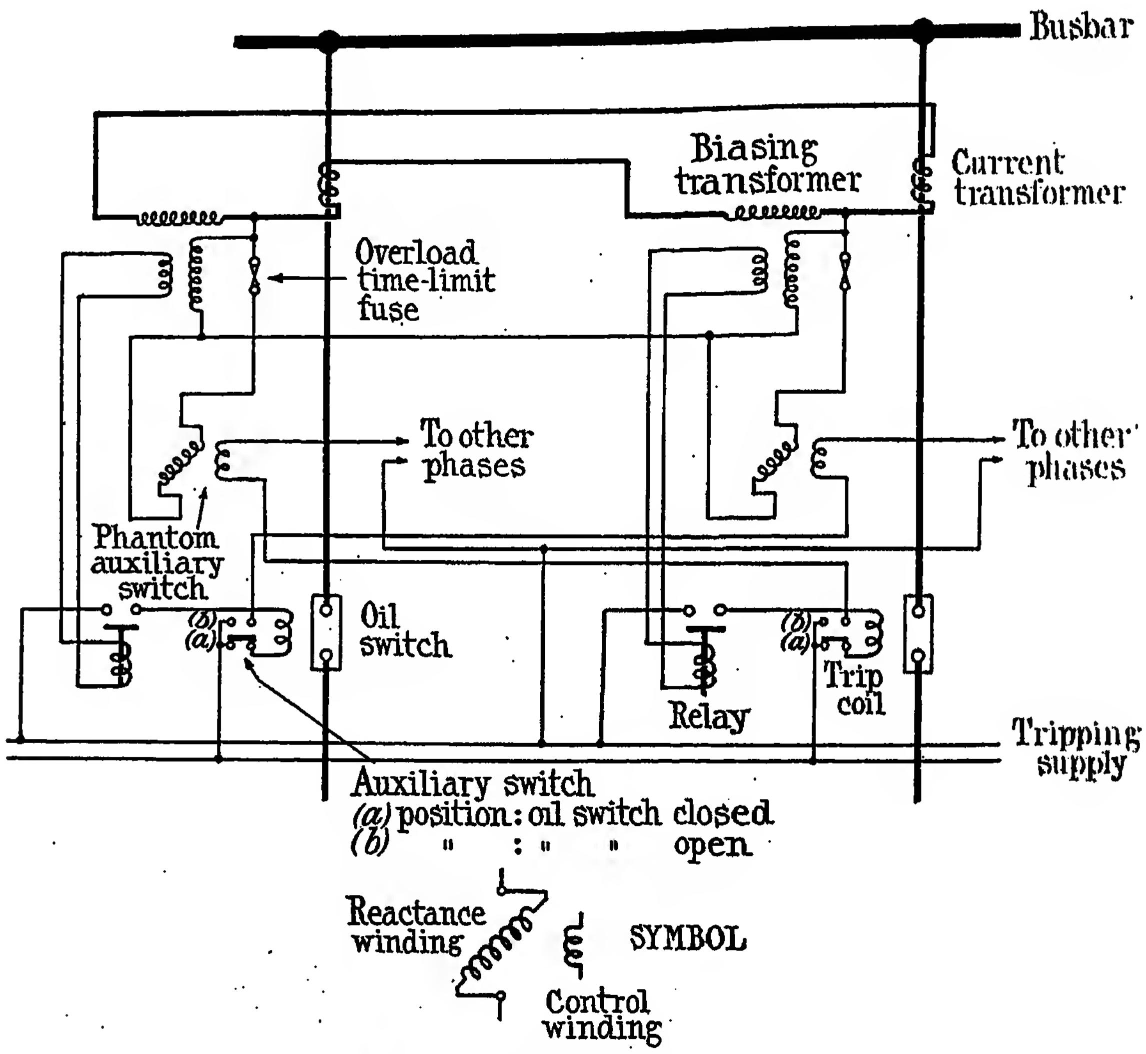

FIG. 37.—Balanced-current circuit with stand-by protection for single line.

(not, of course, of a discriminating nature) by the balanced-current gear. Such an arrangement is given in Fig. 36. On either feeder coming out of service a restraint is applied to the relays associated with the remaining line. The magnitude of this restraint can be controlled by a resistance, or designed for a constant value, such that a heavy overload or short-circuit will operate the relay. As an alternative, fuses or other time-lag devices can be connected in parallel with the operating windings in series with phantom switches so that the overload protection provided on the single remaining line shall not be instantaneous. This scheme is shown in Fig. 37. Attention is particularly directed to the fact that in both the latter arrangements no switching is carried out in current-

in order to preclude the possibility of such action. Clearly this must occur with apparatus devised for tripping the line carrying the greater current, since one feeder will carry the total transmitted load whereas the current in the other will be zero.

The inconvenience of this effect may perhaps be more evident if it be pointed out that when a double feeder equipped as above is carrying normal load, the inadvertent opening of a switch at the far end may cause complete interruption of the supply unless the fault setting be definitely in excess of the maximum load corresponding to the rating of both lines. Unless this latter condition be complied with it will be found that, in general, not only will incorrect operation be possible on the occurrence of faults of an order of

magnitude comparable with load current, but that tripping of the protective gear will take place if the switchgear be operated by hand, according to the normal exigencies of service. Consider an earth fault occurring on a feeder in such a position that initial operation occurs at the end remote from that at which the gear in question is installed. If the pair of lines be carrying currents of the order of their rated load, the sound feeder may be overloaded when the switch at the far end opens. Evidently the faulty line can only be cleared when the earth fault exceeds in magnitude the current in the sound cable, and moreover, if the resistance of the fault be such as appreciably to limit the current, the sound line may come out, thus resulting in a complete shut-down.

difficulties may be entirely obviated in a simple manner by designing the apparatus on the lines already indicated in connection with the opposed-voltage circuit, earth faults and line faults being dealt with separately.

Very successful results have been realized by parallel-feeder systems operated on the balanced-leakage principle, the method of application of the biasing transformer to such schemes being seen in Fig. 9. In forms of this system requiring transformers which entirely surround the three cores of a cable, the connections would, in fact, be practically identical with those in this diagram.

Where ordinary current transformers are used the arrangement, which possesses the following properties, is as in Fig. 38. Only currents of which the vectorial resultant is other than zero will excite any of the biasing transformer windings. All load or other currents not of this nature will circulate in the current transformer secondaries only. If either feeder carry an earth or leakage current greater than that in the other, a corresponding difference current will appear in the operating windings of the biasing transformers, and tripping will occur on the relay corresponding to the feeder carrying the greater leakage current, as indicated in Fig. 9. In the event of an earth fault being present on some portion of the supply system beyond the protected feeders, this will appear in equal proportion in both of the lines and will accordingly give rise to a circulating current in the restraining windings. Thus, even though the fault is not exactly equally shared, due to variations in feeder impedance, the relays cannot trip.

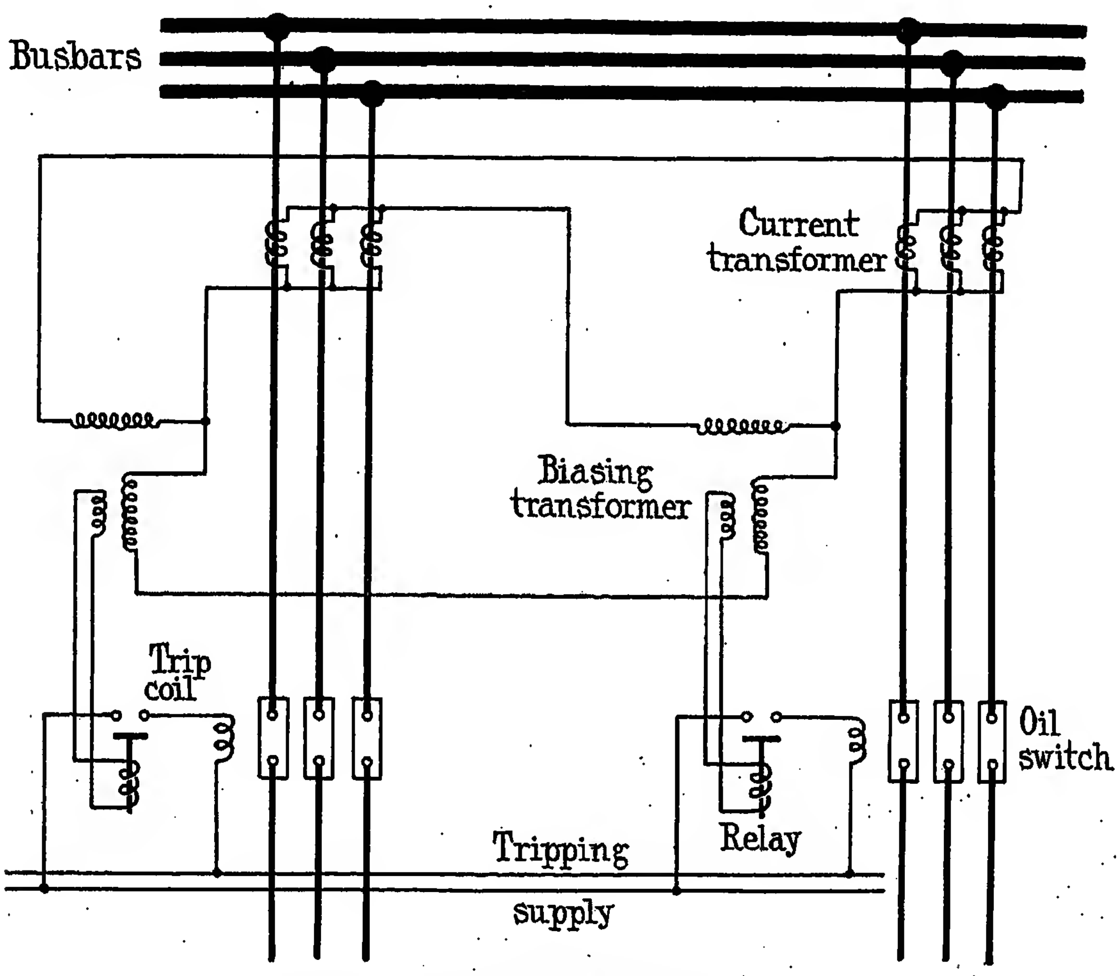

FIG. 38.—Balanced-leakage protective circuit.

With regard to the latter point, it is impracticable to close up the feeders at all under conditions involving appreciable load, except in special sequence or unless the protective gear be first rendered inoperative by hand switches or other means. The normal connections can only be restored when all switches have been duly closed.

It is felt that protective gear in general cannot be recommended if it in any way adds to the switching operations involved in normal service, or if restrictions are introduced by its use. Moreover, the use of such hand switches is further to be deprecated on account of the possibility of closing a switch on to a fault.

The arrangements above described should, therefore, be limited to insulated systems or to those on which the neutral is solidly earthed.

Improved form of balanced-current circuit.—The above

Fig. 38 shows the simplest possible form of this arrangement, while Fig. 39 shows an improved scheme capable of superior results. By providing an overload restraint in this manner it is possible to get even more additional protection is obtained against all forms of line fault. The complete circuit is indicated in Fig. 40, and it will be noticed that the connections providing protection from line faults correspond to those in

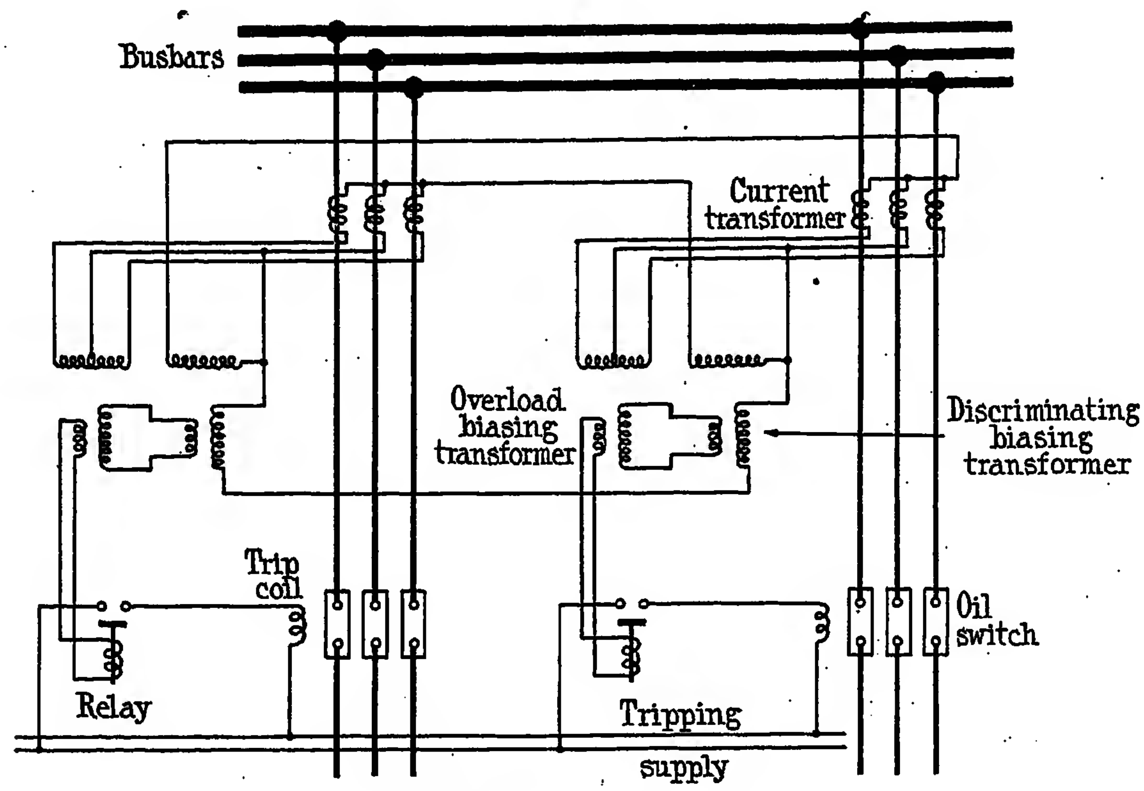

FIG. 39.—Balanced leakage with overload restraint.

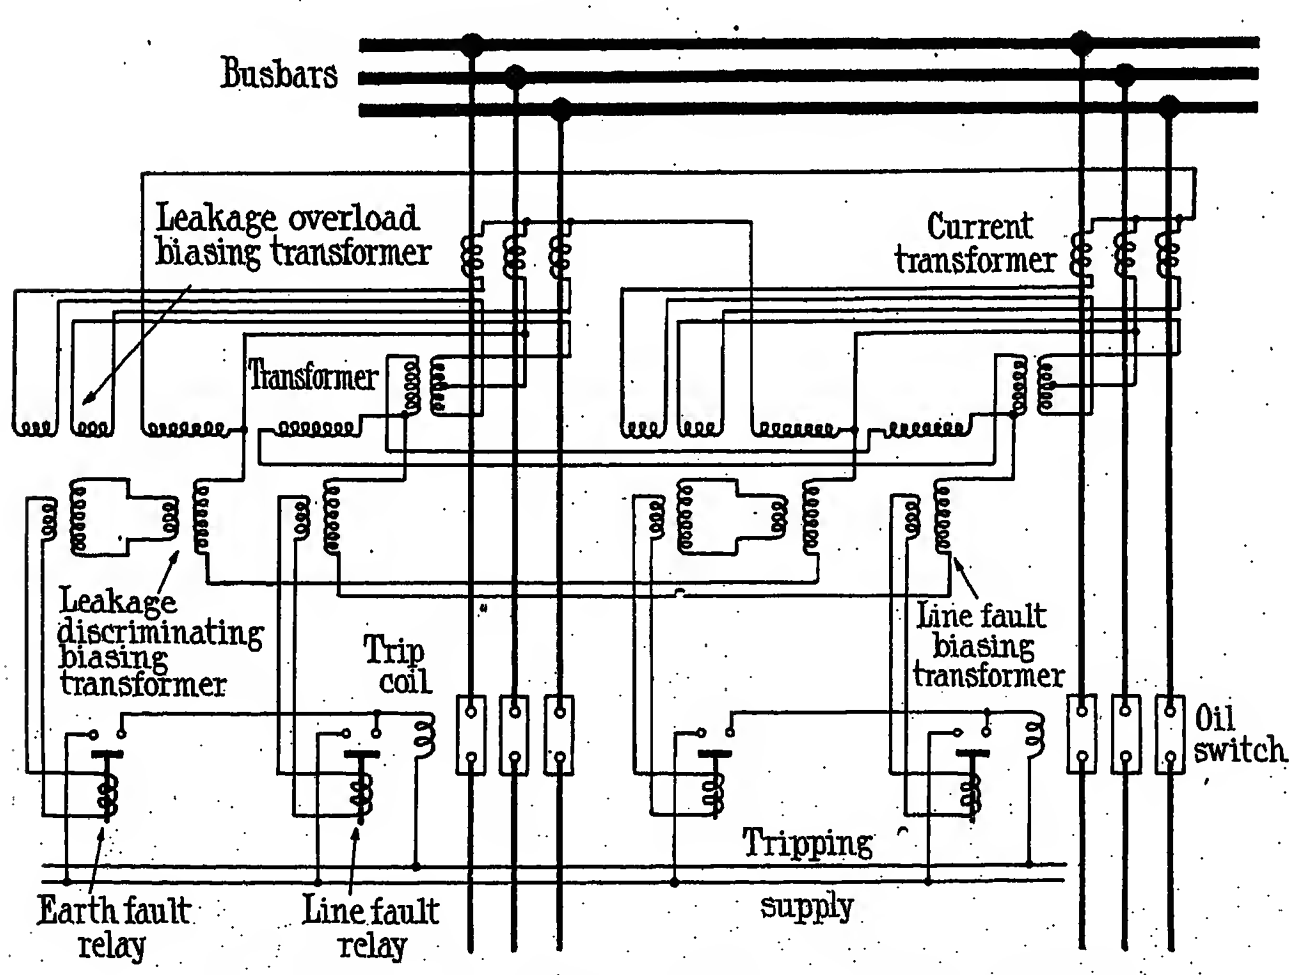

FIG. 40.—Balanced-current circuit for earth- and line-fault protection.

sensitive operation, complete general immunity being at the same time provided. By the provision of a small current transformer, together with a further discriminating biasing transformer energized from this, Fig. 9 if the secondary of the transformer, which is excited by such faults in Fig. 40, be considered to represent the current-transformer windings in Fig. 9.

The following characteristics will be associated

with the final arrangement according to Fig. 40. (1) "Through" earth currents will set up a circulating current which will appear only in the restraining winding of the leakage discriminating biasing transformers. (2) "Through" line faults or overloads will excite the leakage overload restraining windings

In this diagram no provision is made for utilizing the apparatus for any further measures of protection in connection with the operation of a single feeder. On one line coming out of service the protective gear is rendered inoperative by short-circuiting the line-operating winding and opening the leakage-operating winding by

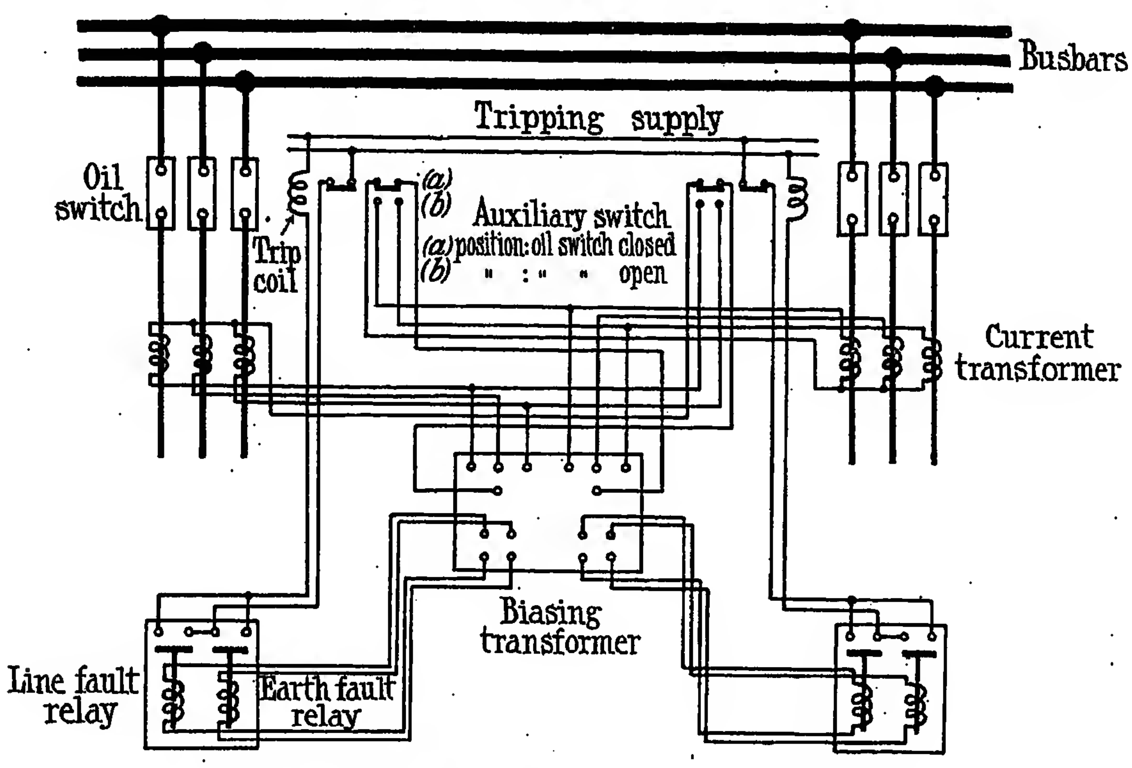

FIG. 41.—Wiring diagram of balanced-current system.

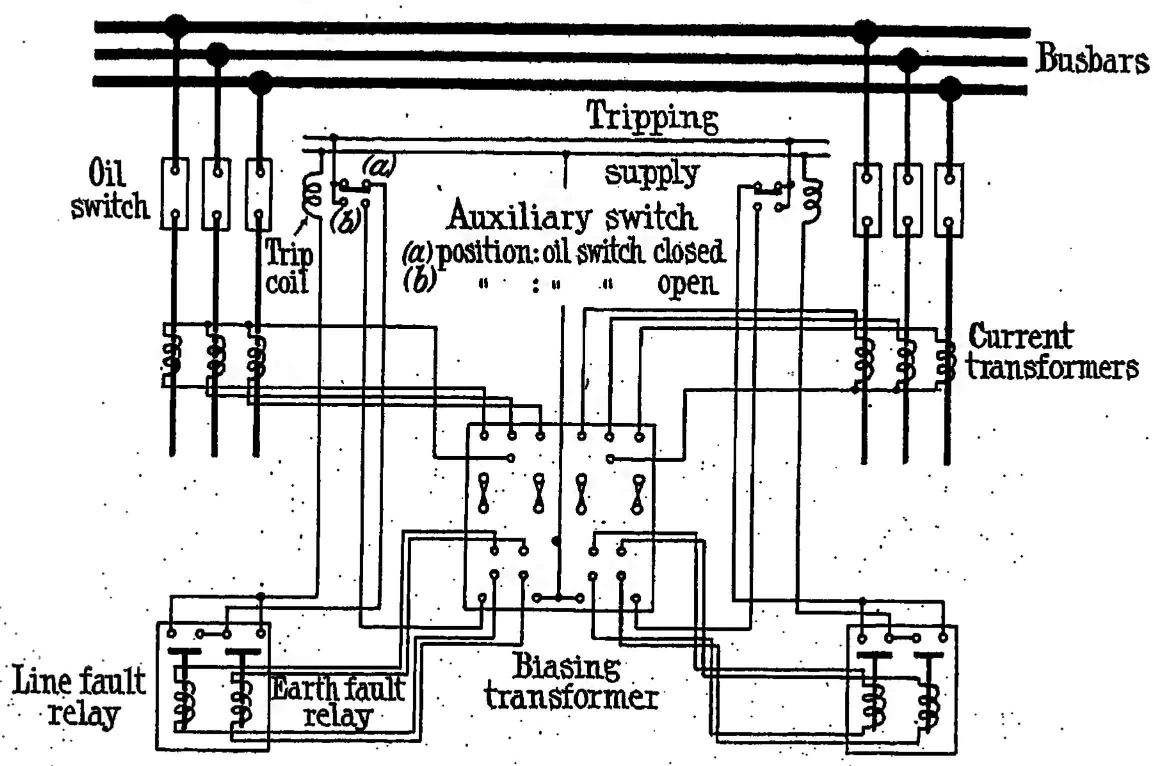

FIG. 42.—Wiring diagram of balanced-current system with stand-by protection for single line.

and also the restraining windings on the line-fault biasing transformer. (3) Earth faults on either feeder will operate the leakage relay on the defective line and will restrain that on the sound circuit. In a corresponding manner line faults will effect correct operation of the line-fault relays.

Fig. 41 shows the actual wiring diagram involved. It will be seen that no notable complications are added.

means of auxiliary switches. Evidently it is possible to avoid all contacts in the transformer and relay circuits by an arrangement similar to that given in Fig. 36.

Again, a scheme analogous to that shown in Fig. 37 may be provided. This scheme is given in Fig. 42. The remaining single line is, according to this arrangement, automatically protected from sustained short-

circuits or earths on any portion of the supply system to which it transmits energy. It is to be noted that should the leakage fuse be removed by hand subsequent to single-line operation having occurred, instantaneous leakage protection is achieved. Similar arrangements may be made for protecting multiple feeders.

Where the above systems of protection are applicable it is found that, using bar-primary current transformers of ordinary design and not exceeding 400 ampere-turns, operation of the protective gear may be effected on current differences equal to 20 per cent of the normal rating. In the case of earth faults, these figures may obviously be improved upon by the employment of special transformers. The corresponding figure in regard to line faults is recommended to be in the neighbourhood of 200 per cent of full load, but the apparatus may be provided or adjusted over a wide range in this respect.

It is particularly desired to direct attention toward the fact that, with the settings referred to, the presence of the apparatus may be entirely disregarded from the point of view of normal operation of the supply system, to exactly the same extent as obtains with pilot-wire systems for single lines.

Balanced-power system.

Operating conditions.—This system must be employed in any circumstances where, amongst a group of parallel feeders differentially protected, the occurrence of a fault cannot be depended upon to set up an excess current in the faulty line. These conditions are peculiarly associated with the receiving ends of parallel lines and they arise more particularly in connection with double feeders. Since, however, in the majority of instances in which three or more circuits are involved, it may be necessary from time to time to operate with but two lines in service, the employment of such gear is not restricted to the double-feeder case only.

The method of application of the biasing transformer may perhaps be more clearly indicated in relation to the more usual case of the protection of the receiving end of two parallel lines. The general conditions of operation of parallel feeders, as regards freedom from interference with normal functioning of the supply system, have been discussed above in connection with the balanced-current system. It has been shown that unless fault settings exceeding normal load currents be employed, the presence of the latter will cause unnecessary tripping of the protective gear under certain circumstances due to operation of the switchgear. These effects are less inconvenient when occurring on apparatus concerned with the protection of the receiving ends of parallel lines. The reason is that when switches are operated at the remote end the resultant unbalancing of the load currents is more likely to trip the line already opened than to cause interruption of the supply after the manner described in regard to the protection of generating ends. The use of fault settings of less than normal load, however, will prevent the feeders from being closed up except in the conventional order and may give rise to other troublesome effects. Under any conditions of emergency or abnormal working, petty hindrances in re-establishing supply, etc., are inclined to present exaggerated disadvantages.

It has been shown how such difficulties may be avoided by the separate treatment of line and earth faults, and it is now proposed to describe means of carrying into effect the same principle in connection with directionally functioning apparatus.

Fig. 43 shows a simple differential arrangement based on Fig. 11. It will be seen that the operating windings of each biasing transformer excited from

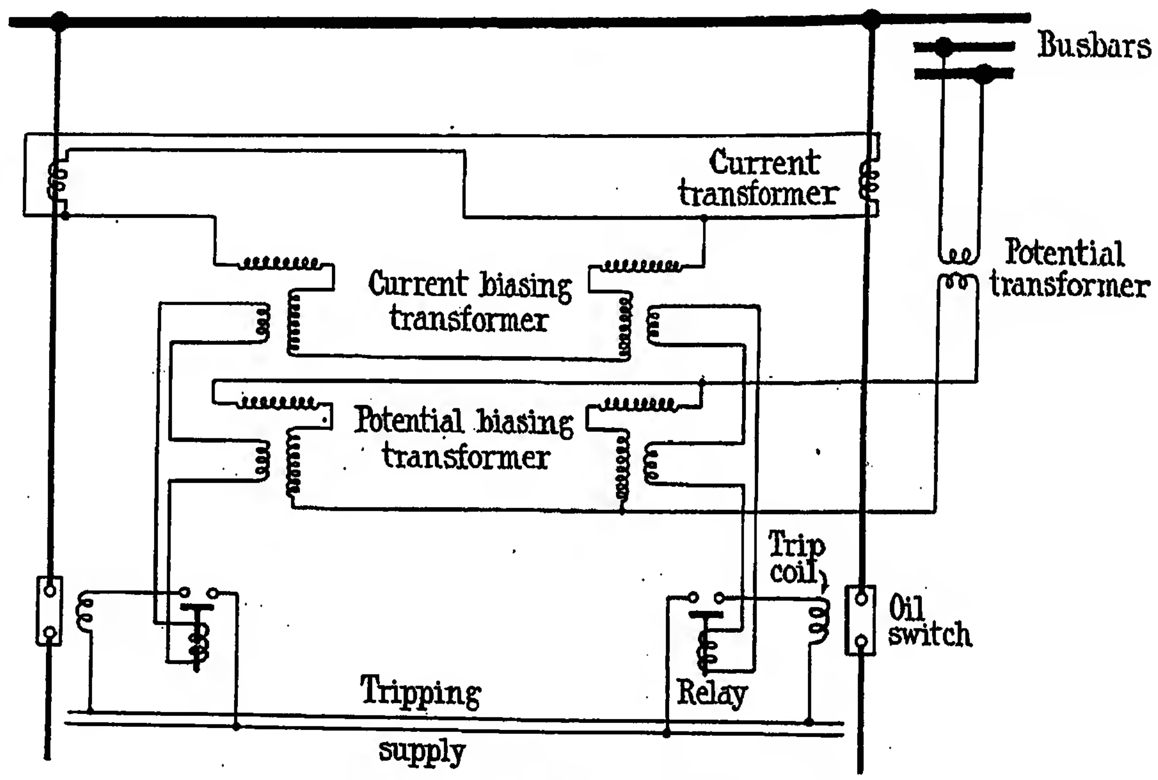

FIG. 43.—Simple balanced-power circuit.

current-transformer secondaries are connected between equipotential points in a circulating-current system according to the usual practice. In such an arrangement no current will be found in these operating windings unless a difference in magnitude or phase exists between the currents in the parallel conductors. If there is such a difference, due to a fault on one of the lines, one or other of the relays would be operated by the combined effect of the current and potential biasing transformers.

It may be stated generally that the operation of such differential directional circuits, whether installed at receiving or generating ends, will be somewhat as follows: The faulty feeder will be that which is receiving the largest amount of power flowing from the busbars into the feeders. Thus a faulty feeder will carry the greater current at the generating end but may carry the lesser current at a receiving end. The faulty feeder would be carrying a forward difference of power at a generating end and a reverse difference at a receiving end.

Such a protective circuit would, however, under all conditions operate at a fixed value of fault current and, having regard to the principles discussed in Section I and the systems of protection already described, it is doubtless superfluous to recapitulate the arguments in favour of biased circuits, i.e. those in which an overload restraint of such magnitude as will ensure adequate immunity from operation on heavy through faults is introduced, there being present the usual unbalancing in primary conductors and current transformers under such circumstances.

Moreover, it was pointed out that the arrangement depicted in Fig. 13 possessed certain advantages when operating in conjunction with currents of low power factor. In the same figure a displacement transformation possessing no restraining element was shown, but it was mentioned that it might be expected to be present in practical applications of the device. This is illustrated by the present example in which overload restraint is applied to this second transformation, the resulting diagram being shown in Fig. 44. Under conditions involving heavy "through" currents correspondingly greater secondary currents will flow in the circulating-current circuit in which the overload restraining windings are connected, and the apparatus will thus be rendered less sensitive to any unbalancing effects that may be set up.

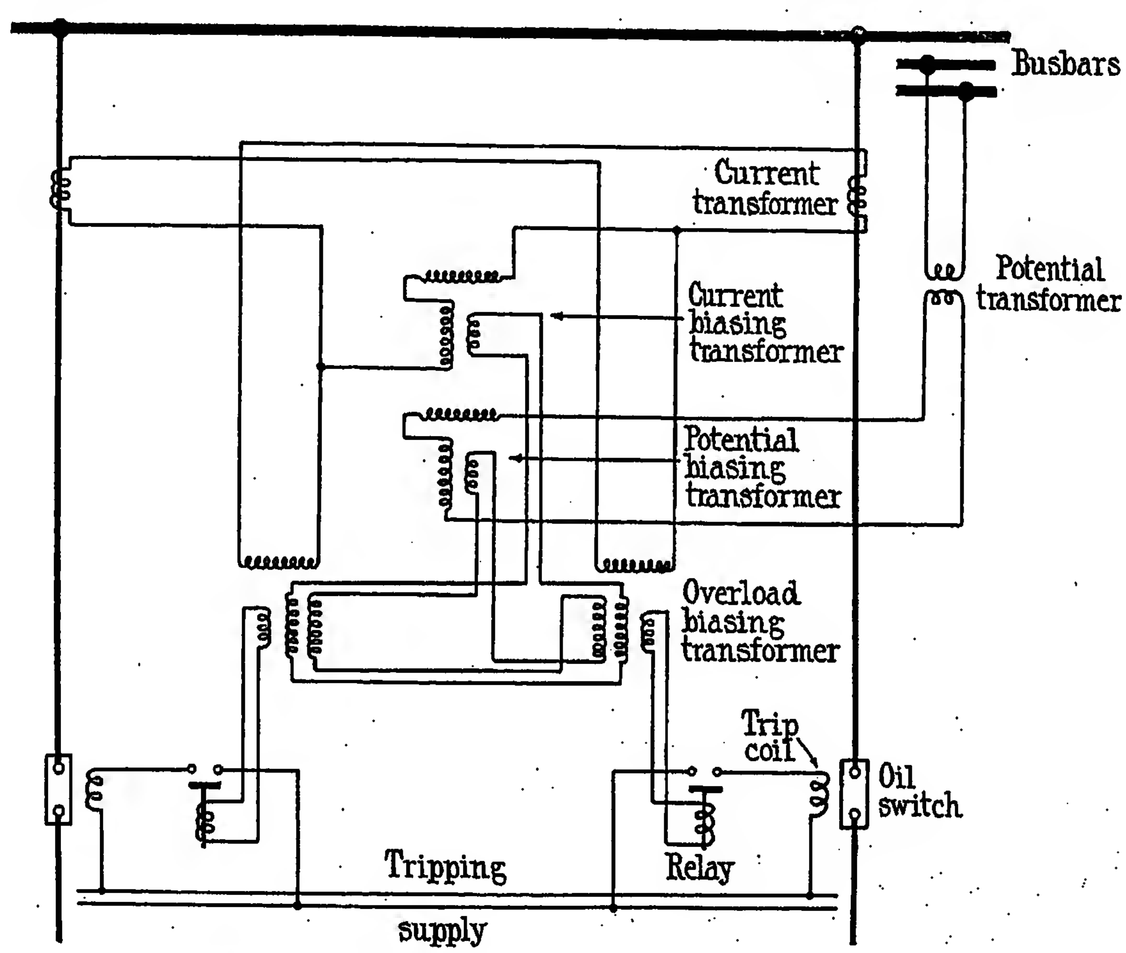

Fig. 44.—Balanced-power circuit compounded by current.

The diagram differs in arrangement from Fig. 43 in certain other features, including a certain simplification in the connections. For instance, instead of the two operating windings excited differentially by the current transformers one only is necessary. Moreover, it is found possible to dispense with one of the potential biasing transformers, the necessary excitation from this source being provided by a single unit. Although, for reasons of detail, the connections in this respect are not entirely in accordance with those indicated in Fig. 13, their effect and function are identical. It is in general desirable to reduce to a minimum the energy output from potential transformers, and by the use of one biasing transformer unit only, excited from this source, the volt-ampere consumption is exactly halved.

A further characteristic of utility, however, may be provided by the circuit indicated in Fig. 44. This may, perhaps, be more easily explained if attention is once more directed to the operating conditions peculiar to directional systems. It has been pointed out that the special circumstance rendering essential the provision of such gear, rather than apparatus operative by current alone, is the protection of two incoming feeders. It will be seen that the portion of the fault current which affects the protective apparatus concerned will be present in both sound and defective feeders. Load currents, therefore, being for the moment neglected, the current transformers will be excited by currents equal in magnitude, though the power represented by these currents will be opposite in direction. It is thus evident why current-balancing apparatus will be inapplicable in this instance, and if the effects of load current are now considered it will be realized that it is possible under certain conditions for the sound feeder to be carrying the heavier current.

If this particular circumstance be examined in regard to Fig. 44, it will be noticed that under the conditions specified, i.e. when a fault is being fed from the generating station through the substation busbars, neglecting load current there will be present in the two overload restraining windings equivalent currents equal to exactly one-half of that flowing in the operating winding due to the fault. In order to obtain correct directional operation it is evident that the relation between the current in the differential operating winding and that in both of the relays should be precisely in accordance with Fig. 12 (*a*), potential excitation being for the moment disregarded. The apparatus, therefore, is designed so that this result is achieved with the specified flow of current.

Whilst it has been pointed out that this arrangement is particularly associated with double feeders at their receiving ends, such apparatus may be installed at both ends where the normal flow of power may be in either direction. Under other conditions the occurrence of faults may sometimes set up such a flow of current that balanced-current gear would correctly discriminate. That is to say, there will be in the defective feeder a current greater than that in any adjacent circuits.

Another condition relevant to the point under discussion is the existence in a receiving substation protected in this manner, of live loads, e.g. rotary converters, motor-generators, etc. It has been stated that where a fault is fed through a substation containing no source of generating plant as such, the currents in the sound and faulty feeders may be equivalent in magnitude. It often happens, however, that when a sudden short-circuit occurs transient balanced-current conditions may exist due to the momentum of rotating machinery; in other words, it is possible that the substation plant may feed into a fault immediately it occurs.

It is generally felt that of all the various methods of protection available, potential-operated arrangements are the least reliable. It is thought, therefore, that desirable features may be provided in apparatus of this nature if advantage be taken of the occurrence of such circumstances as have just been referred to.

In the circuit shown in Fig. 44 it is found possible to arrange that the apparatus functions correctly in a purely directional manner in conjunction with potential excitation when this is necessary, and that when balanced-current conditions obtain, i.e. when the faulty feeder is, in fact, carrying a greater current than any other, the operation of the protective gear may thereby be assisted and rendered more certain. The apparatus is accordingly designed so that the relay current, as in Fig. 12 (*a*), is produced by a flow of current corresponding to the direct effect of a fault flowing into and out of the substation bars, such current-flow exciting the gear in question.

In Fig. 45 curves resembling Fig. 12 (*a*) are again shown. Curve (*b*) in Fig. 45 is, in fact, identical with that shown in Fig. 12 (*a*).

If consideration be now given to the flow of current in the operating and restraining windings occurring when the conditions are such that the current in one

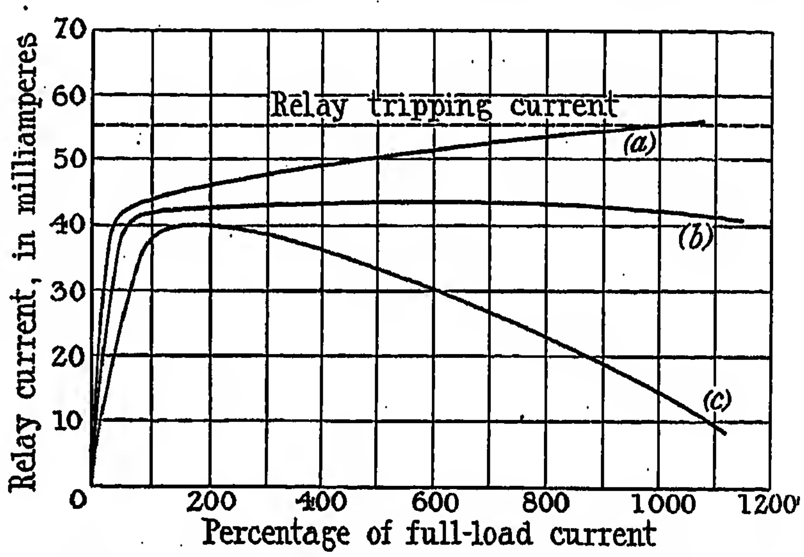

FIG. 45.—Characteristic curves of biasing transformer compound directional operation.

feeder is very much greater than that in another, it will be seen that, in regard to the relay associated with the feeder carrying the heaviest current, there would be a restraining current less than one-half the operating current. On the sound feeder, however, the restraining current would exceed one-half the operating current. Curve (*a*) in Fig. 45 indicates the excitation produced by the former circumstances, and curve (*c*) refers to the latter. As in Fig. 12, the effect of potential is not referred to.

The effect of this arrangement on the operation of the relays is as follows:—

It has been explained in Section 1 and in regard to Fig. 10 or 14 that relay excitation, according to curve (*a*) in Fig. 12 [that is, curve (*b*) in Fig. 45] causes tripping of the relay over approximately 180° of phase relation, the relay being inoperative throughout the remainder. It will therefore be seen that if the relay current be increased, as shown in Fig. 45 [curve (*a*)], the relay will be operative over a greater angular range. In fact, it is found that in the event of complete extinction of voltage, tripping of the relay will still

occur on a very severe fault, due to the curve intersecting the line corresponding to the relay tripping current.

On the other hand, in the case of a healthy feeder the excitation of the relay due to current is so reduced, according to Fig. 45 (*c*), that the relay is operative over a smaller angular extent than 180°. Moreover, if the fault is sufficiently severe it will be impossible for the sound relay to trip, no matter what the phase relation between current and potential may be.

Thus in the case of a rotary substation fed by a double feeder, the effect of a sudden surge of power due to the mass of the rotary armatures feeding a fault on one of the feeders would increase the tendency of the faulty relay to trip and would help to keep the healthy feeder immune.

In Fig. 46 the complete wiring diagram appropriate to the protection of a double feeder on the above lines is shown. This arrangement is equally applicable to the protection of a double interconnector. It will, however, be necessary to provide auxiliary switches, and it will further be essential that the fault settings employed shall exceed normal load currents for precisely such reasons as have been fully explained in regard to the protection of generating ends of feeders.

Improved form of balanced-power circuit.—The evident advantages which accrue in the case of balanced-current protection by the use of apparatus capable of differentiating between line faults and earth faults render very desirable the achievement of similar methods in regard to directionally operated protective gear. Not only does the employment of this principle preclude interference with normal switching operations, but in general it enables increased sensitivity in regard to earth faults to be achieved, due to the fact that reduced disturbances in connections, peculiar to leakage faults, are set up in the protective circuit when the feeders concerned are subjected to heavy overloads or line faults. It has hitherto not been found possible to achieve this result on a commercial scale.

Means of providing for a flow of current in the secondary circuits of a protective system directly due to leakage faults are well known, but, in order to discriminate in accordance with the direction of the leakage fault, this must necessarily be referred to the potential associated with the phase on which the fault occurs. Previous methods have arranged for this by connecting the potential elements of the relays between an artificial or other neutral point in the supply system and earth.

Normally there will be no potential between these two points, but on the occurrence of an earth fault a potential difference of a value depending on which of the phases has suffered the fault will exist. Objections have, however, been raised to the additional potential connections involved, and this particular arrangement would not appear to have been largely employed. In the present instance a solution of the problem has been sought in a different direction. Instead of providing a special leakage relay, as in the balanced-current gear, a triple-pole relay is used, each pole being responsive to faults on the corresponding phase. Special means are provided whereby the relays become energized to a greater extent on the occurrence of an earth fault than will be the case where line faults are concerned.

The relay, therefore, whilst itself operating at a constant value of sensitivity, is more easily tripped by earth faults than by line faults. It is necessary, therefore, for a system of connections to be devised in which an augmented flow of current shall be set up on the occurrence of a leakage component in the energizing circuit. Instead, however, of this additional current appearing in a single neutral lead, it must be present

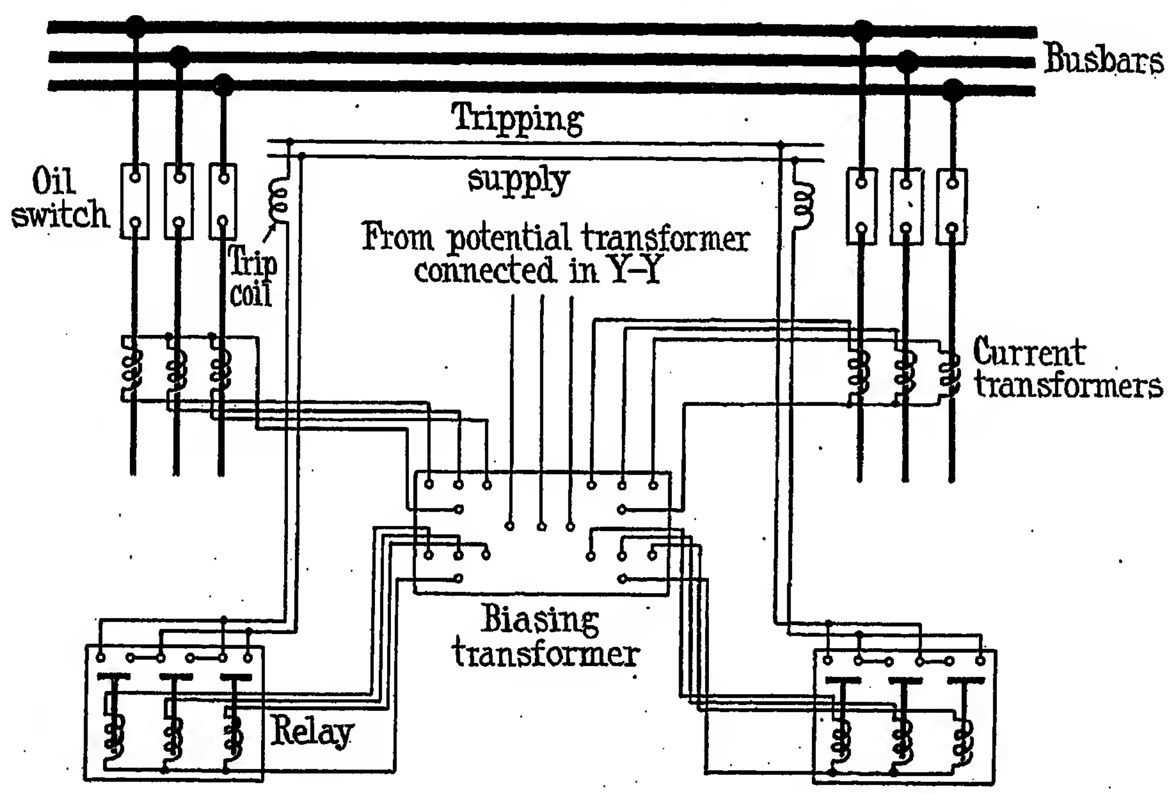

FIG. 46.—Wiring diagram of balanced-power system.

in one of three directionally operative circuits, according to which phase has suffered the earth fault. It is evident that only in relation to the potential associated with the faulty phase may proper directional discriminating operation be achieved.

An application of the principle employed is illustrated in Fig. 47, in which current connections only are shown. It is to be understood that this arrangement will in general form a "difference" circuit and that the secondaries of the biasing transformers will supply directionally operative relays, or the equivalent biasing transformer circuit already described. For the sake of clearness, only those connections relevant to the particular principle to be explained are indicated in the diagram. The three windings shown at the top of the figure may therefore be considered to be the secondaries of current transformers or any other similar source of three-phase current. They excite three biasing transformers, a common or neutral return being employed in the usual way. Each biasing transformer has two operating windings and two restraining windings and is provided with a single secondary for energizing the directional relay, etc., referred to above. It will be seen that one of the operating windings and one of the restraining windings are connected in series with each phase, whereas the other operating and restraining windings are connected in series with the neutral lead between the common point of the biasing transformers and that of the energizing transformers. The number of turns on the two restraining windings will be similar.

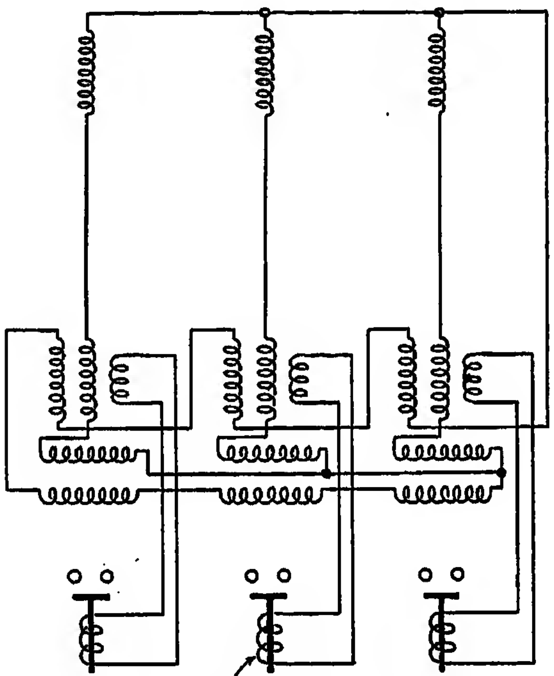

FIG. 47.—Diagram of biasing transformer arrangement for sensitive directional operation on earth faults.

If a current be considered to flow in the secondary of one current transformer only, returning via the neutral lead, then the two operating windings mentioned are so arranged that their exciting ampere-turns are additive. Further, under this condition it will be seen that the two restraining windings are in opposition, and there will therefore be no restraint at all on the biasing transformer appropriate to the phase which has become energized. The secondary of this transformer will receive maximum energy. If the current transformers, however, are excited by currents which have no leakage component, there will be no current in the neutral wire nor in the corresponding operating and restraining windings.

The turns on the biasing transformers are so arranged that the energy in the secondary, due to either restraining winding and operating winding in series, is such that the current in the relay is negligibly small and cannot possibly affect operation.

It will be seen that when a leakage current occurs it traverses the operating and restraining windings on all three of the biasing transformers. On two of them the restraint will be effective, and negligible energy will be applied to the secondary windings. On the one associated with the phase in which the leakage current flows, however, it has been seen that the restraining windings are in opposition, and accordingly there is no restraint. This arrangement therefore provides that an earth fault current on any phase operates the relay only in conjunction with the potential appropriate to that phase.

The simple arrangement shown in Fig. 47 does not function entirely correctly on the occurrence of simultaneous earth and line currents in opposite directions, but it is applicable to a number of conditions, more especially in connection with differential circuits, and in other cases special means may be taken to overcome the difficulties referred to. If therefore the apparatus shown in Fig. 47 be now considered to be excited differentially, after the manner indicated in Figs. 43 and 44, it will be seen that it will only become energized on the occurrence of a fault between lines or to earth on one or other of the feeders protected. In the complete protective circuit, therefore, will be found all the features enumerated in regard to Fig. 44, plus the additional characteristics peculiar to Fig. 47. It is not, however, considered essential, in connection with earth faults, to take into account severe disturbances in the voltage of the system, nor in general will faults occurring on systems operating with an earthing resistance give rise to highly reactive currents flowing to earth. Accordingly the phenomena associated with Figs. 14 and 45 are not arranged to be present in the operation of leakage faults, since both these conditions refer especially to circumstances accompanying the existence of fault currents approximating in value to the short-circuit current.

The leakage discriminating biasing transformers are therefore added to the arrangement shown in Figs. 43 and 44, their secondaries being connected in series with the existing secondary circuits which energize the relays. The operation on line faults is unaffected by the addition and is as described in connection with the above diagrams. The provision of the extra biasing transformer units will slightly modify the dimensions of the biasing transformer shown in Fig. 46, and there will necessarily be a number of additional connections inside the biasing transformer. It is not found, however, that the addition of the circuits concerned with

leakage sensitivity in any way adds to the connections external to the biasing transformer. Fig. 46 shows the complete arrangement appropriate to the protection of a double feeder at a receiving end by means of apparatus of the general nature described.

An entirely analogous arrangement appropriate for the protection of multiple feeders might be provided, it being understood that the apparatus is chosen with a view to operation from time to time with only two lines in service.

The following performance may be provided with this gear, utilizing exactly the same relay as has been referred to in connection with all other schemes mentioned in the paper, namely, an attracted-armature relay capable of operating at about 0·5 volt-ampere.

It is found possible to provide settings which give rise to tripping of the relays on line faults on the occurrence of difference currents of the order of twice full-load current. Due to the effect of the power factor of the fault, definite figures of sensitivity cannot be specified without the provision of special curves of performance. In general, however, it is found that, due to the phase displacement action and other circumstances, the figure would lie between twice full load and four times full load, although different settings can be arranged if desired. These figures give complete freedom from disturbance under all normal conditions of operation. On the occurrence of an earth fault, however, the appropriate pole of the relay would trip on difference currents in many instances considerably less than 20 per cent of normal full load.

As indicated above, no extreme abnormality of potential is considered in regard to the clearance of leakage faults, but these conditions are particularly envisaged in connection with line faults. Single-phase faults, which cause distortion of the normal phase relation, are correctly cleared due to the connections employed. For the same reason, reduction of pressure between the faulty phases, due to impedance drop, will not affect the operation.

Where the fault gives rise to fall of pressure, due to reaction in generating plant, the sound phases, between which the potential connections in question are excited, may be affected, but to a less extent. In the event of a complete short-circuit occurring simultaneously on all three phases, the apparatus is found to function at pressures down to 25 per cent of normal pressure. It is realized that this figure compares unfavourably with the performance possible with dynamometer relays of suitable type, but it may be improved in proportion to the amount of potential excitation employed. It is felt that the more simple installation may present advantages which may be offset against the above shortcoming, which is particularly associated with the type of relay employed. Moreover, an accident of the nature referred to is distinctly uncommon and is hardly possible except as the result of a switching error, such as is commonly guarded against by interlocking. Experiments made by the author on testing circuits in connection with this type of gear, in which short-circuits were applied by dropping a bar across the three phases, almost invariably resulted in the fault clearing as a short-circuit between two phases.

It must be pointed out that the above figures refer particularly to actual balanced-power conditions, i.e. to a receiving substation supplied by two lines. Whenever differences in current magnitude occur, these figures will be improved upon, tripping being possible in severe circumstances with no potential at all on any of the phases.

Use of dynamometer relays.—In the arrangement described, the employment of a simple relay operating directionally after the manner described in Section 1 was indicated. It may be of interest to point out, however, that the special characteristics, such as overload restraint and sensitive leakage, that may be provided by a biasing transformer of the form just described are not inseparable from such an arrangement. A dynamometer type of relay which, as indicated, is essentially an instrument of greater precision than the contactor type of relay, might be employed with very little departure from the connection shown in Figs. 44 and 46.

Section 3.

Application.

The selection of means of protection for any given system or item of plant will call for consideration of the following circumstances:—

(i) The capital value of the plant protected.

(ii) The value of the service, either directly or indirectly. By this is meant the cost per minute to the supply company of an enforced shut-down or, alternatively, the extent of the inconvenience experienced by the consumers and corresponding loss of goodwill, etc.

(iii) The arrangement of the machines, transformers, feeders, etc., necessitated by the conditions of supply.

(iv) Whether the circuits to be protected already exist or if they may be laid out with a view to the provision of efficient protective gear.

Generating and distribution systems, for which it may be necessary to specify means of protection, may be broadly classified as follows:—

(*a*) Those in which the importance of continuity of supply and the expenditure already incurred by the provision of large and costly generating and control units fully justify the additional cost of installing what is considered to be the most suitable and reliable method of affording adequate protection.

(*b*) Systems in which the nature of the load supplied and the value of the plant installed do not warrant more than a limited investment in protective gear, or where, on a lay-out already existing, the provision of such apparatus is only possible to the extent of the installation of additional switches, relays, etc., as distinct from the laying of special conductors or the rearrangement of existing connections. The measure of discrimination obtained in such cases depends to a large extent, in the case of feeders, on the form of network involved.

(c) Small undertakings of limited plant capacity not in general subject to heavy disturbances due to faults, nor supplying loads of the nature in which an occasional interruption of supply gives rise to more than momentary inconvenience. Parallel feeders will not frequently be found on such systems, and instantaneous discrimination is usually limited to the simplest circuits.

So far as generators are concerned, the usual practice is to employ circulating-current protection with suitable field-suppression gear on all machines above, say, 1 000 kW at 3 300 volts. Biasing transformers may be usefully employed for the protection of generators on systems coming in the first category, where low fault-settings are specially desirable.

It is usual to employ circulating-current protective gear for all large transformers, and also for small transformers on important systems, where both primaries and secondaries are connected in parallel. Biasing transformers are particularly useful where low fault-settings are desired, or where the protective transformers have inherently different magnetizing characteristics.

Feeder protection has to be considered with reference to the classification of systems detailed above.

Systems (*a*).—Opposed-voltage protective systems have been more widely employed than any other form, since the use of a pilot wire enables any circuit to be protected without reference to the remainder of the system. It is considered that the particular form described in this paper possesses the following advantages over certain other combinations:—

(1) No sheath is required for the pilot wires.
(2) No air-gap is needed in protective transformers.
(3) Protective transformers are interchangeable.
(4) A low earth-fault setting is obtained with a robust relay.
(5) Immunity from incorrect tripping is obtained at very high currents.

Split-conductor protection, while avoiding the use of pilot cables, necessitates a special form of cable and usually more expensive switchgear, and there seems little tendency to install it at the present time, except for extensions to a system where it has already been used.

Systems (*b*).—In systems of this character, the operation of feeders in parallel permits the use of discriminating protective gear without serious expenditure.

In general, balanced-current gear is chosen for the transmitting end and balanced-power gear for the receiving end. A low earth fault-setting and a relatively high line fault-setting is provided, so that feeders may be switched in and out of circuit without consideration of the protective gear. This protective gear will operate even if the line potential has fallen to zero, except in the case of two incoming feeders at a substation, and even there the potential connections are so arranged that correct tripping will occur with any two lines short-circuited. In practice it has also been demonstrated with an apparently instantaneous three-phase short-circuit.

Systems (*c*).—There is little chance of discrimination in systems of this character, and it is usual to install leakage trips and graded overload time-limits. In certain cases a reverse relay with sensitive leakage setting can be used with advantage.

Conclusion.

Advantages in use of biasing transformer.

(1) Any type of relay may be used.
(2) A single type of simple relay may be used for any of the systems of protection described.
(3) Different forms of biasing transformer may be made of standard components.
(4) Transformer-operated relays are not disturbed by stray direct currents.
(5) The relay is protected from mechanical damage due to heavy faults.
(6) The apparatus requires minimum attention.
(7) Static discriminating apparatus is not likely to deteriorate under service conditions.

Advantages of separate line and earth settings.

(1) Sensitive operation on earth faults is more easily achieved.
(2) Sensitively set relays are not disturbed by short-circuit currents.
(3) Ring cores may be used for opposed-voltage protective system.
(4) Parallel-feeder protective system not disturbed by switching.
(5) Small "tee" loads on protected feeders are possible without interfering with protective arrangements.

Finally it may be mentioned that the British Thomson-Houston Co. have subjected all the devices described in the paper to such tests under service conditions and also at the factory as are essential to prove their practical capabilities, and that exhaustive experiments have been carried out on each of the complete protective circuits, special arrangements having been made to simulate the various service conditions which it has been possible to foresee and reproduce.

Of the eight principal systems of protection described, actual equipments have been supplied except in the cases of two systems, in lieu of which other methods described in the paper are available.

In conclusion, the author desires to thank the British Thomson-Houston Co. for their kind permission to publish the results of investigations largely carried out at their works, and also particularly to acknowledge his indebtedness to Mr. H. Trencham for setting forth the conditions to be met and for his guidance during the progress of the work involved.

DISCUSSION BEFORE THE INSTITUTION, 28 FEBRUARY, 1924.

Captain J. M. Donaldson: The author suggests that a balance be struck between the cost of the apparatus and that of a shut-down, i.e. the loss involved by a catastrophe which the apparatus is designed to prevent. That is a very sound proposition, but one not very easy to carry out. One point which is sometimes overlooked by the makers of protective gear is that such gear may introduce another weak link in the chain. The majority of feeder protective systems depend upon the use of a pilot cable, and sometimes this is of an expensive type. Indeed, in the case of certain installations it is obviously too expensive to be a commercial proposition. In the majority of cases a fault on the pilot cable will cause the relay to operate when it should not do so, or else the protective gear may be absolutely out of action without the fact being known. I suggested to one maker that it might be a sound scheme to have in the pilot circuit a small direct current, the primary object of which would be to show by its presence on an ammeter that all was well, and the result of such an arrangement might be to increase the sensitiveness of the relay. I was informed, however, that this would be impracticable because the relay setting would be altogether too delicate and would not work. I merely wish to point out that in this particular case the addition of a necessary component of protective gear seriously increases the risk, because troubles on feeders are generally due to mechanical reasons. A large three-phase generator will, according to modern fashion, have a full array of protective transformers. It will certainly have six—three on each side of the main winding—to cut the machine out if internal trouble develops. Then there will be three more transformers the duty of which it is to provide for metering and for recording purposes, and possibly another for the pressure regulator. I believe that the current transformer does form a weak part of the system; moreover, it needs housing accommodation. All these things make for complexity, and each point of complexity is an added source of trouble. For that reason, the author's biasing transformer seems at first sight to add another link to the chain. I think, however, that this is more apparent than real. The biasing transformer, with an ordinary relay of a more rugged type, takes the place of a balanced type relay, and the author's argument would be that his biasing transformer, plus the simple relay, is certainly no more complicated and can be made more reliable than the old arrangement. I think that if the author's claims in regard to the apparatus are justified—as I have no doubt they are—there is a great deal to be said for it. Those who have had experience of protective gear know that often it will operate when it should not do so, or vice versa. The capacity current is often blamed, but, I think, not always correctly. I have found on feeders split up into various sections and controlled by Merz-Price arrangements, that whereas a certain group of transformers will act correctly, or fail to act correctly, another group on precisely the same feeder will do exactly the opposite. The broad principles of design are the same, yet there is this difference between the different makes of transformers, and the answer is obviously that the source of the trouble is not the capacity current but the lack of balance between these current transformers. If, then, the biasing transformer will eliminate such troubles, it is certainly worth a minor degree of complication, and, of course, if it also enables us to do away with the Merz-Beard sheath, that is an advantage which I, for one, shall welcome with enthusiasm, because that sheath is an expensive item when a cable which in itself is not very expensive is being protected. I feel that we are rather apt to legislate at considerable expense for conditions which seldom arise. Of course, one must make up one's mind as to whether an occasional breakdown is to be risked. This may sometimes happen, even if protective gear is installed. There is a good deal to be said for taking a certain amount of risk, as against the method of having everything absolutely invulnerable. A very considerable degree of simplicity can be obtained by omitting relays altogether, not in the sense of refusing to have protective gear of any sort or kind, but by letting the current do its own work unaided. There is at present on the market a device which, by the movement of the operating handle, stores up a certain amount of energy which can be released at the proper time by pulling down a small armature, and I think that this does get over the difficulty a good deal. The relays used in this arrangement are of the size of telephone relays. Among the other troubles attaching to protective gear is the fact that a short-circuit is accompanied by a great deal of noise and a certain amount of vibration. I have known several cases in which relays have operated when they should not have done so, merely on account of the vibration caused by the short-circuit. It has also to be remembered, of course, that the use of a relay almost invariably necessitates some kind of switch of an auxiliary character. I agree with the author that less attention has been paid in the past to these auxiliary switches than they deserve.

Lieut.-Colonel K. Edgcumbe: The author points out that one of the great difficulties met with by the designer of protective gear is the enormous range of currents with which he has to deal. The figures given by the author have a range of 1 to 400. This presents a very real difficulty, because nearly all protective systems depend on a balance between two currents which, under full-load conditions, are very large. The author's scheme is to render the relays less sensitive as the overload increases, and he has certainly done this very effectively. But there are two other methods whereby the difficulty can be overcome. One is to improve the current transformers. The author starts out with the assumption that the current transformers are bound to give bad balance. I do not think that that necessarily follows. The current transformers of which I speak are not the balanced-voltage type mentioned by Captain Donaldson, but ordinary current transformers. The question of balance resolves itself into one of having sufficient primary ampere-turns and making the trans-

former do as little work as possible. The transformer now in general favour is the single-turn type in which one conductor passes through a core. A current of 100 amperes flowing in the feeder at full load gives only 100 ampere-turns, and this is very small for the purpose of a transformer. The popularity of this transformer is due partly to its cost—the transformers are cheap to build—but partly also to the reduction of insulation troubles and the mechanical strength to resist short-circuit. In physical measurements it is bad practice to measure a small quantity by a method which involves measuring two large quantities and taking their difference. What one tries to do is to get some method of measurement whereby what one measures is the actual difference itself. Similarly with protective schemes, in which case it so happens that it can be very simply done with current transformers operating on the core-balance principle. If the three phases of a three-phase feeder are passed through a current transformer, the secondary current of that transformer will correspond to the difference extremely accurately. Therefore, any question of the dissimilarity of the transformers is eliminated. The author points out the great importance of keeping the leakage discrimination and the overload discrimination quite distinct, but I do not think that he pushes that idea to its logical conclusion. If they are kept quite distinct it means that the range which one has to cover, instead of being 400 to 1, becomes something like 5 to 1 in the case of leakage, and perhaps 10 to 1 in the case of overload. Those are ranges which the ordinary current transformer, if properly constructed, can easily cover, and bias thus becomes an unnecessary complication.

Mr. J. R. Cowie: I am in agreement with the author when he advocates the use as far as possible of a straight-bar primary in current transformers. An endeavour has often been made in the past to obtain a sensitive tripping device by means of multiple-wound current transformers and/or cutting down the amount of iron in the circuit, generally leading eventually to trouble due to surging current, etc., making the device operative when it should not function. The author's scheme appears to some extent to be on similar lines. At the first glance it would appear that the sensitive settings claimed by the author cannot be obtained because he is using a restraining device on his relay, but on going further into the matter one finds that he is advocating the use of practically solid-core transformers having a higher driving force than multi-gap transformers, and he is balancing one fact against the other. Personally, I think that he is not correct in so doing and that the proper place to get the requisite balance and characteristic is in the transformer itself. This can quite easily be done and a balanced characteristic for fault currents can be obtained much in excess of any figures shown in the paper, a robust, simple and sensitive relay still being retained. It seems to me that the main application of the author's device will be on a line which is giving trouble because a system has outgrown the older types of protection originally installed. The author again raises the question of parallel-feeder protection and employs his biased transformers for these devices, but parallel-feeder protection is known to be fundamentally wrong in that the operation of the relays, no matter what their type, is at the mercy of the load current, and such apparatus may function, may not function, or may function incorrectly. If parallel-feeder protection were a satisfactory device, the Merz-Price system would not have come into existence, nor would split-conductor protection or other discriminating forms have been evolved. On page 585 the author advocates the use of his device on split-conductor apparatus. Such an addition appears to me to be unnecessary, and this is best illustrated by a few practical examples. At one time I had to control a system where two 0·2 sq. in. 3-core cables were joined in parallel on one split-conductor switch and an important converting station of some 5 000–6 000 kW capacity was fed from the end of the line. An industrial load of 250 kW was tapped off one of the 3-core legs and this worked in an entirely satisfactory manner for a number of years, but was afterwards balanced out with an additional leg from the second 3-core cable when this practice was commercially justified. My point is that it was found possible to work without using any auxiliary device where a failure would have meant disaster. In another instance, two 3-core cables in parallel were satisfactorily used where the difference in length of two legs was some 7 per cent. I should like to emphasize the fact that fault settings with this simple device are in the region of 25 to 45 amperes, either between phases or to earth, independent of the length of the line. This condition cannot obtain with the author's device. Split-conductor protection is the most sensitive and stable form of protection of which I have knowledge, and I have yet to see it operate incorrectly on straight-through fault currents. There is a third example working in this country of an overhead 20 000-volt split-conductor line in which the step-up and step-down transformers are included within the zone of split-conductor protection. At present the line is carrying some 10 000 kW and at a future date will carry 20 000 kW. On the secondary side of the transformers there is a relay which will indicate which side of the line has developed a fault, and devices which will permit the engineers to switch in again on the sound half of the line until such time as the fault can be repaired. It should be noted that no charging devices are fitted in the switch. The author claims that his device will take care of the case where a faulty joint has been made in a split-conductor cable. I have had experience of such a joint, and the standard split-conductor protection showed it up. One wants a device which will show up an incipient fault on the system and not hide it. Sensitive settings appear at the present time to be in favour, but in my opinion these indicate a very retrograde step. The fault currents which any system can give are inherent to the system, and nothing that can be done in the way of protective devices will reduce the magnitude of this fault current. If, as I think the author suggests, a smaller earthing resistance should be used, there is a great danger of leaving a large percentage of his alternator windings unprotected. This matter was fully dealt with in Mr. Kuyser's paper,* and need not be stressed further.

Mr. R. W. Biles: The paper may be summed up as

* *Journal I.E.E.*, 1922, vol. 60, 761.

an application of a biasing transformer to all the well-known balanced systems of protection. The question naturally arises as to why the use of a biasing transformer or any stabilizing device has been found necessary. The answer is that a demand has arisen for very sensitive operation. To obtain this sensitive operation many engineers fit some device to limit the flow of current in the case of a fault to earth, and this usually consists of a high resistance in the neutral. The question is a very difficult one to decide, since experience varies to such a large degree, and it depends chiefly upon the local conditions. I would suggest that engineers should take more pains to measure the ohmic value of the earth from the remotest point of the system. The method of bonding the earthing leads is important, as is also the number of points that are earthed on the system. Multiple earthing requires very careful consideration and many protective advantages can be gained by its use. Personally, I favour earthing through no resistance at all, and it is quite obvious that in the design of any protective system allowance must be made for a heavy flow of current in the case of faults between phases, and no high ohmic value of neutral resistance will tend to diminish such a large flow of current in view of the possibility of simultaneous earth faults. The effect of earthing solid is also to ensure clearance of all earth faults, which is a very valuable feature. In some cases also it is useful to have a low operating setting consistent with stability, with the result that only a negligible risk is run of a fault occurring on the system of a value insufficient to operate the protective gear. I have no doubt that the author applies a bias transformer chiefly for this purpose and not for use with a high neutral resistance. He very ingeniously applies it for use with crude current transformers, which require no balancing during manufacture, but it is questionable whether any

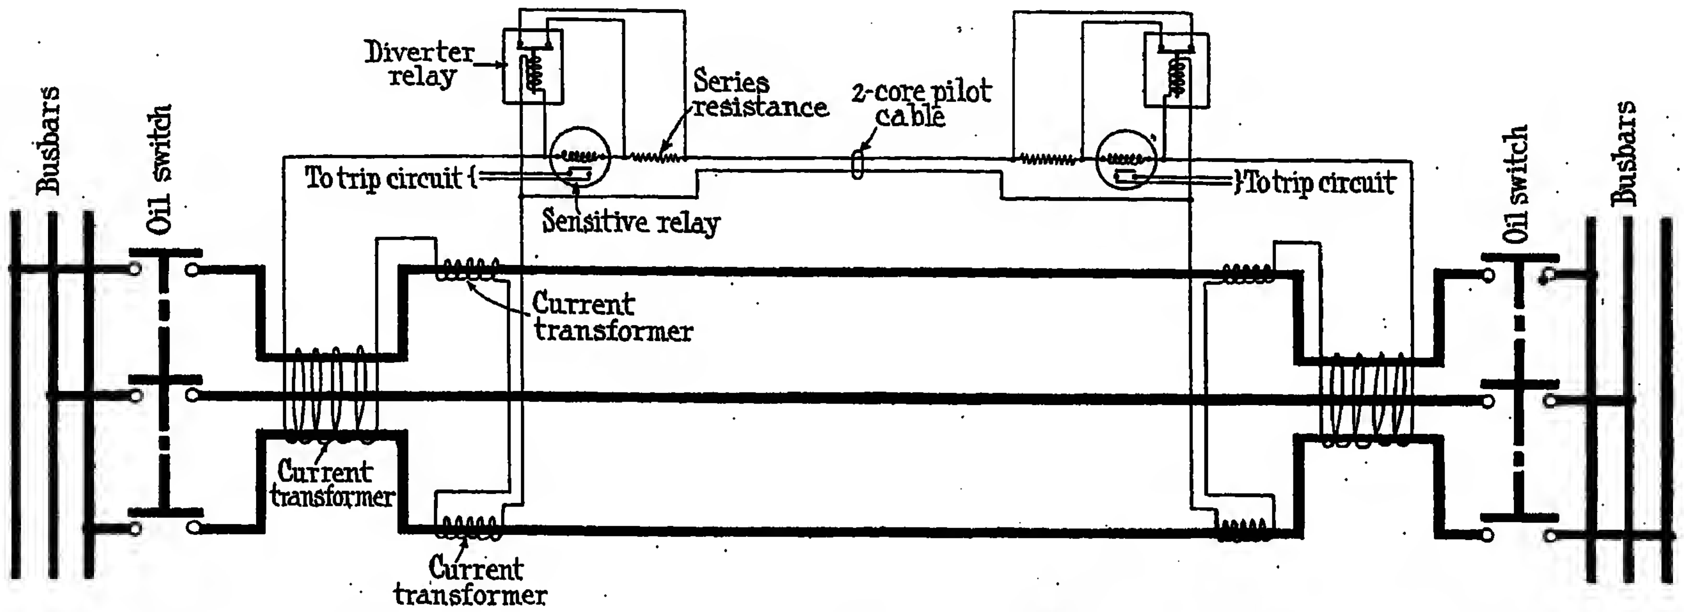

FIG. A.—Diverter relay applied to combined balanced earth leakage and Merz-Price protection; for low fault settings.

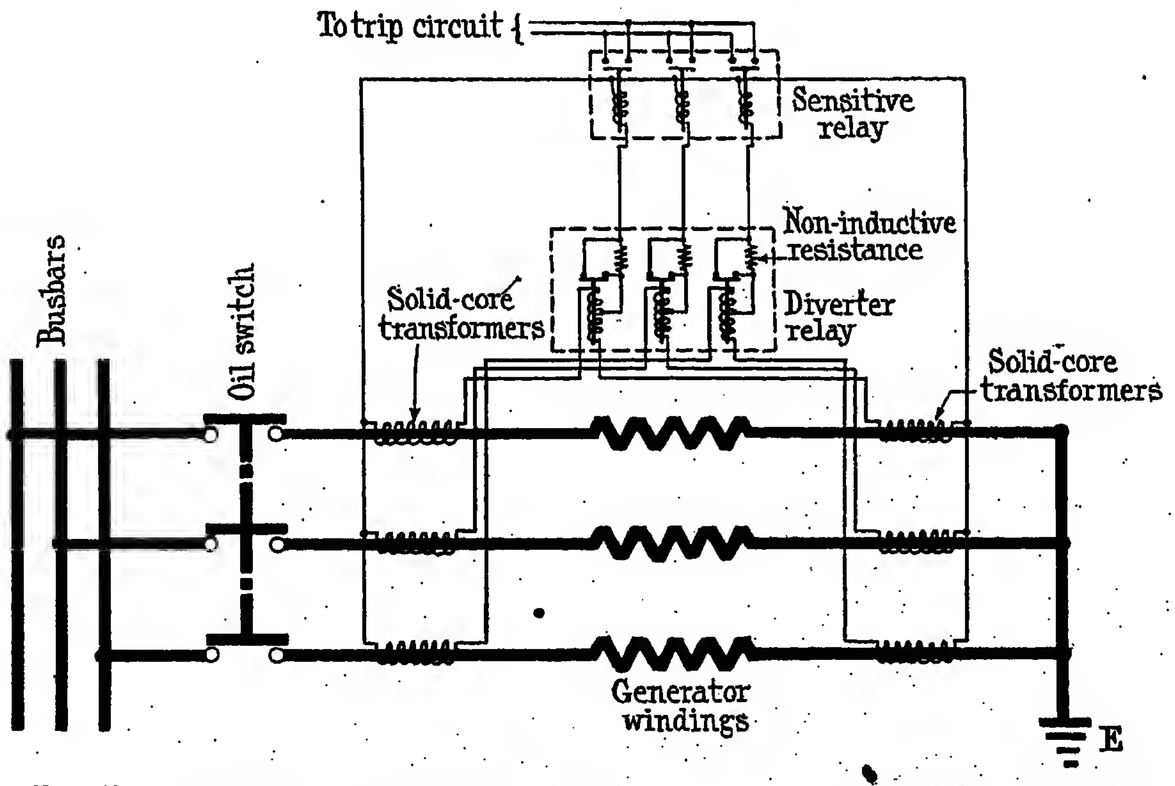

FIG. B.—Diverter relay applied to generator protection; for low fault settings.

economy is effected by this. In any case the cost of the extra bias transformer must be offset against the simple balancing tests that are required. The bias transformer is specially constructed and wired, and requires skilled attention during testing. The difference between a balance transformer and a crude transformer is the simple adjustment of the iron circuit before the windings are put on. I mention this because one of the author's criticisms is the difficulty of balancing. My experience is the contrary, and very little saving is effected. Captain Donaldson, in opening the discussion, made a plea for simplicity; whilst it is a great ideal it is often difficult to achieve, especially in circumstances where sensitive settings may be required. Fig. A shows an alternative arrangement employing a diverter relay. The diagram illustrates the arrangement of three current transformers at each end of the line. The secondary windings are connected in series with two single-pole relays, one at each end of the line, and a two-core pilot cable. Across the pilot cable, also at each end of the line, is connected the diverter relay. The operation of the relay increases the setting of the sensitive relay by introducing a resistance in series. The sensitive relay operates at something less than 0·1 sec. and the diverter relay works at a high speed approximating to 0·01 sec. The arrangement is particularly economical and has the following advantages: (1) Two-core pilot cable only; (2) two single-pole operating relays; (3) sensitive earth-fault protection; (4) stability against overloads; (5) stability against pilot capacity current; (6) no sheaths are required for the pilots; (7) air-gap is optional in current transformers; (8) protective transformers are interchangeable; (9) robust relays may be employed; and (10) same sensitive setting for faults between phases as for earth faults. The advantages over the author's proposals are Nos. (1) and (10). The diverter relay is equally applicable to generator protection and, in fact, any system of balanced protection. In the case of the protection of generators (see Fig. B) the diverter relay is connected in series with the pilot wires, where a current-balance system is used. Settings as low as 4 per cent of full load have been demonstrated with perfect stability and with unbalanced current transformers. The use of this setting may be permissible in certain circumstances. For feeders on a 10-mile line, earth-fault operation can be obtained between 50 and 70 amperes. If wound primaries were used on the same core this value would be considerably reduced. In conclusion, I would say that although I appreciate the author's effort towards the solution of parallel-feeder protection, I am not convinced that the proposal is satisfactory under a simultaneous three-phase fault condition. Such a condition is very unlikely, but when it does occur it is very serious.

Mr. H. Trencham: I should like first to refer to the matter of distinguishing between faults to earth and faults between phases. It is customary to hear engineers deploring the large amount of money which has to be spent in switchgear and switchgear apparatus generally. Phase faults are largely the cause of this outlay and, if the general practice of the industry be examined closely, it will be found that a very determined effort is being made to eliminate such faults. Engineers in the United States have gone so far as to build what substantially amount to separate switch-houses for each phase of a three-phase circuit, and it seems to me that if phase faults can be definitely avoided or if they can be reduced to that small proportion which Captain Donaldson suggests may be regarded as negligible, one is thoroughly justified in legislating for every benefit that earth leakage protection can give. It seems to me that the justification of working with earth faults instead of phase faults will be amply demonstrated if in the future we can use switchgear which is proportioned to deal only with currents such as occur under normal load, because abnormal currents are impossible. It stands to the credit of this country that switchgear which bids fair to meet this condition has been built, and built to a size and at a cost which, I submit, will compare very favourably with that of a scheme such as involves three separate switch-houses for a three-phase equipment. I am referring to totally enclosed or ironclad gear. In the larger sizes of this class of equipment it will generally be found that a phase-to-phase fault is quite impossible. In the smaller size the insulation problem is sufficiently well in hand to make phase-to-phase faults almost an impossibility, although actually in many cases there is no definite earth partition between the phases. The logical following up and improvement of designs of this kind will, I think, in the not distant future provide us with a means of avoiding the very destructive faults and consequent troubles due to phase short-circuits. Captain Donaldson referred to protective gear in a way which is thoroughly typical of the user, as he stated that it does not do what it ought to do and that it does what it ought not to do. Yet the need for it is proved by the fact that it still continues to excite much interest. In addition, I think that the user is not entirely without blame in reference to the bad name which protective gear gets. I say this while quite recognizing the difficulty that has to be met in designing protective gear. It is designed for unknown conditions or, at least, for the extraordinary or the unexpected condition, and makers have to imagine as well as they can what will happen, and provide for something to look after it. If protective gear holds a place in the economic world, then I think that it has not yet been treated with the attention it deserves. If one build a power station and install a steam turbine and a large generator, a great deal of money is spent in testing the equipment and making quite sure that it does what was specified, and, whilst recognizing the difficulties in the way of providing the unusual conditions which would be necessary thoroughly to demonstrate the efficiency of protective gear when installed, I think that they can be surmounted with the expenditure of very much less time and money than is habitually expended in looking after units larger and probably more spectacular. As contrasted with this possibility there are undoubtedly users in this country who have flatly refused to make any tests whatever on protective gear installed on site.

Mr. C. L. Lipman: How does the author propose to apply this scheme when the transmission pressures are

considerably increased? It seems to me that under such conditions it would be an absolute failure, as the extremely low ampere-turns of the line current transformer would be unable to provide the necessary power for energizing the biasing transformer, etc. This scheme is obviously meant to apply to future needs and conditions, so that it is necessary to forecast its availability in circumstances which are likely to arise in the future. I think that the scheme described in Fig. 9 is quite satisfactory, but it appears to me that it will probably cut out the sound feeder as well as the faulty one, and to prevent this the auxiliary apparatus is suggested. I think that this is a mistake, particularly when one realizes that it is possible to design a discriminating relay for parallel-feeder protection which will not cut out the sound feeder unless the load in the latter has increased by more than, say, 200 per cent above its normal capacity, after the faulty feeder has been tripped out. One advantage of the existing relays is that a person using them knows exactly what he is protecting against, and he can set the relay as he wishes. Another advantage of the existing directional (reverse-current) relay and discriminating relays is that the apparatus can be seen working and is often fitted with flag indicators giving positive indications of having operated in a certain way, but the relay as described by the author is an ordinary current relay and will never show in which direction it has operated. I should certainly advocate the practice of having a particular relay for a particular job.

[The author's reply to this discussion will be found on page 619.]

North-Eastern Centre, at Newcastle, 25 February, 1924.

Mr. H. W. Clothier: During the days of the development of Merz-Price balanced protective gear in this district, which commenced about 20 years ago, the following fundamental principles were definitely established: (1) The operation should apply to all conditions of fault, including earth faults, and short-circuits between phases and between all three phases and earth. (2) The protection should have universal application whether used on a ring main, parallel feeders, interconnectors, tees, etc., and should be made so that extensions to the systems by addition to feeders shall not necessitate alteration to the original protective apparatus. (3) There should be a rigid elimination of avoidable parts and connections. (4) Absolute stability under "straight through" fault conditions. (5) The avoidance of the potential element in relays, and the elimination of the potential transformer as a component of protective gear equipment. The author includes the following main features as they appeal to me: (*a*) The treatment of the much-discussed bias method in the Merz-Price protection by means of a biasing transformer in place of the biasing relay explored by McColl. (*b*) The development of this biasing transformer into parallel-feeder or double-feeder protection. (*c*) The combination of the principles of the old "core" leakage protection into balanced protection for feeders. Applying to all three the original subject matter we get the method of using an auxiliary transformer for introduction of the biasing effect, this being an alternative to the better-known system of biasing by means of relays. There is a further way of dealing with the problem known as the "diverter relay" system and in course of development by the Reyrolle Company, as illustrated in Fig. C. In both the transformer and relay bias the bias is always tending to restrain the operating relay. On the other hand, in the case of the diverter relay the restraint does not appertain until the straight-through fault current has approached a dangerous limit. At this stage the diverter relay operates and introduces a non-inductive resistance into the pilot-wire circuit. The resistance is such that the operating relay is insensitive to the maximum effects which would tend to cause inadvertent operation on straight-through fault currents, but it should be noted that it still remains responsive to internal fault currents though in a coarser degree of setting. The diverter relay system, therefore, has characteristics somewhat similar to those of the bias systems. It has the advantage that it is very simple and that it may be used in addition to standard air-gap transformers where a more sensitive setting is required than that procurable with the ordinary robust relay. In regard to the second

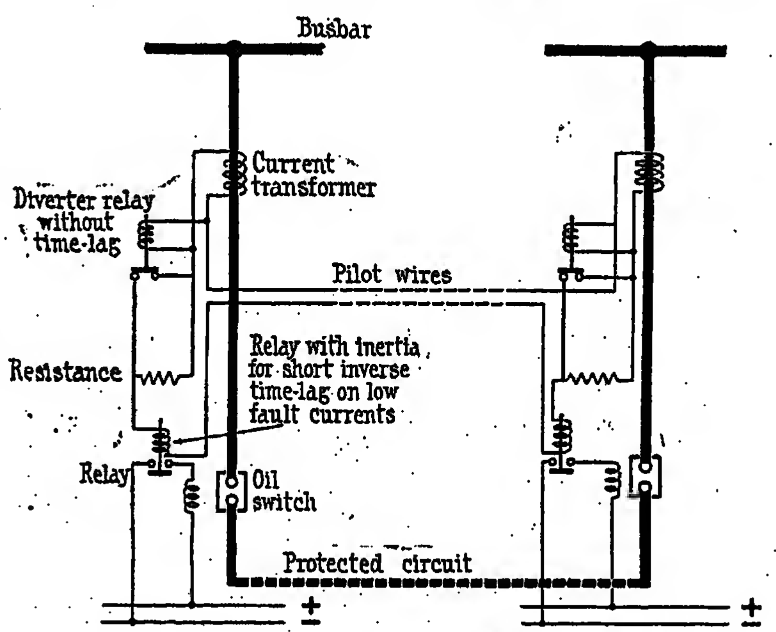

Fig. C.—Diverter relay applied to Merz-Price feeder protection for sensitive tripping.

feature, the development of the biasing transformer into parallel-feeder protection is extremely interesting and has entailed much thought. The ideal in parallel-feeder protection by interconnected balanced relays without pilot wire, after consideration of several stages of protective-gear development from time to time, has always appeared to me to be a myth. It is never possible to meet all the required conditions in service even when attempted in such an elaborate manner as is shown in the author's figures. I long since came to the conclusion that it was best to join the pair of feeders together and so form a simple split-conductor system which would allow both feeders to trip out for

a fault on one, and then the sound line, having overload protection, could be restored. In regard to the third feature, the use of core leakage in balancing with the pilot wire was considered on the North-East Coast network at one time, particularly in order to obtain the advantages of light settings for faults to earth which were thought to be advantageous for the protection of falling overhead lines. There was no difficulty in combining core-leakage protection with the ordinary air-gap transformer system, but the principle of balanced earth leakage was not generally accepted as a practicable solution for feeder protection. [It was only approved for generator protection (Porter system) and even in that case it did not reach a practical application stage.] The author mentions the reason on page 584. It is that, according to the experience on large power systems, a fault to earth on one phase is likely to be accompanied simultaneously by a fault to earth on another phase, and the second fault may be on another cable on another part of the system. The effect of this is to cut out the saving factor of the earthing resistance, and the fault currents to earth become practically as great as the fault current between phases. Therefore any considerations dealing with leakage protection must take into account straight-through currents of the same magnitude as those occurring on faults between phases. That being so, is there need to complicate the feeder-protected circuit by a separate system dealing with the earth leakage? The author does not state the fault-current settings for faults between phases, nor the measure of stability in terms of straight-through current which has been achieved by his bias system on feeders. It would be interesting to know whether any better results are obtainable with his solid-core transformers than with the air-gap transformer. The latter was found from the first stages of Merz-Price development to be the best means of obtaining stability under straight-through fault conditions. Later on it was improved by the introduction of a larger iron core and a multi-air-gap, proposed after investigations into the means of the avoidance of interference by external field which was experienced with the original single-air-gap transformer. At present most multi-air-gap transformers are adjusted and tested for balance with the standard up to 10 000 amperes. No difficulty is now experienced in manufacturing to comply with these tests, and accurate balance is possible under even greater currents. These precautions in manufacture have sufficed to meet the ordinary demand for feeder protection, using a simple relay having fault settings of 400 to 800 amperes when fed through one transformer at one end of the line only. It is remarkable that the simple treatment has survived notwithstanding the improvements suggested from time to time by many investigators who have studied the problems from the users' and manufacturers' points of view. Troubles there have been, but in the majority of cases these have been attributable to a mistaken endeavour unduly to cut down the operating currents, thus introducing a state of instability during straight-through fault currents. This has sometimes been done for no better reason than the saving in initial cost of the earthing resistance. It might be better in many cases to earth the neutral direct and save the whole cost of the earthing resistance, than to strive for ultra-sensitiveness at the expense of stability. Those instances where this special degree of sensitiveness is required may still be dealt with by the standard form of multi-air-gap transformer, utilizing the diverter relay method before mentioned. In this case the operating relay may be of the sensitive dynamometer type (such as the Fawssett-Parry) with inertia to avoid inadvertent operation on impulses, this being preferred to the author's solid-core transformers and biasing transformers. The leakage protection may be used in either case when it is considered to be safe. Two other phenomena which have been experienced on balanced protective systems have been more pronounced on systems of 33 000 and 66 000 volts in conjunction with very large power generation, and have not been disclosed by the author as a result of his practical investigations. One is interference by voltages induced on the pilot wire by heavy main single-phase fault currents. This condition may be aggravated by imperfect bonding of the main cable, allowing the return current to stray from the immediate surroundings of the cable. Inadvertent tripping of the relays occurs in the event of a pilot wire being earthed at one end, or when the insulation of the pilot wire breaks down. The remedy proposed by Mr. Porter is to add "drainage coils" to the pilot wire at each end, an expedient which is found necessary for a similar phenomenon in connection with telephone service. The other phenomenon is the production of an out-of-balance current in the pilot wire due to straight-through resonance currents occasioned by arcing faults to earth. In such cases there will be an actual difference of current in the two ends of the main line. It is, in fact, the exception to the principle upon which the Merz-Price balanced systems were originally based. Will the system of bias always take care of this? A convenient remedy is to make the relay inoperative by currents of frequencies other than the normal. This may be partially accomplished by shunting the relay coil with a non-inductive resistance, but a "reed" type relay is likely to be most useful for this purpose, the operating reed having the physical property of vibrating only within small variations from the normal frequency. These phenomena, however, are experienced only in the exceptional cases mentioned above. For the normal practical lay-out of cable systems for 6 000 to 20 000 volts, the original Merz-Price protection with multi-air-gap transformers and simple relays meets all service requirements, provided an unduly sensitive operation is not attempted. On reading foreign technical papers and studying practices in the application of protective gear in other countries, one cannot help but be impressed with the greater activities of British supply undertakings and manufacturers in the matter of efficient balanced systems of protection. Whilst other countries have tried to solve the problems with graded time-limit devices, the British industry has adopted the broader policy—notwithstanding the extra expense of the pilot wire or a special cable—of cultivating the art of true discrimination by the balancing methods. Unfortunately for the ideas in protective gear, it takes so long to explore fully a new method. Test-room

experiments do not always reveal the difficulties which occur under serious fault conditions on the network of cables with large amounts of power available. The bias system is no new thing, although the author's method in detail has not been on trial for long. No doubt, however, he will be able to assure us as to its efficient service on large power supply systems.

Mr. B. H. Leeson: The author, accepting the well-proved principles of balanced differential protective systems, has set out to obtain lower earth-fault settings, and, as a result, has devised a very ingenious piece of apparatus which he calls a "biasing transformer." The use of this additional apparatus is occasioned by the employment of solid-core unbalanced-type transformers, and this combination is advocated by the author as an alternative to the simple air-gap balanced-type transformer. This policy, however, does not harmonize with the principle of simplicity so rightly advocated at the beginning of the paper; and I question whether an extra biasing transformer is really necessary, seeing that an alternative simple air-gap transformer can be balanced without any difficulty to a "standard," so as to form a negligible factor in the determination of a satisfactory service fault-setting. The author's advocacy of very low earth-fault settings appears quite attractive at first sight, but I am of the opinion that it cannot be universally applied with advantage, owing to the many other factors which determine the safe setting value, quite irrespective of the capabilities or limitations of the protective apparatus itself, as referred to in the paper. Assuming, however, a given low earth-fault setting to be obtained with stability of the system, the advantages or otherwise must be considered in the light of the following arguments. If the principal advantage of a *low* earth-fault setting on the network is to limit the disturbance or shock on the system, then a correspondingly *high* ohmic value of neutral-earthing resistance is required to limit the fault current to a comparable amount. On the other hand, the principal object in generator protection is to leave unprotected as small a percentage as possible of the generator winding from the neutral point; and as this is governed entirely by the ratio of the fault-current setting to the current passed by the earthing resistance, a *low* ohmic value is needed in this case if any advantage is to be gained by the low fault-setting. Further, the use of an earthing resistance of high ohmic value is dangerous, as the system approaches the condition of an insulated one, and when an earth fault occurs on one phase the other two will be instantaneously subjected to $\sqrt{3}$ times the transient voltage existing during the fault. This very rapid pressure-rise, probably at the resonant frequency of the system, will search out any weak spots in the insulation of the other phases, and experience shows that in actual service such conditions produce simultaneous earth faults on separate phases. In addition to this increased risk to the insulation, faults which are too limited by the earthing resistance may be difficult to locate, and in all probability the procedure of burning them out will be finally resorted to. Is not the better way, therefore, to allow a heavier fault current to pass which will not only be sufficient to burn out and clear the fault in one operation (thus avoiding delay in resuming service) but will also reduce the surge energy on the sound phases and lessen the risk of further failure? Generally speaking, I think that the compromise is in favour of the low-ohmic-value earthing resistance; and it is interesting to note that, whilst the smaller systems are employing a limiting resistance in the neutral, the tendency in the large modern stations is towards solidly earthing the neutral point. A low fault-setting on the network is only obligatory, therefore, if the system is earthed through a high resistance (in order to ensure operation), and this may be accomplished either by the inherent addition of the biasing transformer in the author's scheme or, in the case of existing Merz-Price systems, by the simple addition of a diverter relay. On the other hand it is questionable whether any extra complications are justified in the majority of cases where the current passed by the earthing resistance has been determined upon the lines discussed above, as experience proves that it is often preferable to sacrifice the low fault-setting to simplicity and stability by employing the Merz-Price system in its simplest form. The author describes the occurrence of simultaneous earth faults as being exceptional. He limits his statement, however, to pressures not exceeding 11 000 volts, but I take it that he does not intend to imply that the successful operation of his systems of protection is similarly limited. No system of protection can be successful unless it works satisfactorily under the condition of a straight-through fault which is not limited in value by the neutral earthing resistance. In other words, the setting employed for obtaining stability for an earth fault must be equivalent to that necessary for a fault between phases. By employing solid-core transformers a large unbalance will be caused with a straight-through earth fault of between-phase value, and, in view of the fact that a low earth-fault setting is employed in the author's schemes, I should be glad to know whether stability is assured in this case under service conditions. In the case of generators the fault-setting should be as low as possible, consistent with stability. I should have expected the author to have specially advocated a low fault-setting here, and I should like to know his views upon this point, as no specific reference is made under this heading in the paper. With reference to the author's remarks on page 598, presumably referring to the Merz-Price system, it is not essential for a sheath to be employed on the pilot cables; this is only one of the methods by which capacity currents may be compensated for, and is only used where lower fault-settings are desired. With regard to air-gap transformers, when these are employed there is no possibility of the relays becoming damaged under short-circuit conditions, the danger of which is referred to by the author. All air-gap Merz-Price transformers are carefully balanced to a standard, are completely interchangeable, and during very high currents form a negligible factor in obtaining stability. Incidentally this is much simpler and cheaper than the use of a separate biasing transformer. My remarks above have already shown that the advantage of a low earth-fault setting may be outweighed by other considerations. The Merz-Price system is also stable under conditions of simultaneous earth faults

of between-phase value, probably to a greater degree than the author's alternative. With any form of Merz-Price protection, low fault-setting may be obtained by the employment of the diverter relay, in cases where such additional sensitivity is desirable. Seeing that very low fault-settings are obtained with the existing split-conductor system, I find it difficult to appreciate the necessity for the extra complication proposed by the author. In the case of transformer protection the author proposes to use a d.c. auxiliary restraint which comes into action during the closing of the main switch. I hardly think that this is a solution of the problem, as it makes no provision for current-rushes which occur after the switch has been closed, such current-rushes or surges being due to rapid changes of load under fault conditions. I shall be glad to know whether low fault-settings can be made stable and are recommended by the author under these conditions in service. The being connected to the protective relay and the other to a fault-indicating relay. Overload transformers are also provided for single-line protection. This scheme is exceedingly simple and operates correctly under all conditions of service on a ring main. No auxiliary switch is employed and isolation is positive and depends only upon the value of the current, no potential elements being employed for the tripping operation. As the lines are separated in the form of two cables or otherwise, all faults are either between phases or to earth, and thus complete protection for every operating condition is obtained. If step-up power transformers are employed in the two outgoing lines, then complete protection is afforded to them, both on the high-tension and low-tension sides. Earth-fault indication may also be obtained by providing current transformers for the neutral leads on the secondary side of the step-up transformers. When a fault occurs, both lines are

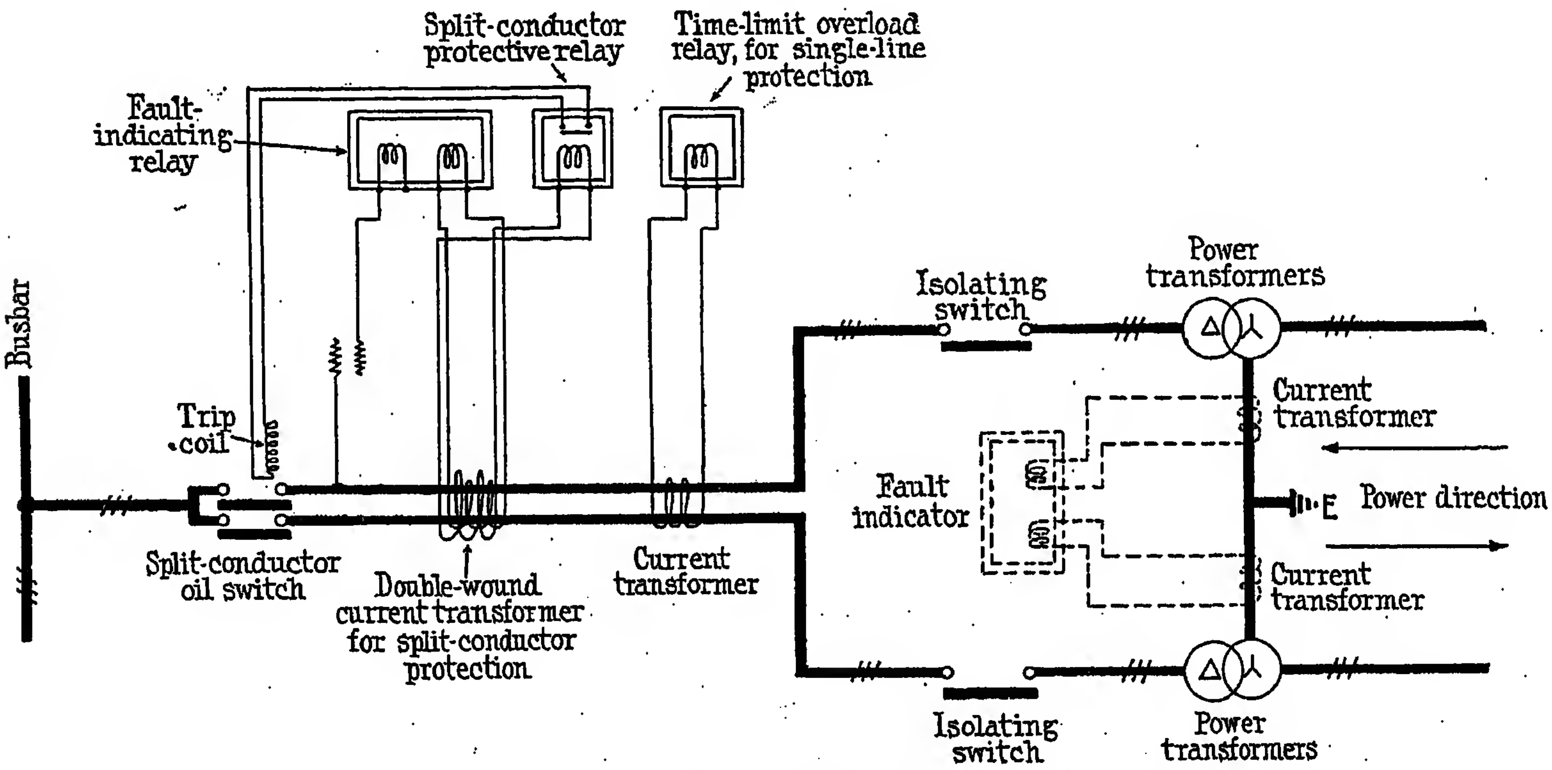

FIG. D.—Split-conductor principle applied to parallel feeders with faulty-line indication.

author applies the principle of the biasing transformer to various forms of parallel-feeder protection. I am not quite clear as to the true advantage of the use of the biasing transformer for such protection, as it only applies to known systems which are admittedly far from ideal. He acknowledges the fundamental difficulties, and in the scheme advocated by him, employing a balanced-power arrangement, no protection would apparently be obtained on simultaneous three-phase short-circuits. The great disability of many of the systems shown is that they are only suitable for a power feed in one direction, which practically debars them from modern networks, where ring mains are more or less essential. The split-conductor principle may be applied to parallel-feeder protection in a very simple manner, and this is shown in Fig. D. The two lines are fed from a standard split-conductor oil circuit-breaker and are passed through standard split-conductor transformers each having two windings, one winding switched out and the indicating relay shows which is the faulty line. The sound line can then be closed in immediately. In view of the complete and positive protection afforded, there is very much to be said in favour of this extremely simple form of protection.

Mr. H. Trencham: Protective gear of the type using pilot wires was first seriously taken up in the North-East district, but its real importance is not yet realized as it should be in many parts of the country. Mr. Clothier touched on a very interesting subject when referring to the new difficulties which occur in adapting pilot-wire protection to high-voltage schemes. In the United States and on the Continent such development has been avoided, but it does not necessarily follow that the subject is entirely intractable. In my opinion the success which has in the past attended the work done in this country augurs well for the successful surmounting of the new difficulties which appear.

Mr. W. A. A. Burgess: It is to be regretted that

the author's efforts have led him away from, rather than towards, that simplicity which is the ideal in the electrical and also every branch of engineering. In looking back upon the process of evolution of the majority of successful engineering products, one can usually trace an original and comparatively simple idea through a maze of complication to a final simplified form still embodying all the advantages towards which the more complicated forms were aimed. To my mind the author's scheme of biasing transformers is still in that complex though useful stage which, while insufficient in itself to meet the aims of those responsible for its development, is still a definite and necessary step towards their ultimate simple fulfilment. The need for certainty of operation under predetermined fault conditions (and there is nowadays no need to go to extremes in sensitiveness in fault settings on a well-designed system) and for equal certainty of non-operation with heavy normal currents is undoubted, but the simplest and soundest way to secure this is surely to improve the design and balance of the main protective current transformers rather than to endeavour to correct errors of bulk manufacture by introducing an additional piece of apparatus to the circuit, even though that additional part be much more simple than that proposed by the author. A case for the improvement of existing forms of apparatus may be instanced where two feeders are provided with "parallel feeder" protection, a very common expedient in modernizing the older networks. Even the author's equivalent of a wireless receiving set replete with fuses will not prevent the healthy feeder from being automatically switched out, nor will it assist him in the quick determination of the faulty line. As an instance of intermediate over-elaboration, I once attempted to apply Merz-Price protection to a three-phase overhead ring main with 12 tees off it, each capable of passing current both into and out of the ring main. The object of the ring main was to equalize the load on ten 0·25 sq. in. low-tension feeders in an industrial works, to save additional copper. The product was a particularly valuable one; the processes involved were continuous and the cost of the protection, if it would work within reasonable limits, was justified. My first inclination was to connect all current-transformer secondaries in series with a ring cable broken at the relay, "star" one end, connect the relay across the other end and join the neutrals to effect the E.M.F. balancing. Next, to reduce the fault setting and still use straight-through current transformers, I investigated current balancing, which appeared to require at least three secondary leads from every current transformer to be brought to a common relay centre, involving a number of very long lengths of pilot cable of relatively heavy section and the possibility of compensating resistances. This was very nearly the author's method and I was frankly appalled at my creation. I next decided to try the effect of paralleling all current-transformer secondaries on a common ring pilot, starring one side. At this stage I obtained the necessary current transformers from Messrs. Reyrolle. A preliminary test proved the system to be workable and it was afterwards found that, using standard 7/21½ S.W.G. 3-core pilot cable, the relay could be put at any point of the ring pilot without affecting its successful operation. The system has now been in commission for 6 years and operates with great promptitude whenever a crane jib fouls the overhead wires or a piece of corrugated iron short-circuits them. The total possible current input to the ring main is about 3 000 amperes, and a motor connection requiring 50 amperes teed off within the protection will operate the relay. In conclusion I should like to advocate the consideration of the application of the balanced-protection idea to the more mechanical side of engineering, to buried gas and water mains and to the indication, at least, of heat leakage and waste all the way from the fuel to the unit of electrical energy. I am sure that no biasing apparatus would be tolerated in that field, and it hardly seems necessary in the field covered by the author.

[The author's reply to this discussion will be found on page 619.]

North Midland Centre, at Leeds, 26 February, 1924.

Mr. W. B. Woodhouse: It would be of interest if the author would give some indication of the cost of the apparatus which he describes in the paper, as compared with that of other forms of protective gear in general use.

Mr. D. M. Buist: When protective gear was first introduced, it was considered to be relatively unimportant. Some supply engineers in those days contended that it was unnecessary to protect against troubles that they never or seldom encountered, while others contended that the remedy was worse than the disease, and in the majority of cases such arguments were unassailable. The first contention has now been refuted, however, chiefly due to the rapid growth in the size of individual undertakings, whilst the second contention has been reversed by the improvements effected in protective gear in recent years. The present paper is indicative more of improvements than of the introduction of new systems. The outstanding feature of the paper, is, of course, its advocacy of what is really a radical departure in the design of protective gear, namely, the use of biased transformers in place of biased relays. This transference of the bias from the relay to the transformer certainly constitutes a notable improvement as it not only permits of the use of a more simple and robust and yet less sensitive relay, but also affords greater overall sensitivity, as this feature is transferred with the bias to the transformer. At the present day, users of protective gear are divided into two schools, those who prefer high settings and those who prefer low settings. I, personally, belong to the former school, preferring to install sensitive relays of the Fawssett-Parry type, not necessarily in every case employing the minimum setting, however, but rather allowing experience of the network and the growth of the undertaking to decide the correct setting. The installation to

which I refer is only in its embryo stage at present, and I fully anticipate that I shall change my opinions with time, but another reason for my choice of such a flexible arrangement, quite apart from the two reasons already given, is that, despite the use of Beard compensated pilots and recent improvements in the transformers, I wish to incur no risks from the presence of triple-frequency currents which recent oscillograph tests have displayed. In point of fact, we are even now seriously considering leaving the secondary circuit unearthed for this reason, as in any case the general practice of earthing at one end only of the secondary circuit is no adequate protection to the operator should he be engaged on the protective gear at the opposite end. The possibility of operation by triple-frequency currents applies to all systems of protection employing leakage relays or earthed-neutral supply systems. I should therefore like to ask the author if he has taken cognizance of this point, particularly as none of his feeder diagrams shows an earth connection in the secondary. I believe I am correct in stating that this paper is the first one on this subject to deal almost entirely with the design of protective gear, or at least to keep design to the forefront throughout. Its value would have been greatly enhanced if the results achieved in practice in those installations referred to in the penultimate paragraph had been described with a detail equal to that displayed throughout the paper. A set of curves showing the comparison between the author's gear and existing systems, from the points of view of tripping current and stability on "through" short-circuits, would also have been valuable, as supply engineers as a body are too busy to digest thoroughly the contents of such a lengthy paper as this is. While on this subject of sensitivity, particularly on feeder protective gear, I should like to ask the author's opinion of the following statement: The more sensitive a setting and therefore the less disastrous the effect of a fault, the more difficult it is to locate the fault. An increase of sensitivity results in tripping the oil switch earlier but, in my opinion, the fraction of time thus saved is negligible. Moreover, as the sensitivity is increased, slight variations in the mechanical time-lag in the operation of the oil switch assume relatively greater importance. An interesting experiment to substantiate or disprove the foregoing contentions would be to apply the author's proposals to a circuit already protected by Merz-Price gear and to carry out a series of tests with varying fault currents, including a dead short-circuit. I think that it will be agreed that the rapid growth of the fault current would reduce the interval of time in passing from a tripping current of, say, 100 amperes for the author's gear to a tripping current of, say, 400 amperes for the ordinary Merz-Price gear, to such an infinitesimal amount that both relays would appear to trip instantaneously. For this same reason I would ask the author if, for stub-ended feeders, combined overload and leakage protection is not equally as efficacious as any system he has put forward, because, after all, it is merely an application of the Wedmore principle.

Mr. M. Wadeson: The less protective apparatus is used the better, and I think that if simple overload protection will suffice that is the best system. It is, I believe, now becoming quite general in large power systems to do away with much of the complicated protective apparatus and use overload protection as far as possible.

[The author's reply to this discussion will be found on page 619.]

North-Western Centre, at Manchester, 4 March, 1924.

Mr. H. A. Ratcliff: The paper deals with apparatus for the protection of alternating-current circuits, and the author frequently refers to protective devices. "Protective" appears to be a misnomer, and a better description would probably be "isolating" or "locating." No form of protective gear protects in the sense that it prevents a fault occurring, although it may be correct to say that it protects other portions of a system from the effects of a fault on the automatically isolated section. The author emphasizes the importance of clearing small earth faults instantaneously, but it is equally, if not more, important that short-circuit faults should be cleared instantaneously. Up to a year or so ago it was the general experience that 99 faults out of every 100 originated as earth faults and as a rule they could be cleared before they developed into short-circuits, but recent experiences in various parts of the country with extra-high-tension cables have indicated that the same sequence of fault development and clearing is not likely to obtain. The real essential in connection with protective gear is discrimination between one circuit and another, and between one portion of a circuit and the remainder of the circuit. That is the principal reason for the design and development of pilot-wire systems of protection. It is possible to attain a certain measure of discrimination by means of time-lags on the relays, but their use should always be avoided where possible. Time-lags on protective gear are always most undesirable, but where there is no possible alternative means of discrimination they are probably the lesser of two evils. The author emphasizes reliability, with which I associate stability. Unfortunately, that is the one feature which much of the so-called protective gear on the market does not possess. As the author clearly shows, the safe operating range which a protective relay has to cover is enormous and is perhaps not always fully appreciated by either manufacturers or users. As mentioned in the paper, the ordinary range of operation for electrical apparatus is perhaps 10 : 1, and in the case of most a.c. instruments it rarely exceeds 5 : 1. Protective apparatus may, however, have to withstand a current-range of 400 : 1, and as the resulting forces usually follow a square law the difficulties incidental to the designs of suitable relays, etc., are very pronounced. With reference to reliability, it is obvious that protective gear must be absolutely above suspicion; otherwise it is worse than useless and merely creates a sense of false security,

which is extremely dangerous. It is therefore unfortunate that much of the gear on the market is flimsy, badly constructed and frequently unreliable. That, perhaps, is not entirely the fault of the manufacturers. It arises from the fact that protective gear when it was first introduced was regarded as a somewhat novel luxury and consequently, in order to create a demand for it, the price was cut and the quality suffered accordingly. It is now realized, however, that protective gear is an absolutely essential requirement of all involved distributing and transmission systems, and consequently there is more inducement to the manufacturer to develop high-grade apparatus. Apart from the relays, the main trouble with protective gear undoubtedly arises from the limitations of the ordinary current transformers, and it is in recognition of these limitations that the air-gap current transformer has been evolved. Admittedly the air-gap type possesses certain advantages, but the outstanding feature of the author's arrangements is the use of closed-iron current transformers instead of the rather delicate air-gap type. This has been rendered possible by the author's biasing scheme. The idea of controlling certain effects by induced magnetic saturation is not novel, but full credit should be given to the author for the development of his ingenious adaptation of it. It would appear that the principal source of trouble on e.h.t. systems, apart from actual breakdowns, is likely to be the comparatively heavy transient current-rushes resulting from switching operations in connection with large transformers or cables having considerable capacity. For example, the normal balanced charging current of an ordinary 33 000-volt 3-core cable at the normal frequency of 50 cycles may be of the order of 2½ amperes per mile, but in the event of one phase becoming earthed the resulting unbalanced capacity current may be of the order of 3½ amperes per mile at normal frequency, and possibly 100 times greater under surge conditions. No doubt the author had these conditions in mind when developing his biasing transformer, and it would therefore be interesting to know to what extent he has succeeded in meeting them. My actual experience of his gear has not been sufficient to justify a definite opinion on its behaviour under the conditions arising from severe transient disturbances on a large e.h.t. three-phase system. The limitations of ring transformers have been referred to in the paper and it is advisable that they should be recognized. There is a tendency nowadays to load single-turn ring transformers with instruments and overload and protective relays, etc., and then to expect the instruments to be accurate and the protective gear to be reliable. Very few instruments are shown in the protective circuits given in the paper. It is certainly inadvisable to have both instruments and protective gear on one transformer. If separate transformers are employed for the protective gear there is undoubtedly a good case for the single-turn type, and within its limitations it is, under such conditions, very satisfactory. Probably the best and simplest arrangement for protecting a power transformer is to use a plain ring transformer having a large window, and to thread all the phase conductors and the neutral conductor through it. This method of employing the simple phase-balance system of protection overcomes the difficulty experienced with separate current transformers in each conductor owing to magnetizing current switching transients. The paper contains many diagrams which will repay careful study, but it is difficult to avoid the conclusion that some of them are unduly complicated, for, after all, as the author states, one of the essential attributes of protective gear is simplicity, and it is rather difficult to associate simplicity with some of the figures. When compounded into tanks with a few terminals on the covers, the biasing transformers do not appear to be unduly elaborate, but the complicated nature of the circuits becomes evident when checking connections or locating troubles. To me the most interesting figure in the paper is Fig. 25, showing the evolution of the feeder protective gear. It indicates very clearly how the scheme has gradually evolved from simple balanced earth-leakage protection to full fault-discriminating and biased protection. It also shows the very important characteristic feature which distinguishes this particular arrangement from other opposed-voltage systems, i.e. the purely local circuit through the biasing transformers at each end of the line. The result of this is that the current transformers are actually loaded instead of being merely voltage transformers, and consequently ordinary standard types having closed magnetic circuits may be employed. The possibilities of the author's biasing system appear to be almost illimitable, and in Fig. 22 a very ingenious compound bias is shown. First, there is the a.c. bias, and then in addition there is a d.c. bias. The arrangement is shown applied to a transformer which it protects throughout, from primary to secondary terminals. No doubt the arrangement is very effective, and it would therefore be interesting to know whether the author considers the scheme to be satisfactory for the overall protection of a generator and step-up transformer. The problem of devising a satisfactory system of overall generator and transformer protection is by no means a simple one. The screened pilot cable has been a necessity with certain types of opposed-voltage gear in order to eliminate or minimize the effect of the capacity currents in the pilot conductors on the relays. Screened pilot cables do not, however, overcome the difficulties incidental to the capacity currents in the main power cables. I should be glad if, in that respect, the author would say to what extent his biasing system will render his gear immune from the effects of heavy current-rushes due to the capacity of the main cables, and also whether the gear gives immunity from the effects of triple-harmonic currents. The comparison between a.c. and d.c. relays is very interesting. Most of the latter, of course, follow a square law and the pull increases enormously as the gap in the magnetic circuit closes. With a.c. relays, unfortunately, there is frequently more or less of a floating effect, and consequently in certain cases they are apt to be unreliable. The difference in the operating forces with the two types is very clearly shown in the paper. The resonant a.c. relay is both interesting and ingenious. I am more particularly interested in the possibilities of the device for overcoming the difficulties experienced with certain forms of protective apparatus due to transient effects.

On a somewhat similar scheme being proposed recently it was condemned for the very reason which the author recommends. The author would be well advised to limit his various protective schemes to arrangements employing current transformers only, since extended experience has shown that protective schemes which necessitate the use of potential transformers are unreliable.

Mr. H. Pearce: The separation of earth faults from line faults, referred to in the paper, is a procedure which is not supported in every quarter, but I think that there is a growing tendency to realize that earth faults must be provided with a low setting because of the limitation to the fault current by the neutral resistance. This limitation does not apply to the line faults—faults between phases—and there is therefore no reason for limiting the setting of these relays to such a low value. In the early days of protective gear many troubles occurred due to the earthing resistance not being rated at a sufficiently large current. For this reason I would urge designers of protective gear to insist upon having ample current to operate the relays. In the case of certain installations carried out some years ago difficulties occurred in this direction. The gear had been installed for some time and under such conditions that it could not possibly operate, yet this was only discovered after several breakdowns of expensive plant had actually occurred, so that the operating engineers had been under a false sense of security until the actual troubles developed. This leads me to mention the importance of testing protective gear on site. The tests should be carried out by the application of actual fault current to the primary conductors without disturbing the secondary connections. This is not merely a refinement; the secondary connections require to be tested as much as any other part of the protective gear. Manufacturers are able to produce protective gear which will meet, very largely, even the severe requirements of the large systems of the present day; but it is not sufficient to design and construct gear which will operate when first installed. To obtain satisfactory service it is necessary for the gear to be maintained to the same extent as any other part of the power equipment. Unfortunately, the tendency is to maintain all the important pieces of plant very efficiently but to ignore some of the less important items—the items which do not actually produce revenue—and protective gear in the past has definitely suffered on this account. The two main objects in installing protective gear are to limit the damage to expensive plant on the occurrence of faults and to localize the disturbance by preventing healthy circuits from being cut out when faults occur in other parts of the system. If it is worth while paying for apparatus to fulfil these functions, it is equally worth while to spend care and attention in testing and inspecting the equipment at regular intervals to ensure that it carries out the functions for which it is installed. It is only by the supply engineers co-operating with the manufacturers that we can arrive at the best results from protective gear, as with any other piece of apparatus. Furthermore, no branch of engineering can advance adequately until detailed facts are carefully scheduled, tabulated and analysed. For these and other reasons protective gear, when installed, should pass through acceptance trials in just the same way as any other piece of apparatus.

Mr. G. A. Cheetham: Many years ago I experimented with a biased relay and decided that it was not a piece of apparatus to put in a protective circuit. The author appears to have overcome the difficulty by including the biasing in the transformer. In the old days the necessity for biasing relays arose due to the difficulty of balancing transformers. I suggest that this difficulty is practically non-existent at the present time. There are many protective systems now in operation which depend purely upon balanced transformers and give excellent results. I know of a system in which generators of a large capacity are operating and feeding two substations in series through feeders protected on the balanced-voltage system, the generators themselves being protected by the ordinary Merz-Price circulating-current system. When a dead short-circuit occurred on the busbars of the second station, which was outside the protected area, the pressure on the main busbars in the generating station was reduced from 6 000 to 2 000 volts, indicating the severity of the fault. None of the protective relays tripped, indicating that, under those conditions, the balancing of the transformers was quite good. I may say that it is possible to have stability on generators, and, with a slight modification of the Merz-Price circulating-current system, it is possible to protect 92 per cent of the generator winding with an earthing resistance which on a dead fault (phase to earth) will allow full-load current to pass. With the Merz-Price system it is not possible to protect quite so much of the winding, but many generators in the country are working with the Merz-Price connections and obtaining excellent results. We have had many examples of short-circuits on the generator with the protective gear not operating under the conditions of a straight-through fault when, of course, it should not operate, which proves good transformer-balancing. The author gives some tentative figures, but he suggests that it is possible to get less than 10 per cent setting on the relay. I suggest that it is possible with the system mentioned above to get less than 10 per cent. If self-balancing is applied to the generator the operating current is, of course, a definite quantity. It is possible to obtain a setting with stability of 50 amperes, and on a high-capacity machine this represents a very large percentage of the winding protected. Generator reactance limits the short-circuit current to reasonable values, but on feeder circuits the short-circuit current varies very much according to the capacity of the feeder. In this case it is obvious that the smaller the capacity of the feeder the higher is the fault current compared with the normal capacity of the feeder, and therefore it is possible to set the relays much higher on a feeder with safety, provided the gear acts quickly, and I do not think that there should be any argument on that score. It has been proved in practice that, provided the fault is cleared quickly, very little damage is done to the apparatus which the gear protects. I wish to emphasize this point as in my opinion it is an important factor;

I have seen breakdowns in which the resulting damage was a mere pinhole. On page 568 the author instances a case where there is no current on the one feeder and a current on the other, and under those conditions the relay is operating without restraint. In the previous section he says that the relay would receive only a limited current no matter how severe the fault might be. I should be glad if the author would explain these apparently conflicting statements. Except in its application in this particular instance, has the author used in practice the method of d.c. control suggested on page 573, and, if so, for what purpose? I know it has been used on the Continent, but I have never seen any results of its operation. With reference to the relay section of the paper, it has never been our practice to use this augmented-contact system on a relay. We have preferred to use a "drop switch," and this has found increasing favour with supply engineers. It has the advantage that it definitely locates the fault. The operator has to go to the relay to reset it by hand, and he is therefore bound to know where the fault has occurred. The phantom system of auxiliary switch,

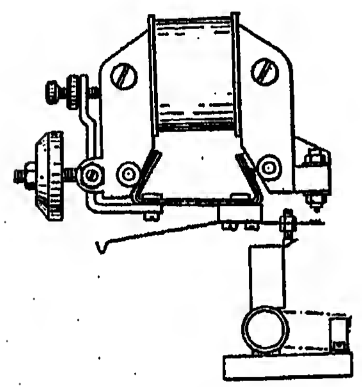

FIG. E.

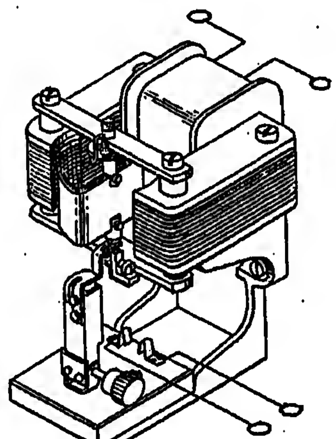

FIG. F.

which is suggested in the paper, is particularly neat, but it seems to me that it is largely a makeshift where one is forced to provide something because one cannot get auxiliary switches on the oil switch. On page 579 the author suggests a scheme for the adequate protection of a transformer, but of course he is disturbed by the transient currents which occur during switching. That is a common difficulty, which in the past has led to very high settings for protective apparatus for transformers. Some time ago a system was designed in which during switching operations a fuse was inserted across the relay winding for the purpose of temporarily raising the setting. This worked very well indeed. The author objects to air-gap transformers for feeder protection, but I am very strongly in favour of air-gap transformers with a straight-line characteristic. I have had excellent results with those transformers and I see no reason why their use should be discontinued. Of course, one is faced with the problem of increasing the sensitivity of the relay. This appears to me to be more an imaginary than a real difficulty. People seem to conclude that when a relay is made sensitive it is a very unstable piece of apparatus. Figs. E and F indicate how a relay can be made more sensitive without reducing its stability. Fig. E represents an ordinarily constructed armature relay using a conventional form of drop-switch attachment. There is an ordinary magnetic circuit excited from a single coil, and the attracted armature is balanced with a flat balance weight. There is also a mechanically latched drop-switch which descends by gravity and completes the tripping circuit. This relay, when designed some years ago, was considered to be fairly sensitive, as on 50 periods it operated with about 0·15 volt-ampere. To meet the demands of the balanced-voltage protective gear it was decided that a more sensitive type of relay should be used. The relay was, therefore, modified in the following way, as shown in Fig. F. Practically the same iron circuit was used as in the first case, except that the air-gap at the bottom was curved to allow an iron piece to swing in the centre. It was seen, of course, that in order to balance the relay in the original design and obtain the necessary setting, more weight had to be added to the pivots instead of balancing the armature itself. In the figure the armature itself is balanced, and furthermore it swings on a footstep bearing which reduces the friction considerably. The same drop-switch was used. A friction wheel was introduced and an ordinary strut was brought out from the relay shaft, which simply held the drop-switch. When the winding is excited it pulls the armature round. The results of these modifications of design reduced the necessary actuating force from 0·15 to 0·005 volt-ampere. The relay was quite stable, and has been found to give very good results on the balanced-voltage protective scheme.

Mr. O. Howarth: In regard to d.c. restraint in the case of transformer protection, such as is shown in Fig. 22, I should like to know whether there is any trouble due to the building-up period required for the direct current. Obviously, the flux does not appear absolutely instantaneously, and the period will depend upon the relative time for the flux to build up and the switch to close. Again, in the case of the phantom auxiliary switch closing the d.c. circuit in order to short-circuit the secondary of the current transformer, the switch which opens and closes that d.c. circuit is liable to have heavy duty, and possibly some trouble may occur if the switch is not good enough for an inductive circuit. In the case of feeder protection, has the author considered the incorporation of a tee off a feeder? I believe it has been done in Merz-Price protection, so that when any fault occurs the three switches come out. A statement is made on page 580 that sensitive line-fault settings are not required for feeder protection. If the protection is carried over feeder and transformer, as is done in many cases, then sensitive line-fault settings are required. Of course, the makers prefer to install the extra apparatus and put separate protective gear on the transformer and the feeder, but if overall protection can be installed it involves less apparatus and less expense. That is more important to supply authorities than to manufacturers. In Fig. 27 one end of the feeder protective cable is shown, the operating winding for the earth leakage being taken from the centre of the overload restraining winding on the earth-leakage transformer. Does the author find it necessary, when he adopts the construction shown in

Fig. 1 (*c*), to use two separate restraining windings connected in series; and does he take the tapping from the connection from one to the other? The reason for my question is that if the tapping is taken from the connection from one limb to the other, then that restraining winding will operate under some circumstances as an operating winding. I notice that in Fig. 41 the author short-circuits the transformers on the feeder which is put out of action by means of a switch which short-circuits the two outer current transformers. Is that quite satisfactory? Is the impedance of the circuits to the mid-point, as picked out in the biasing transformers, low enough to allow of that being safely done? In referring to Fig. 44 the author says that the potential transformer has only half the load on it compared with the arrangement shown in Fig. 43. I should have thought that it would have been rather more than half the load because it has two relays to supply, although it does not supply two potential biasing transformers. If it does bring the load down to half, it suggests that the biasing transformers put a rather large load on the potential transformer as compared with the relays. The author makes a point of the simplicity of the external wiring, but I am not sure that much is gained by boxing-in the complications, as a mistake is very troublesome to locate. One of the principal reasons for the installation of protective gear is to prevent failure of the supply. Most modern transformers and generators are built to withstand short-circuits. Makers of protective gear do not, I think, always sufficiently realize that the essential thing is to clear the fault quickly before the rest of the system has been shut down, as will be the case if the voltage at the busbars falls to a low value and remains low for more than a second. Mr. Pearce referred to the testing of protective gear after it has been installed and the last secondary connection has been put on. The idea seems attractive, but one does not like to put artificial faults on a big high-tension system, because they are liable to be as destructive as the real ones. It does seem to me that if protective apparatus is thoroughly tested out we ought to be able to rely on its correct installation and its accurate operation without running risks with our supply systems. In conclusion, the paper describes what is an undoubted step forward towards 100 per cent perfection.

Mr. S. Ferguson: The figures in the paper exclude the connections between the relays, tripping supply and oil-switch trip coils. These connections are well understood, but I wish to indicate how increased reliability may be obtained by the elimination of the relays and these various auxiliaries. Relays and separate tripping supplies are looked upon as necessary evils; they introduce complications in the wiring on the control board and also many weak links in the chain of connections, the breaking of any one of which will render the protective gear inoperative. Fig. G shows the scheme of connections including relay and auxiliaries, whilst Fig. H indicates a scheme of connections possible with a super-sensitive tripping device, which is now available. In Fig. G the first source of weakness is the tripping battery or independent supply. In the majority of substations, primary batteries have to be relied upon and are very expensive to maintain, requiring constant attention. In generating stations a source of supply which is in some way or other dependent on the main busbar voltage is frequently relied upon. This is unsatisfactory, because when a severe fault comes on the system the pressure is likely to drop and there is not the requisite potential to trip the breaker. The second source of weakness is the fuses, which are necessary if the supply is any other

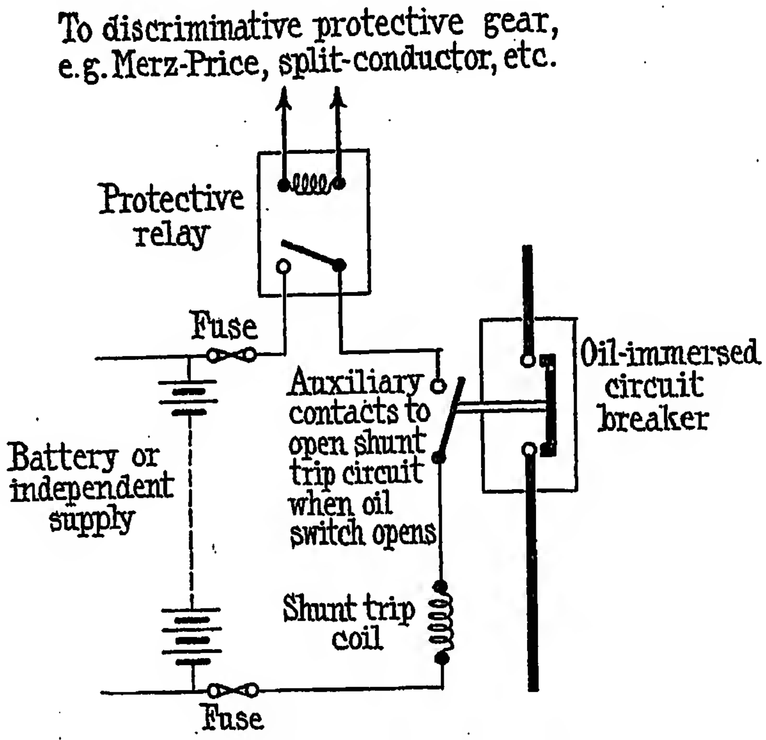

FIG. G.—Connections with relay.

than a primary battery. It is well known that these small fuses do not receive the attention which their connection in such an important circuit merits. The next source of weakness is the auxiliary contacts on the breaker and relay. These are usually very light in construction and can easily fail to make proper contact. This is especially so if a low-voltage supply is used for tripping, as a little dirt between the contacts will break the tripping circuit. The next source of weakness

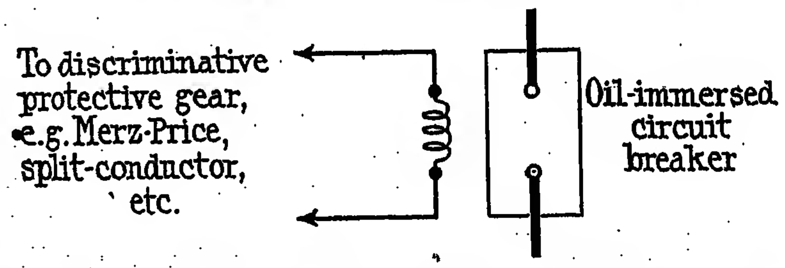

FIG. H.—Connections without relay but with supersensitive tripping device.

is the shunt trip coil. This is usually designed to withstand the pressure of the tripping supply only momentarily. If for any reason it is maintained for too long a period it will burn out and break the tripping circuit. It will be seen from the above that there are five weak links in the chain of connections, any of which might fail and render the protective gear inoperative. I am convinced that fully 50 per cent of the failures of protective gear are due to one or other of these weak links in the tripping circuit. The simplified scheme shown in Fig. H is accomplished by employing a super-

sensitive trip coil, which is as sensitive as any of the ordinary standard relays. This trip coil takes the place of the relay and is operated by the fault current direct. The basic principle of the design is that when the breaker is being closed, either by hand or electrically, sufficient mechanical energy is stored to trip out the breaker when required. All that the fault current has to do is to release this stored energy. It is found that a current of 25 amperes through a ring-type current transformer is sufficient for this purpose. Very few systems adopt lower fault-settings than 25 amperes. It should be noted that the work to be done by the fault current is a constant quantity and not variable with the size of breaker, as it has merely to release a definite amount of stored energy and this is made sufficient for tripping any size of breaker. I believe that in the future the tendency will be to eliminate the complications indicated in the schemes employing relays and adopt the simple tripping arrangement, as it is merely a mechanical problem which has now been satisfactorily solved. It is quite possible to construct the device so that it is perfectly stable even when subjected to considerable vibration. I am pleased to note that biasing can now be embodied in the transformers and not in the relays, as it renders possible the use of the above-mentioned simple tripping device. I feel, however, that biasing is only justifiable, if at all, on a few of the very large systems. It would certainly not be advisable to apply it to the numerous cases which the author has cited.

Mr. T. W. Ross: It is not so many years ago since protective gear was looked upon by nearly all engineers as a nuisance. I think that nowadays, however, their views have changed, and anything which can improve the design of protective gear is always acceptable both to the manufacturer and to the operating engineer. I am surprised that the author experiences no trouble with the internal balance of the biasing transformers. When balancing current transformers my experience has been that if any joints are introduced into the laminated iron circuit, or if the windings are not symmetrically placed round the core, internal balancing troubles always ensue. The author says that, owing to the small size of the transformer, internal balancing troubles are eliminated, and I should be glad of some information on this point. If biasing is necessary for the protection of generators—and I do not admit that it is necessary—it seems to me that the introduction of such a transformer for this purpose, unless it is very carefully built, may be a source of more trouble than that which it is supposed to remedy. Designers of machines are always asking for more sensitive protective gear to protect the windings much closer to the neutral point, but my experience has been that protective gear with a setting which will protect 85 per cent of the winding is quite satisfactory. If that is so then there is no need for biasing, because stability is assured with a suitably designed relay and a balanced secondary circuit. On page 585 there is a series of diagrams showing the evolution of the application of the principle of earth faults and line faults to the protection of feeders. Of course the final result is really a core-balance protection with the addition of line-fault or short-circuit protection. My experience of core-balance protection is that three similar carefully-built current transformers—and by that I mean that each transformer has the same amount of iron in it—will balance correctly, provided no great impedance is added to the circulating-current portion of the circuit. In order to get short-circuit protection the author introduces an impedance into the circulating-current portion of the circuit. He admits that it is necessary to balance the current transformers, but this impedance will upset the balance. I realize that there is a similar impedance at the other end of the feeder which should counteract any such out-of-balance, but I am inclined to think that the unbalanced currents may be out of phase with each other and may give rise to trouble at comparatively small overloads. The author will, of course, answer that the biasing transformer will overcome this, but if the gear becomes unbalanced at comparatively small overloads the biasing will not have any great effect. The suggestion of using a biasing transformer as a means of providing directional protection is very ingenious. I have not studied the diagrams very closely but I should say that the scheme has decided limitations. It seems to me that if directional features are going to be used, a dynamometer or induction relay will be essential. I regret that no mention has been made of the induction relay which has found very great favour in the United States and has also had considerable success in this country. Such relays can be designed to operate successfully at very low voltages, say 3 per cent of normal, at 5 to 10 per cent of normal power. If a current element is added it is possible to have a relay very nearly approaching a directional current relay. With such an instrument protection can be provided for parallel feeders, ring mains, or any other combination of network with a discrimination which, if not so perfect as that in the case of the differential system, is much better than that given by plain overload and leakage protection. The author mentions that his directional relay could be arranged to trip out on very heavy loads with forward power. That, I consider, is a disadvantage, as all discriminating properties are immediately lost. I believe that Col. Edgcumbe tried that feature some years ago in his relay, but he abandoned it as it gave trouble on power networks. On page 585 the author suggests that a biasing transformer could be inserted in the secondary circuit of the ordinary split-conductor transformer. As the output of such a transformer is usually limited it would be difficult to obtain sufficient current to energize a relay from a biasing transformer, and apparently the author prefers the scheme shown on pages 586 and 587. In this arrangement there are two biasing cores in addition to the split-conductor core. To my mind this is a disadvantage, as two other transformers which, of necessity, must be balanced are added to the split-conductor transformer in which no balancing is necessary. The author admits that it is more difficult to balance two magnetic circuits than one magnetic circuit, but in this scheme he resorts to the former practice to overcome something which, as my experience shows, does not exist. With a simple split-conductor system having settings of 50 to 70 amperes the stability is perfectly good, and I know that

such systems are quite reliable in practice. I should be glad if the author would indicate what fault settings he recommends for the different systems which he describes.

Mr. F. Clegg (*communicated*): Referring to Fig. 11, it is unfortunate that it is necessary to connect such a weak link as a potential transformer to the busbars of the station, which presumably are not protected. The author himself confirms this on page 594. I think that everyone will agree with the author's remarks on page 574; in fact it is better to have only protective transformers on the main lines of the system and to avoid meter transformers. I am also in agreement with the author that, particularly for large power systems, the only type of transformer which it is safe to use is the straight-through ring type. On page 580 the author refers to troubles which are due to stray-field effects. I should like to ask him whether he has experienced trouble due to induced currents in the pilot wires when neighbouring conductors are passing large transient fault currents, as he makes a point of employing sensitive settings. This trouble has, I believe, been experienced on systems where the plant capacity has been increased and it has been found necessary to raise the fault settings. On page 598 the author refers to an important point regarding the protection of generators. I think it should be recognized that the minimum setting of the relay on the largest generator generally determines the limiting value of the fault current to earth. In other words it determines the current-carrying capacity of the neutral earthing circuits, i.e. when the system is equipped with discriminative protective gear. I should like to ask the author to what extent results have been affected when the circuit breakers have been provided with buffer resistances designed to prevent current-rushes when switching in. I am, of course, aware that this is no remedy for sudden changes of voltage when the transformers are in commission, as the buffer resistances are short-circuited when the oil switches are closed, but this would also appear to apply to the use of hand switches and other devices for introducing a time-lag at the instant of switching-in the transformer and the subsequent automatic removal of this time-lag. In connection with Fig. 34, the author advocates biasing windings on split-conductor transformers. I should like to ask him whether any actual test has been carried out by passing heavy currents through the transformer, and whether he found the arrangement suitable. On page 577, referring to Fig. 20, which shows the application of phantom auxiliary switches, the idea of changing the impedance of a coil in the ratio of about 1 : 250 is undoubtedly very ingenious and should enable a number of auxiliary switches to be eliminated. It also ensures simultaneous operation in the case of three-phase switches. It should, however, be remembered that there is still in the d.c. control winding one auxiliary switch, the failure of which would nullify all that has been gained. In conclusion, I should also like to ask the author what will happen when the d.c. supply fails. Apparently the set of parallel feeders will be brought out.

[The author's reply to this discussion will be found on page 619.]

Scottish Centre, at Edinburgh, 11 March, 1924.

Mr. C. W. Marshall: In my opinion, the biasing current transformer is the most promising invention for the improvement of standard balanced protective systems that has yet been made public. I think, however, that it is imperative that independent tests of the stability and sensitiveness of these, and of all other protective systems, should be made. The author makes so light of the question of balance that it would appear to be possible to use almost any kind of current transformer for Merz-Price work, provided that the system was supplemented by a balancing transformer. It is obvious that the best results could be obtained by using the balancing transformer to the smallest possible extent. Several speakers in the discussion have stated their objections to protective gear in any shape or form, but anyone who has had extensive operation experience on a large system must realize that continuity of supply cannot possibly be maintained on an interconnected system without discriminative protection. Until such times as we can obtain plant, switches and cables immune from faults, protective gear is a necessity, and it really lies with the manufacturers to get rid of the very bad reputation which they have gained by selling protective apparatus that is not suitable for the conditions under which it operates. So far as I have observed, none of the large manufacturers has adequate plant for testing protective gear under short-circuit conditions. The author states that protective gear must be stable up to 200 times full load, but in the special case of the delta-star transformer, standard Merz-Price circulating-current gear supplied for its protection is unstable at less than 10 times full load. The experience with protective gear on the system of the Glasgow Corporation Electricity Department has established the following facts:—

(1) *Alternator protection.*—Complete stability can be obtained with relays set to operate at 30 per cent of full-load current.

(2) *Combined alternators and step-up transformers.*—Merz-Price circulating-current gear cannot be safely set below 50 per cent of full-load current, and the relays must be used in conjunction with parallel fuses if immunity from tripping, due to straight-through currents, is to be obtained.

(3) *Merz-Price balanced-voltage systems.*—The minimum permissible fault setting on feeders protected in this way is 100 per cent.

(4) *Split-conductor protection.*—It was found that the first setting adopted, viz. 15 per cent of full load, was too sensitive. Several faults were cleared with success before they had developed between phases; in such cases the

> discriminative action of the protective gear is perfect. Even with this setting, however, faults occasionally seem to start between phases, and considerable trouble was caused on account of the opening of split-conductor cables due to straight-through currents. It has therefore been necessary to set up the split-conductor protection to 50 per cent of full load.

The conditions prevailing in Glasgow are such that the maximum possible current on the 20 000-volt system is approximately 20 000 amperes, and on the 6 600-volt system 60 000 amperes (R.M.S. values). On the Glasgow system there are 15 alternators, all protected on the Merz-Price circulating-current system; 78 split-conductor feeders; 78 feeders protected on the Merz-Price system; and 252 transformers. All these cables and machines are concentrated in such a small area that a fault on any one piece of apparatus inevitably affects all the others, and it is absolutely imperative that any fault should be cleared with the minimum delay. In the past 6 years the protective relays have been called on to clear an average of 6 faults per annum, and, except for a few instances of defective stability, the action of the gear has been fairly satisfactory. The Glasgow Corporation has no cause to regret the installation of protective gear, in spite of its weaknesses, but every step towards complete stability without undue loss of sensitiveness will be very welcome.

Mr. D. Martin: The author states in the summary to the paper that biased systems have established themselves and are accepted as being superior to any other, but "any other" includes the Merz-Price and split-conductor systems. The author is obviously a follower of Mr. Wedmore, and mentions his name nine times to the exclusion of others, but does not that prejudice his case somewhat? His scheme throughout seems to be that of adding an additional transformer winding to all the previous well-known systems for the purpose of obtaining an electrical bias. That appears to sum up what may be termed all the original matter in his contribution. In so many words it is an alternative to biasing by relays, such as is done in the McColl system. Fundamentally, therefore, it is not a departure from the already tried systems, but rather the addition of a complication to them. Is that desirable? I have no experience of the new biased transformer arrrangement, but my experience of the Merz-Price, split-conductor and other systems is such as to lead me to hope that development might be along lines which would retain the simplicity of those older and well-tried systems. It is remarkable to note that these older systems have withstood and still survive the onslaught of numerous attacks and improvements to the original patents. Indeed it is difficult to foresee at present on what lines improvement can take place without utilizing the well-known characteristic of the Merz-Price invention fundamental to all protective systems. That leads me to suggest the ideal upon which development should take place: (1) The elimination or a reduction of the number of pilot wires; (2) the elimination of all unnecessary parts and connections, i.e. simplicity; (3) to be as equally sensitive to faults to earth as to faults between phases; (4) stability against heavy straight-through overloads; (5) stability under all working conditions, such as switching on to static transformers using heavy magnetizing currents; (6) interchangeability of the protective transformers; (7) relays to be simple and robust. The split-conductor system eliminated pilot wires, but there was a little difficulty in balancing short lengths of feeders, which affected the stability under heavy straight-through overloads, otherwise it is the ideal for long feeders and satisfies all the above conditions, and is much preferable to parallel feeders under working conditions. If extremely sensitive setting is desired (and that is still a matter of opinion) then the following simple arrangement is available. Mr. Biles of Messrs. Reyrolle has brought out a diverter relay system in which only two pilot wires are necessary (see Fig. A on page 601). This diverter relay does not interfere with the fault setting of the relay until the straight-through current reaches a dangerous limit, at which the diverter relay operates, bringing into circuit an operating relay which latter remains insensitive to heavy straight-through currents but still remains sensitive to fault currents. This system, while it involves the use of an additional relay, is thus simpler and more reliable or stable than any biased type can ever hope to be. Then there is the Fawssett-Parry relay of the sensitive dynamometer type with inertia to avoid inadvertent operation on impulses.

Mr. E. Seddon: We in Edinburgh have decided to adopt this system of protection for the main trunk feeders between Portobello station and the principal substations on the system. We waited some considerable time before adopting any leakage protective gear on these cables, and after looking into a number of other forms of parallel-feeder protective gear we came to the conclusion that the method advocated by the author was the best pilotless system developed up to the present time. To my mind the biasing principle is the basis of all good protective gear. Whether the bias is in the beam relay as in the McColl system, or in the biased transformer, the result appears to be the same, except that with the biased transformer a simple form of relay can be used. Before deciding to adopt this system, a temporary set of transformers and relays was connected to protect the cables between Portobello and Cowgate substation. Definite faults to earth and between phases were made on the e.h.t. side. These tests proved that the gear was in every way satisfactory, and orders were placed for the protection of three sets of three parallel feeders and two sets of two parallel feeders. All the apparatus is now installed, and we shall shortly make further tests on all this gear by introducing definite faults. The fact that the author's biasing transformer is buried in compound will be appreciated by engineers, as it will thus withstand considerable abuse.

Dr. S. Parker Smith: I do not regard protective gear with favour, and I think that it is a pity that it has to be used, but just at the present time it seems to be an unfortunate necessity. In what way is protection to be afforded when a turbo-alternator loses its exciting current, i.e. when the exciter fails? It seems to me that this is a time when protection is necessary, although

as a machine designer I should like to think that my machine would be perfectly safe even under these conditions.

Mr. H. Trencham: The time spent on the work covered by this paper has been about four years and a careful survey has been made of protection in general, with the object of getting down to fundamentals and evolving something in the way of standardization of protective gear so as to eliminate much of the uncertainty which exists at the present day in regard to the functioning of the apparatus. I should like to say a word in regard to protective gear in general. From time to time one or two criticisms have been levelled against us merely because of the fact that we have dealt with other systems as well as with the Merz-Price or circulating-current systems which may be regarded as peculiar to this country—but it should be remembered that in other countries there are electrical power schemes of quite considerable size in which Merz-Price gear has never been heard of, and one has also to bear in mind that very frequently the idea of protection never enters the heads of the engineers handling a job until they are in trouble and until they have got the system into such a state that it is impossible to apply ideal protective gear conditions, and it becomes necessary to do, not what one would, but what one can, and hence we feel that in dealing with the subject at all we must deal with it as particularly as possible and apply our methods to every scheme of protection which has shown intrinsic merit.

Mr. F. E. Meade: The object of all protective devices is to ensure continuity of supply. Different parts of a system such as the generators, feeders, distributors and service mains require different methods of protection because the conditions under which they should be switched out of circuit are not the same in each case. Only consumers' service mains call for automatic devices actuated simply by overload conditions. Overload protection in interconnected systems, and particularly in generator circuits, is simply conducive to total shut-down, and the design of apparatus should be such that it is proof against damage from overload. The criterion of a fault in a generator working in parallel with others is that the machine is no longer supplying power to the busbars. Generator trouble may be due to the failure of the steam supply, a breakdown between the terminals of one phase, breakdown between phases, and failure of the exciting current. The first two faults involve a reversal of power, but neither the current-balancing nor the split-conductor system gives protection unless a fault on one of the phases develops into a breakdown between phases. Failure of the excitation on one machine does not result in a reversal of power unless this machine drops out of step, and the gear described in the paper would not operate until this takes place. Has any adequate system of guarding against this contingency been evolved or been found necessary? The author's application of the biasing transformer should add greatly to the effectiveness of the current-balancing system for generators and transformers where low values of fault settings are desirable. It may be pointed out that with the ordinary arrangement of balanced transformers where the natural circulating current flows in the secondaries, contrary to the statement on page 565, ordinary current transformers may be used and measuring instruments included in the secondary circuit. The greatest care must of course be taken that the points across which the relay is connected are suitably chosen (see Fig. 3). It is in connection with the opposed-voltage protective system for feeders that the advantages of the addition of the biasing transformer are most clearly seen. Hitherto the trouble due to saturation in the transformer cores and consequent difference in the induced voltages has been avoided at the expense of decreased sensitivity. On the occurrence of a short-circuit on other parts of the system, perfectly healthy feeder sections may be called upon to carry enormous currents for a short time. Even if the transformers are perfectly balanced, the large E.M.F. induced gives rise to capacity currents in the pilot wires. Unless the fault setting of the relay is made high, these may cause it to operate and disconnect the sound feeder. The use of the biasing transformer avoids the additional cost of compensated pilot cable, and accurate balancing of the air-core transformers is unnecessary in order to secure immunity from incorrect tripping under these severe conditions. The author's statement that the balanced-voltage protection will be used in the future more extensively than the split-conductor system which on some power schemes is superseding the former, will probably be challenged. The elimination of pilot wires is of such importance that the difficulty of obtaining equal impedance in the two halves of the split conductor when joints are made is relatively a minor one. To obtain sensitivity the split must be carried through the switch. Can the author say if any development of his system is likely to result in the split switch being unnecessary?

[The author's reply to this discussion will be found on page 619.]

South Midland Centre, at Birmingham, 30 April, 1924.

Mr. F. Forrest: The simplicity and reliability of the circulating-current protective system as applied to alternating-current generators has been amply demonstrated over a number of years, and many of us thought that we had reached something like finality in this matter. I am not satisfied that the application of biasing transformers to circulating-current protective circuits is justified. It undoubtedly adds to the complication and introduces a number of additional circuits and connections, the failure of any one of which would lead to trouble. It is of the utmost importance that all relays and protective apparatus in connection with a.c. generators and feeders should be regularly and systematically tested for correct operation, and especially is this the case where the relays operate with almost minute forces. The arrangement shown in Fig. 22 seems very complicated and would be rendered unnecessary if all transformers were switched in through a charging

resistance capable of passing, say, 10 per cent more than the magnetizing current. These charging resistances are coming more and more into use, and serve the double purpose of reducing the current-rush at the moment of switching in and the building-up of potential between the end turns, which is such a fruitful cause of breakdown. The satisfactory protection of parallel a.c. feeders is still one of our biggest problems, and it is questionable whether in many instances it is wise to couple such feeders in parallel at the substation end. If the substation busbars can be sectionalized and the load adjusted, as it usually can be, to suit the capacity of the feeders, there is very little to be gained by connecting the feeders in parallel, whilst the arrangement of running isolated feeders has much to commend it, especially on a big system.

Mr. W. Wilson: There is much in the paper with which we should all agree. In the first place, few people now question the value of protection for alternating-current circuits and apparatus. The restriction of the damage to a trivial amount consequent upon a breakdown of the installation, and the localization of the trouble to the particular section in which it originated, are such valuable results that the comparatively small outlay entailed by the installation of protective gear becomes an extremely cheap form of insurance. I was recently able to inspect a portion of a feeder which had sustained a short-circuit. Thanks to the balanced protective gear the damage was restricted to a small metallic bead not much larger than a pin's head, requiring in the present instance only a very small amount of attention to repair it. This should be compared with the extensive damage that is usually sustained by unprotected lines or apparatus when a breakdown occurs. For example, a turbo-alternator of, say, 6 000 kVA, or above, can be, and usually is, completely burnt out in a space of about 10 seconds following the development of a fault in the stator windings. The author's case in favour of biased protection is also a strong one. The protective gear must be designed to give satisfactory operation under the extreme conditions that are likely to occur in practice, and these are represented by the occurrence of a dead short-circuit beyond the current transformers, permitting the passage of something in the vicinity of 20 times the normal full-load value of the current. In this event any slight error of balance that exists or can develop on overload in the current transformers is multiplied by the same factor of 20; and if the relay is set to trip at a comparatively small percentage of the normal full-load value, and is not rendered less sensitive at higher loadings by the application of a bias, the magnified error is sufficient to trip it at a time when there is no fault in the circuit to be protected.* For this reason unbiased systems require very high settings to prevent them from operating incorrectly upon overloads, but are thereby rendered very insensitive under ordinary conditions. The "resonant" relay shown in Fig. 17 with a capacity method for increasing the power factor of the winding is, in particular, an interesting proposal for overcoming a difficult problem. There are, however, a number of respects in which I cannot help differing from the opinions which have been expressed. On page 562 it is stated that "difficulty is met with in designing biased relays in forms sufficiently sensitive to be operated by the limited energy available, on account of the considerable force which they must withstand without operating." This is an unfavourable criticism of existing biased relays that in my experience is far from being justified. If it be supposed that the "limited energy" is derived from the smallest current transformer used in practice, viz. the 40 VA pattern, as employed for switchboard ammeters, etc., and that the robust beam relay of the McColl pattern with plungers $\frac{3}{4}$ in. or even 1 in. square be used, then the scheme possesses the following characteristics: The relay is more than strong enough to resist any possible force that can be imposed upon it in practice, the energy supplied by the transformer is amply sufficient to operate it, and the protection given is of a high degree of sensitiveness. To quote a specific instance of the last feature, a dead-ended feeder when protected by an unbiased system on the usual opposed-voltage principle may in practice require a leak to operate it equal to 250 per cent of the normal full-load current. Using the biased system just specified, reliable operation will be given for faults equal to only 5 per cent of the normal full-load current, and the limit has not yet been reached in the downward direction. These particulars will, I think, compare very favourably with the similar particulars given in the paper. I have mentioned the McColl system, first because so far as I know it is the only one in use, apart from Mr. Wedmore's parallel-feeder scheme, which employs a biased relay, and secondly because several figures in the paper are simply the McColl figures with the biased transformer inserted in place of the relay. For example, Fig. 2 is equivalent to Fig. 16 in Mr. McColl's paper,* with the two windings in the current-transformer circuit removed from the relay and placed upon a transformer which has a secondary winding actuating a separate relay. In connection with this similarity a further point should be mentioned. The author has rightly enforced the necessity for the utmost simplicity and robustness in connection with the design of protective gear. Yet comparing these two diagrams it is seen that, first, the author has added to the simpler one a complication in the shape of the biasing transformer, and secondly, he still uses a delicate form of relay. The design of the latter is shown in Figs. 15 and 16, and I consider that it is too finely proportioned and moves through too small a distance to be classed as a robust article. With regard to the addition of the biasing transformer, Fig. 11 shows two of these added to a single scheme, while Fig. 13 actually shows three additional transformers, which would presumably make five transformers in all, counting the one at either end of the apparatus to be protected. Surely the author cannot maintain that these additions bear out his ideal of simplicity. He has evidently great faith in the reliability of transformers; it should nevertheless be remembered that these involve the addition not only of numerous windings but also of separate leads and joints, and all of these constitute additional members of the installation which introduce further possibilities of failure. It has been my experience that the current transformers of a protective system

* "Automatic Protective Devices for Alternating-Current Systems," *Journal I.E.E.*, 1920, vol. 58, p. 525.

are the most likely portions to give trouble, the number of cases in which I have found the connections of units made by different firms to be wrongly marked being quite out of proportion to defects in the rest of the apparatus. The author proposes on page 577 to employ a transformer to do the work of an auxiliary switch. He further suggests on page 579 that an auxiliary d.c. switch and a transformer should be employed instead of the three a.c. auxiliary switch contacts in order to render the apparatus less sensitive to the initial rushes of current that are experienced when switching a power transformer into circuit. Now the difficulty attending the solution of this problem is to prolong the short-circuiting of the protective gear for the few periods after the transformer is switched in during which a high transient current lasts. The movement of the oil switch from the closing of the arc-tips to the final position of the contact is in the vicinity of 3 in., and allowing ¼ in. break for the auxiliary switches, and a closing speed of 5 ft. per second for the main contacts, the time taken by the switch to travel this short distance is at most 0·04 second, which represents only one period for a 25-period current. Thus, it is practically impossible to avoid by a simple switching arrangement the effects of this transient switching current, as a short-circuit of only about one-period duration is not sufficient to exclude it from the protective gear. It is necessary with the ordinary a.c. pattern of auxiliary switch to employ some species of time-lag to keep the protective gear out of action a few periods longer. It would not appear that this difficulty is solved by the d.c. switch and transformer arrangement proposed by the author. Dealing with the reliability of auxiliary switches, it is my opinion that these are at least as reliable as the main switches. Consequently I am in favour of using them in preference to transformers. I do not quite follow the author's arguments in favour of a statical method for obtaining the bias. The great aim in designing protective gear, as with other forms of electrical equipment, is to obviate moving parts as far as possible, since they are always points of weakness. Now it is impossible to do without a moving element altogether, since a relay is an essential part of the scheme. If, then, the number of moving parts is restricted to one, and the number of leads, contacts and statical portions generally is reduced to the smallest limits, the maximum of reliability will be obtained, quite irrespective of the functions of the different parts of the apparatus. For example, a relay is no more unreliable because its fulcrum has been moved a slight distance from the central position, thereby endowing it with a bias. I can appreciate the author's wish to employ a single form of relay for every species of protection, but this is by no means confined to the system that he has described. The McColl systems employ exactly the same pattern of beam relay for feeder, generator, transformer and parallel-feeder protection, the windings and the position of the fulcrum only being modified to suit the particular cases. A further scheme with special characteristics, in which an induction directional relay is used, is provided as an alternative for generator protection, and the same type of relay is preferable for the distant end of parallel feeders since it gives somewhat more complete protection than the beam pattern. In connection with the operation curves shown on page 565, it would seem that the most sensitive operation is given at no load. There is a wattless current passing into the apparatus and not passing out of it at this value; it thus functions as a leak and would trip the relay if the latter operated at less than about 5 per cent of normal full load at this point. With the beam relay it is possible to raise this end of the characteristic curve by the adjustment of the counterweight, without increasing proportionally the settings at other points, an advantage that would appear to be wanting with other forms of relay. The author's scheme shown in Fig. 32 for split-conductor protection seems to me to be immune from the criticisms I have made as to complexity, since it possesses one transformer only which is connected by a single circuit to the relay. This system appears to be excellent, and I was somewhat disappointed to find that the author preferred the scheme shown in Fig. 34. I should be glad to know the reason for this preference.

Mr. A. E. Angold: The scheme for using the B/H characteristic of iron as a "valve," which has been so ingeniously embodied in the biasing transformer described by the author, deserves a fuller description. A somewhat similar application, viz. to magnetic shunts for exciter dynamos, was described by Stoney and Law in a paper* read before the Institution in 1908, and one would have expected the principle to be used for a variety of purposes, but probably the losses in the iron due to high densities and a.c. excitation are against it. In this instance the author may be paying too dearly for his static bias. How much larger does he need to make his current transformer in order to provide the extra magnetizing current, or to what degree has he been obliged to reduce the power in his relays as an alternative? The advantages of his scheme are: (1) A static bias instead of a mechanical bias, and (2) one coil on the relay instead of two. The disadvantages are: (1) An extra transformer, and (2) larger current transformers or, alternatively, a weaker relay. The author suggests the use of relays taking "a few volt-amperes" and speaks of a relay operated with 0·5 volt-ampere—presumably that is the amount required to overcome the controlling force. Such relays must necessarily be flimsy instruments and therefore will offset any advantages gained from the employment of static bias. With single-element relays taking 0·5 volt-ampere at 50 periods, the total work done would be about 0·02 ounce-inch, that is to say, an armature moving 0·1 inch would have an initial pull of 0·2 oz. with 0·5 volt-ampere. Disc motor relays of the shaded-pole type would do about the same amount of work with a 45° movement of the disc. This is all used for balancing the mechanical controlling force and, if the relays are to make contact with not more than 10 per cent increase, the energy available for contact pressure would be only one-fifth of these figures for the disc relay, and one-third to one-half for a magnet relay, assuming the armature of the latter to be practically touching the poles at the conclusion of the operation. The author states that it is usual to employ more or less complicated means of augmenting the contact pressure, and the above

* *Journal I.E.E.*, 1908, vol. 41, p. 286.

figures show how necessary it is to do so. It would appear that the more practical way is to put in larger, stronger and more efficient relays, providing this can be done without making the current transformers too large.

Dr. C. C. Garrard: In discussing the paper I should like first to put in a plea for simplicity. Protective gear is rather complicated, but it must be remembered that as it has to be operated by switchboard attendants who are generally not highly technical, the success of the gear depends upon its being easily comprehended by these men. There is no doubt that the principle of the bias applied to protective gear is correct. The older systems of balanced protective gear did not have this bias principle, consequently their action left much to be desired. It must be remembered that these unbiased protective systems are no longer installed, except in those cases where the purchaser is not familiar with the advantages obtainable with the biased systems. The author has compared his system, in a number of instances, with old-fashioned unbiased gear, but it would have been better if the comparison had been made with more up-to-date systems. The bias may be given to the protective gear in various manners, mechanically, electrically or magnetically. The author introduces a special biasing transformer to secure this end; this is a very ingenious method and will doubtless give excellent results, but I strongly disagree with him in his statement that the resulting system scores on the grounds of simplicity. In any case it is an additional piece of apparatus. If we consider the biasing transformer shown in Fig. 22, for example, so far as I can see this has some 30 terminals, and to secure a correct action they must be connected up in a definite order. The number of possible permutations and combinations which can be obtained with 30 terminals is very large, and I contend that Fig. 22 is very much more complicated than the system in which the bias is obtained mechanically in the relay. The author also raised the point that a static apparatus, such as the biasing transformer, is not as liable to alter in its calibration as is, for example, a relay. I do not quite see the point of this argument, as in any case the author's system embodies a relay with its inherent possible faults. Moreover, a transformer, especially if it has an air-gap, has been shown by experience to be liable to alteration in calibration, due to short-circuits. Further, the author lays stress on the fact that he employs only one kind of relay, and claims great uniformity. It would appear, however, that his system requires various types of biasing transformers for the various schemes of protection. From this point of view, therefore, it seems to me that there is not much in the author's contention. Further, as regards generator protection, it is very often deemed essential to protect generators not only against faults to the frame but against reversals, or, what is very much more important, against incipient faults due to short-circuited turns before these have time to burn through the slot insulation and cause a fault to the frame. A special relay which will give this additional protection is, under these circumstances, justified.

Mr. A. S. FitzGerald (*in reply*): The author's thanks are due to the various contributors to the discussion, and particularly to the supply engineers whose experience of the operation of protective gear forms a useful addition to the available information on the subject.

General.—Having regard to the remarks of several speakers it would seem desirable to emphasize the object of the paper, which is, however, exactly that indicated by the title. It is intended to deal with the design of apparatus for all the differential protective systems which have been used in this country, to a sufficient extent to justify their notice in a paper of this form, rather than to discuss at length their relative advantages and disadvantages. It should be no argument against the particular method of designing balanced-power gear described in the paper that this system of protection is not so good as, for instance, a pilot-wire system. Whilst it is realized that no engineer would install balanced-power equipment if it were possible for him to use a pilot-wire system, there are, without doubt, occasions when circumstances justify or (as mentioned by Mr. Trencham) necessitate the installation of the less perfect equipment. Thus the fact that such systems have been installed in a number of cases leads to their being dealt with in the paper. In the same way, the remarks of some speakers in respect of fault settings, although interesting and an undoubted addition to the discussion, do not seem to be relevant criticisms of the methods advocated in the paper. If there were no demand for sensitive fault settings, the design of protective gear would unquestionably be greatly simplified. The principal object of the paper is to show how apparatus can be built which will give low fault settings and be at the same time perfectly stable. It is realized that the apparatus is not necessarily applicable if heavy fault settings are not objected to.

Captain Donaldson has referred to the considerations governing the selection of protective gear and has pointed out that it is not always justifiable to legislate at considerable expense for conditions which seldom arise. The provision of protective gear is a form of insurance and the amount of money expended depends entirely on the justifiable risk. Sometimes it is necessary to cover every possible chance and to put in comprehensive and extensive protective gear. In other instances it is not necessary to do so; yet where equipments of the latter category are installed, it is often remarked that the apparatus is unsound because it only covers the definite conditions envisaged and not every conceivable and less probable class of fault.

By far the most striking feature of the discussion has been the conflict of opinion on general principles of design between the users of protective gear on the one hand and manufacturers on the other. Many of the former complain bitterly of the unsatisfactory performance of protective gear and adopt the general attitude that protective gear is a necessary evil and that the less of it they are compelled to install, the better for all concerned. In contrast to this attitude, the principal comment of manufacturers is that modern

protective gear is so nearly perfect that the author's efforts towards improvement are unnecessary and superfluous. The individual, therefore, must judge for himself as to which of the above standpoints most nearly represents the true facts of the case.

The apparent complication of some of the biasing transformer circuits has been mentioned. In many systems of protection the operating conditions and the problems met with are singularly complex, and absolute simplicity can only be achieved by arrangements which do not cover every requirement, or which are unable to perform with complete satisfaction under severe operating conditions. In the field of protective gear it is usually the case that the more one is prepared to expend, the more simple is the system that may be installed, and in cases where the choice of protective gear is influenced by the desire to spend a minimum amount of money on the same, some degree of complication is a necessary penalty which must be paid.

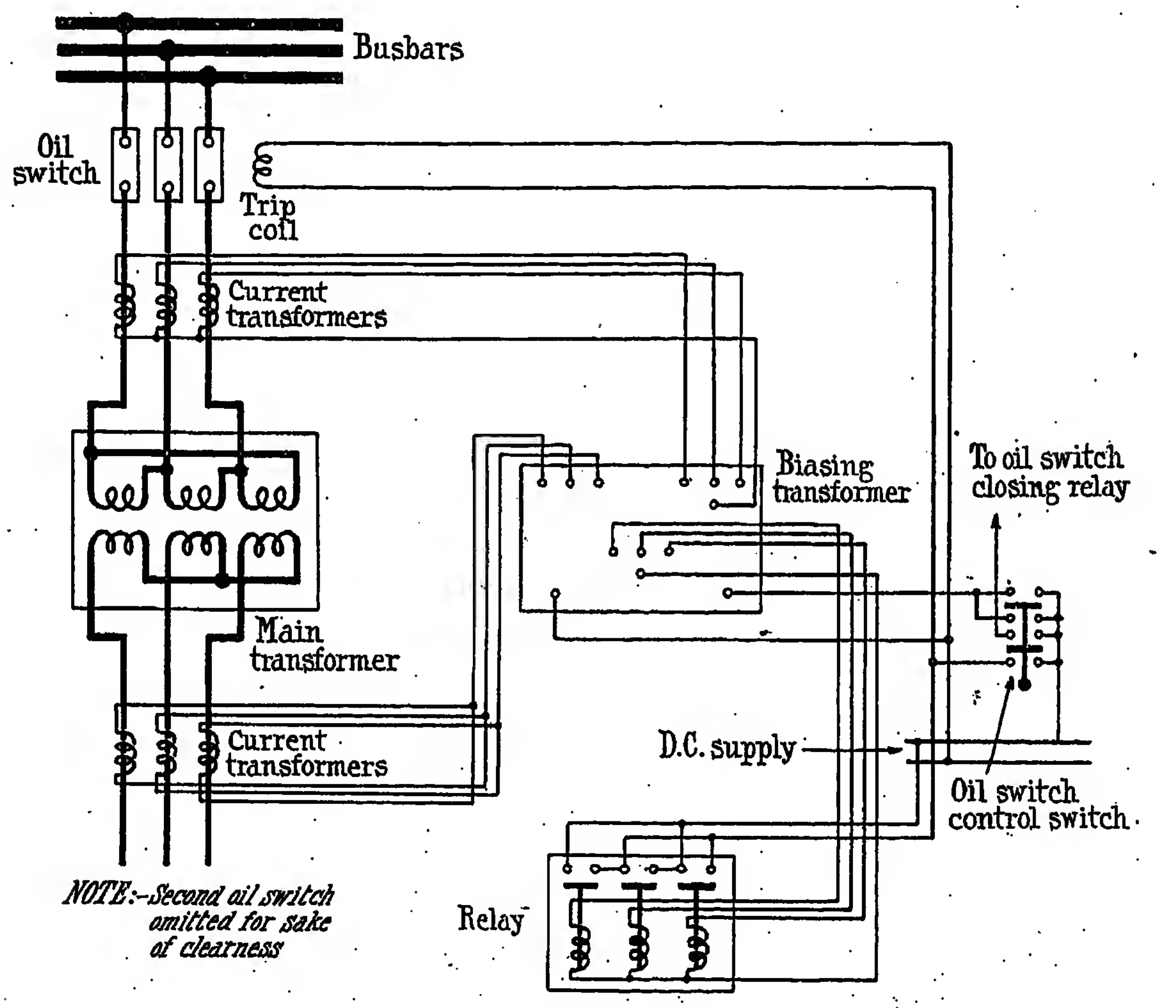

FIG. J.

In the discussion there is inclined to be some confusion between complication in the description and explanation of the circuits, and complication in the actual reality. Dr. Garrard's criticism of Fig. 22 typifies this attitude of mind. Fig. J, which gives the practical wiring diagram corresponding to Fig. 22, shows that Dr. Garrard's animadversions on the subject of 30 terminals are not quite to the point. A study of the various wiring diagrams given in the paper will show that close attention has been given to the grouping of the terminals on the biasing transformers with a view to facilitating correct connection. It can scarcely be contended, for instance, that there is any reasonable possibility of error in making connections in accordance with Fig. J, even though highly skilled erectors be not available.

The author has definitely been at pains, particularly in systems of an inherently less simple nature, to arrange that such complication as may be unavoidable shall reside in the design and manufacture rather than in the installation and maintenance of the protective gear. Mr. Howarth has criticized this policy and it is of course realized that in this respect differences of opinion are bound to exist. Some engineers may prefer to acquire and erect, connect and adjust protective systems and relays, providing a staff competent to understand thoroughly and maintain the operation under all conditions. On the other hand, the author feels that the majority of engineers will find more convenient a form of protective apparatus specially designed to relieve them to a large extent of this responsibility and in which the apparatus is provided in a form requiring the minimum of maintenance and attention.

Stability.—By far the greatest volume of adverse criticism encountered during the discussion has been concerned, not with any particular arrangement devised by the author, but with the fundamental principle of design by means of which stability is to be obtained. Supply engineers have in unmistakable terms voiced their dislike of protective gear in general. It will hardly be disputed that the unenviable reputation gained by protective gear in the past is more associated with instability than with any other shortcoming. It is therefore surprising to find so many speakers who are still prepared to attack the principle of the biased protective system as such and to express their decided

preference for methods requiring accurate balancing of protective transformers.

The author, as mentioned in the paper, has felt justified in assuming agreement with the biasing principle, but it would appear that its advantages are still not appreciated in many quarters. Thus it seems desirable to describe more fully the grounds on which the biasing principle is felt to be the most satisfactory method of ensuring stability. The history of protective systems, as indicated by personal experience and published information, records continual failure to achieve stability. That this would not have been the case had biased systems been more generally employed is supported by the operating experience with such systems. It is, however, now asserted that, as a result of experience, balancing troubles have been entirely overcome. The author has referred to the very great responsibility assumed by a protective system, and several speakers have emphasized this point. It is therefore maintained most emphatically that such responsibility warrants a much greater margin of safety than is ever obtained by balancing methods.

As mentioned by many speakers in the discussion, it is no doubt possible to get current transformers which on a "through current" test of a certain magnitude will not trip the relay. By how much, however, is the out-of-balance current under these conditions less than the tripping current of the relay, and to what extent will the balance be maintained with greater currents? What will be the effect of any possible change in the magnetic circuit over extended periods due to possible ageing of the iron or the effect on the transformers of handling after testing and erecting? It is known that manufacturers of magnetic steel are very careful as to the way in which they handle this material. Balance can never be checked after erection except as the actual result of faults. It is probably not realized, except by those who have actually carried out balancing tests, how extremely minute is the physical change in an iron core, representing the difference between perfect balance and tripping of a sensitive relay, when the core is excited by currents of the order of 10 000 amperes. Minute movements with air-gap cores, or slight changes in closed iron-ring cores due to temperature or varying eddy currents, have a very perceptible influence on the out-of-balance current under such conditions, and manufacturers of protective gear depending for stability on simple balance will seldom accept responsibility for its operation except within definite limits of current. Small differences in the protective secondary circuits due to lack of symmetry of resistance and reactance may set up similar small out-of-balance currents, and the possibility of cumulative circuit and transformer differences renders the whole process somewhat hazardous.

Many instances of perfectly successful experience with such equipments can be cited, but so also can cases of failure to secure stability, many speakers having referred to such instances. Only where a biased system is adopted can the element of chance be avoided. When a biased system is carried out on the lines described by the author, there is no doubt whatever as to its ability to withstand "through" short-circuit currents. There is an ample margin for any contingency, and the more severe the fault the more certain is the stability. The out-of-balance current necessary to trip a properly stabilized biased system when traversed by a current of short-circuit value is very large indeed in proportion to the maximum divergence encountered with ordinary current transformers.

The author's contention is even supported in a measure by one of the speakers in favour of balancing methods. Mr. Biles, after referring to the absence of difficulty in the balancing of transformers, describes a scheme of generator protection devised by him in which he finds it necessary, in order to ensure stability with low fault settings, to employ a diverter relay arrangement. This entails extra resistances and double the normal complement of contacts and moving parts; unless these are specially timed the arrangement will not work. It is frankly an alternative to a biased system, and one which in the opinion of the author accomplishes its object in a much less perfect manner than does the biasing transformer. It is difficult to understand how the extra complication may be justified unless some difficulty in properly balancing the transformers does in fact exist.

Biased relays.—Mr. Cheetham agrees with the remarks in the paper in respect of the advantages of simple relays over the more complicated biased relay. Mr. Wilson, however, prefers the biased relay. The great risk inherent in all balanced-beam relays is the possibility of sudden kicks (such as might be due to momentary overloads) operating in a restraining direction, causing a rebound on to the contact, and this difficulty is not always envisaged in attempting to design such relays.

Design of biasing transformer.—Mr. Clothier, in comparing the action of Mr. Biles's diverter relay system with the operation of the biasing transformer, makes a statement indicating that with a biasing transformer the restraint is always present. This is not in accordance with the facts indicated by Fig. 5 and the accompanying description.

Mr. Lipman inquires as to the consumption in volt-amperes required to operate the restraining windings, and particularly how the biasing transformer may be applied to extra-high-tension installations where, due to the restricted output of bushing and other forms of current transformer, little energy is available in the protective circuit. The amount of power used in a restraining winding in order to prevent operation of the relay varies between an amount equal to the operating volt-amperes and double this figure. The arrangements described in the paper are already being built for 110-kV systems. In these instances it has been found that the bushing transformer output is comparable with that obtainable at the usual voltages employed in this country. Where, however, it is desired to employ the whole of the bushing transformer output for operating, the arrangement of restraining windings shown in Fig. 1 (*a*) and applied in Fig. 34 is particularly suitable, the restraining energy being derived directly from the primary.

Mr. Howarth refers to the method of making a mid-point tapping on a dividing restraining winding. It may be pointed out that where this form is indicated by the symbol shown in Fig. 2, the horizontal winding should be taken as representing a pair of divided restraining

coils; thus two pairs of coils will be provided and connected in series when a mid-point is desired.

Mr. Ross questions the statement in the paper as to the absence of any difficulty as regards the internal balance of the biasing transformer. The facts are, however, exactly as stated in the paper. These may be more fully comprehended if it be recalled that the cross-section of the core of a biasing transformer is of the order of 1/30th of the cross-section of a typical current transformer. Suppose, therefore, that owing to some variation in the iron there is 1 per cent difference in permeability between the two halves of a biasing transformer or between one ring and the other. This will cause a 1 per cent difference in the total flux. The energy developed in the relay as a result of this difference will be a constant multiplied by the difference in flux; thus this difference will be much greater in the case of current transformers than in the case of the small biasing-transformer core, where in fact it is not found possible to detect such differences. In the rectangular type of core, in any case, any difference in the laminations is likely to be balanced between the two sides by the ordinary methods of assembly.

Mr. Angold also refers to the question of the energy necessary to provide the static restraint, the figures being mentioned above. The extra output from current transformers necessary to overcome the loss in efficiency where the biasing transformer is operating as a straight transformer is not serious. The figures are given on page 573. Moreover, so far as overload restraint is concerned—and this is by far the greater field for the biasing transformer—the greater energy is only desired under heavy current conditions when ample magnetizing current is readily available.

Mr. Cheetham inquires as to the meaning of the fifth paragraph dealing with the advantages of the use of a biasing transformer. This particular point refers to the matter discussed in col. 2 on page 565, describing how the saturating effect of the biasing transformer, even when not restrained, limits the maximum current that can be reached in the relay winding. Mr. Cheetham will find in Fig. 22 a practical example of the method of d.c. control suggested on page 573. Fig. 9 is intended only for explanatory purposes, and the limitations mentioned by Mr. Lipman are referred to in the paper. The complete connections of such a system are given in Section 2 of the paper, several diagrams being shown. Fig. 36, for instance, does exactly what Mr. Lipman suggests.

Dr. Garrard rather surprisingly questions the permanence and robustness of the biasing transformer itself. He suggests, for instance, that the air-gap in the biasing transformer may, by alteration, affect the performance of the apparatus. In the first place, a reference to Fig. 5 will show that any small change in the air-gap will have very little effect on the protective gear, as the particular value of overload at which the bias begins to become effective is not a matter of very great importance. Critics of novel apparatus are also sometimes rather liable to mention small points of this nature with a view to questioning the satisfactory operation of the gear, without giving the designer reasonable credit for carrying out his design in a practical manner. Thus although, as indicated, the accurate dimension of the air-gap is not in certain biasing transformers a matter of great importance, in all biasing transformers designed by the author the laminations are pressed hard home on an insulating filler carefully cut to the exact dimensions required. Moreover, the biasing transformer is on completion made solid with compound. It is only by careful attention to such details that satisfactory operation of protective gear can be obtained, and it is possible that a part of the lack of success of protective gear in the past may be attributable to some of the more subtle points not having been given adequate attention. It would seem, therefore, that Dr. Garrard's criticism in this respect is not admissible. He also refers to the question of the use of one type of relay throughout all the different systems of protection, in contrast with the more usual method of designing special relays for each system.

It is suggested by Dr. Garrard that inasmuch as a different design of biasing transformer is necessary, the standardized relay offers no advantages. He will realize, however, that this is not the case if he will consider practical methods of manufacture of an apparatus such as the biasing transformer, which lends itself particularly to standardization of components and tools. Thus a single core of a biasing transformer will be built of identical components in whatever system of protection it appears, and the only variation between one biasing transformer and another will be in the windings and connections.

Protective transformers.—There would seem to be little disagreement with the author's plea on behalf of bar-primary protective transformers. On the other hand, a number of contributors to the discussion favour the air-gap transformer in lieu of the ring-core type recommended by the author. Having regard to the frequent comments heard in the discussion as to the flimsiness of some of the protective relays extant, it is surprising that so little exception is taken to the inherent limitations of the air-gap transformer. The author recently had occasion to test a typical air-gap transformer in comparison with one of his opposed-voltage transformers of comparable rating. For given primary current the output of the latter in volt-amperes was exactly 150 times that of the former. The mere fact that the use of the ring core enables a very much more robust relay to be employed is, in the opinion of the author, the strongest possible recommendation for its use, anything tending to eliminate the necessity for flimsy relays being, it is felt, a step in the right direction.

Relays.—Arising out of the above remarks, it is noteworthy how much difference of opinion exists amongst engineers as to what really constitutes a robust relay. As indicated in reference to the question of protective transformer design, the author feels that the greater the operating forces set up in any relay, and the more robust the relay, the better is the protective system, other considerations being equal. Several speakers, having in mind standard Merz-Price feeder protection, describe as robust a relay that will give with that system of protection a fault setting of several hundred amperes. This relay would trip at something not very much exceeding 0·5 volt-ampere. It is a relay of this

order of sensitivity that has largely been used by the author for operation with the various biasing transformers, and there is no difficulty in making such a relay quite immune from the heaviest mechanical vibration. That this class of relay has not in the past been free from this trouble is referred to by Captain Donaldson.

Mr. Angold, on the other hand, who is evidently concerned with a much heavier class of electrical apparatus, is inclined to regard such a relay as undesirably sensitive. There are on the market, however, relays such as the Fawssett-Parry mentioned by Mr. Buist and that described by Mr. Cheetham, capable of very much finer settings than the 0·5 volt-ampere relay, and, whilst in the opinion of the author these are much too delicate, a certain amount of success has no doubt been achieved by them.

Mr. Wilson criticizes the practical design of Figs. 15 and 16. These figures are, however, intended more as diagrammatic representatives of the principles involved than as an attempt at a practical design. Mr. Wilson suggests that the balanced-beam relay is preferable to the attracted-armature relay, on the grounds that it moves through a greater distance. A probable result of this is that the operating forces are smaller. It is the small air-gap in the attracted-armature relay that gives rise to the large forces set up by this class of relay. A properly designed armature relay, having light moving parts restrained by springs, will unquestionably be less affected by mechanical disturbances than the balanced-beam arrangement having considerable moment of inertia about its fulcrum.

Mr. Lipman disagrees with the proposal to employ similar relays for all purposes, suggesting that it is better to have a distinct type of relay for each different function so that different classes of abnormality may be identified. This may be pleasing but is unquestionably an uneconomical proposition, and in any case it would seem that Mr. Lipman's preference could surely be met by the use of distinctive name-plates.

Reference is made in the discussion to the development taking place at the present time in respect of dispensing with the relay altogether and utilizing a modification of the protective relay, adapted directly to trip the switch. Much may be said for and against this practice. The advantages are that it cuts out a definite link in the chain of events between the occurrence of a fault and its isolation, and as such should provide greater reliability. On the other hand, particularly where sensitive settings are required, it still suffers from the inherent restrictions mentioned in the paper, notably in respect of the limited power available. The electromagnetic element therefore is bound to be a light affair in comparison with the usual switch mechanism, whether it works contacts or releases a series of mechanical latches. As such it will require proper attention if it is to give satisfactory operation. If it is a relay it will be found on the front of a panel properly protected by means of a cover, having probably a glazed front, and will be under constant observation. If, on the other hand, it is built in the form of a light tripping device, it will be buried away somewhere in the switch mechanism and may probably be situated in a part of the power house where the atmospheric and other conditions are less favourable than is the case in the position where the switchboard is installed. Moreover, it is impossible to adapt a sensitive form of tripping device to operate directly the oil-switch tripping mechanism. There has to be some form of link connecting the electromagnetic element with the standard tripping mechanism of the switch. This takes the form of a mechanical arrangement controlled by very small forces, and, unless very special care is taken in this design, it is unlikely to prove any more reliable than the conventional methods of using a relay and trip circuit. The author is of the opinion that any attempt to provide a light tripping device comprising an adaptation of existing forms of sensitive relay will not give satisfaction, for the reasons mentioned above. If, on the other hand, it should be found possible to devise a sensitive relay in a more robust form, and such that it may directly operate the switch mechanism without any mechanical amplifying device, then it should be very desirable and reliable.

Phantom auxiliary switch.—Mr. Clegg asks what would happen in the circuit shown in Fig. 20 if the d.c. supply should fail. Consideration of the diagram will indicate that the most conspicuous result would be the impossibility of opening the oil switch if the tripping supply is not available. The effect on the protective circuit of failure of the d.c. supply would simply be identical with that of failure of an ordinary auxiliary switch to close, i.e. that the normal circulation of current would be impeded by the reactance of the current-transformer secondary windings, and that the protective relays might be operated by "through" overloads, it being assumed that the oil breaker on the feeder concerned is open and that the neighbouring feeders are carrying load.

Generator protection.—Mr. Cheetham refers to the method of protecting a generator on the circulating-current system with an earth relay in the neutral lead. This is quite a desirable arrangement, and the principle of separating earth faults from other faults is fully exploited in the paper. It should not be forgotten, however, that a divergence between the magnetic characteristics of one transformer and its two neighbours will set up out-of-balance currents even in leakage relays, unless the balance is perfect or the device properly stabilized by employing a suitable biasing feature. It will be noted from the paper that all leakage relays operated by three current transformers are provided with overload restraint, on the occurrence of heavy "through" faults, to take care of this.

Several speakers refer to the protection of generators by reverse-power apparatus against failure of the field. The scope of the paper, it will be recalled, is defined as covering only differential systems of protection, under which reverse power protection may hardly be classed. Moreover, the failure of the excitation is not such a serious emergency as a fault in the machine windings.

General dislike of potential-operated protective gear has been evinced during the discussion, and it is open to question whether such methods of protecting generators are really worth while. It is the standard practice in automatic stations to protect all large machines with a low-field-current relay, and this would seem to be a suitable and simple method of accomplishing this object.

Transformer protection.—Mr. Howarth refers to the desirability of low fault-settings, where a transformer is protected by circulating-current balance between primary and secondary windings in order to give adequate protection on the occurrence of faults between turns on a single winding. It is doubtful whether any great degree of effective protection can be given from faults between turns, except in the more improbable case of their embracing a large proportion of the total winding. Mr. Ratcliff, for instance, recommends the separate protection of the primary and secondary windings of a transformer. By so doing, he avoids any difficulty due to the magnetizing current, yet at the same time with such an arrangement no protection is given from faults between turns.

Mr. Howarth also makes a pertinent inquiry in respect the paper, the author is of the opinion that every contact saved is a step in the direction of reliability.

Reference has also been made to the possibility of reducing the amplitude of the magnetizing-current transient by charging resistances. There is much difference of opinion, however, as to the desirability of this device from the point of view of reliability and safety of the oil switch, and the author feels that there is a distinct field for the device described.

Mr. Wilson refers to the question of the effectiveness of the arrangement from the point of view of duration of the disturbance. In general, the larger the transformer the greater is the duration of the magnetizing-current disturbance. In the case of plant of large capacity, one would expect in almost every case electrically-operated oil circuit-breakers, in which case the

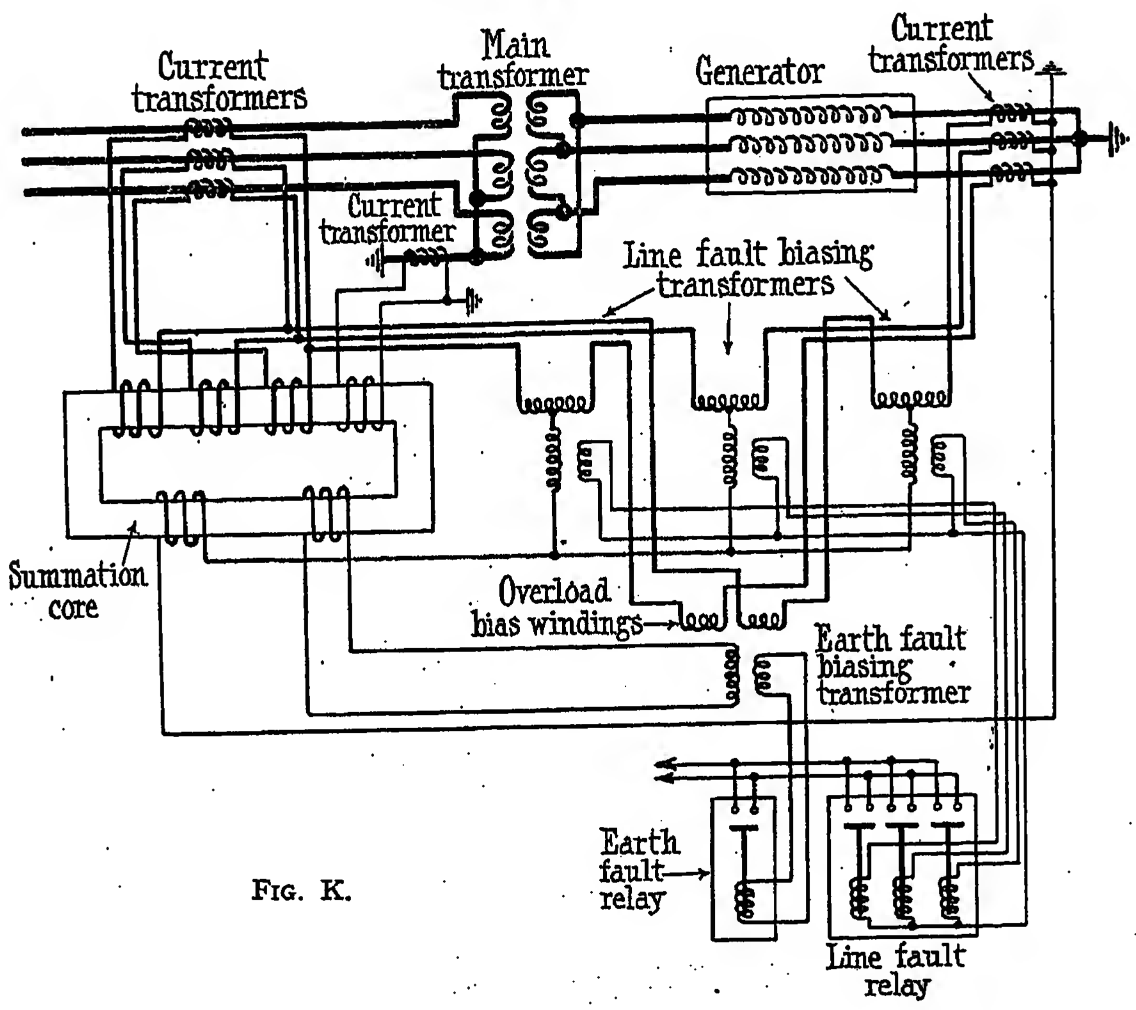

FIG. K.

of the growth of the direct current which is employed in the circuit shown in Fig. 22, to prevent operation of the relays due to the magnetizing-current transient on switching on. Owing to the entirely unknown extent of this trouble in different installations, it is usual to supply a resistance having a number of tappings for connection in series with the d.c. restraining winding. The object of this is two-fold: first, to ensure that the direct current shall grow instantly to its full value, the importance of which is pointed out by Mr. Howarth, and secondly, to enable the extent of the d.c. bias to be suitably adjusted in accordance with the magnetizing characteristics of the transformer protected. Mr. Cheetham refers to a similar scheme by means of which fuses are automatically connected in parallel with the relay windings while the transformer is being switched in. This leads to a triple-pole auxiliary switch, however, and, as stated in connections shown in Fig. 22 would be employed. With this arrangement, the control switch may be held on as long as desired, the full sensitivity of the protective circuit only being restored when the control switch is released. It is generally only the first two or three periods of the magnetizing-current transient which are of serious amplitude, and, where hand-operated oil switches with special auxiliary switches are employed —this arrangement being more commonly found on the smaller transformers—the d.c. circuit remains energized for a sufficiently long time to avoid tripping of the relays, even if the magnetizing current has not quite reached its steady value.

Combined protection of generators and transformers.—Mr. Ratcliff and Mr. Marshall have referred to the inherent difficulties of undertaking the combined protection of generators and transformers on the circulating-

current system. These are associated with the fact that in the event of the alternator suddenly losing its load it is impossible to prevent a transient rise in pressure. With modern highly saturated transformers, such a rise may cause an enormous increase in the magnetizing current. So far as the circulating current is concerned, this is definitely a difference current and corresponds to a fault. In the case of the Manchester Corporation generators, an increase of 20 per cent in the pressure resulted in a tenfold increase in the magnetizing current. The difficulties of protecting such an arrangement are therefore obvious.

Figs. K and L show respectively the schematic and practical diagrams of a suitable circuit for protecting a combination of star-delta transformer and generator. Owing to the magnetizing current difficulty it will hardly be possible, without complicated arrangements magnetizing currents. In order to avoid additional sets of current transformers, a summation transformer is employed in order to arrange discriminating protection in respect of earth faults fed through the current transformers which are connected in delta. In other respects, the diagram is, no doubt, self-explanatory. The summation transformer is incorporated in the biasing transformer itself, and the practical diagram is as simple as can reasonably be expected, having regard to the scope of the protective circuit.

Opposed-voltage system.—The opposed-voltage protective system described in the paper has been adversely criticized by several speakers, who show a marked preference for the air-gap type of transformer, and it has been suggested that the combination of ring-core transformers and biasing transformers has no advantages over the elementary circuit with air-gap transformers.

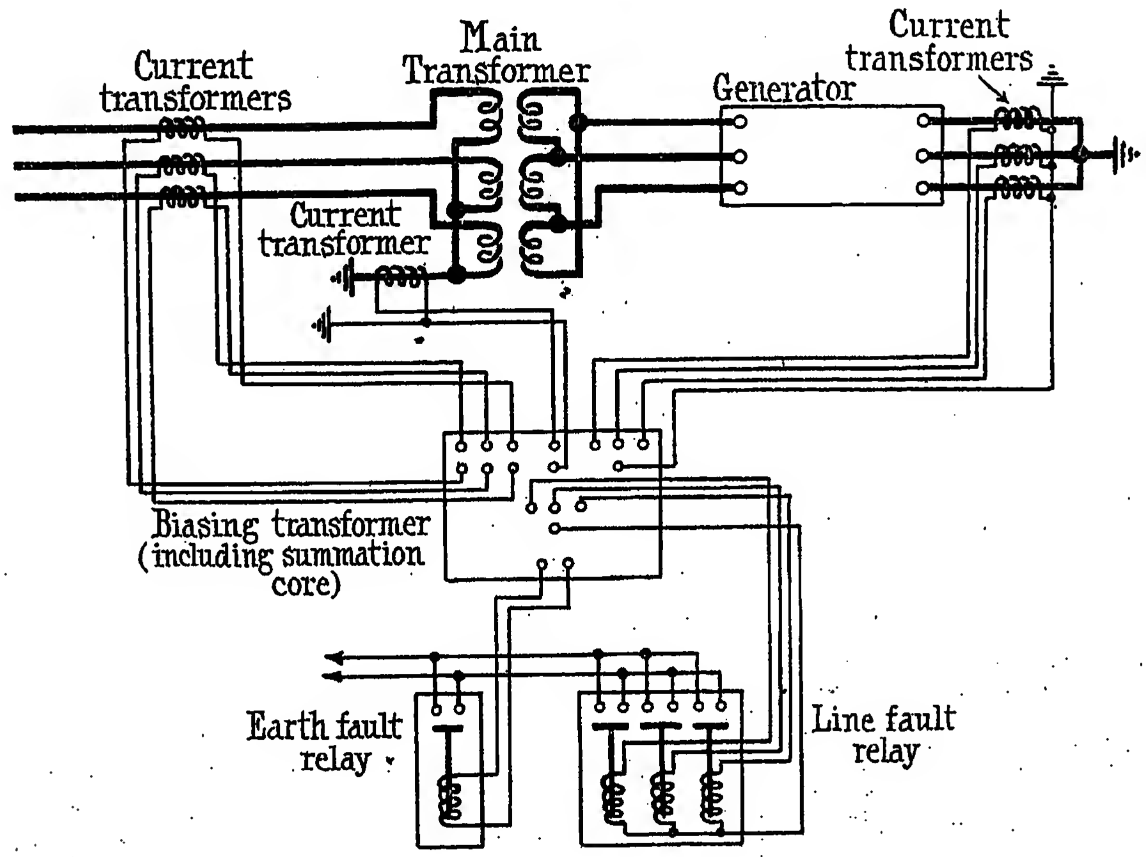

FIG. L.

involving potential, to maintain sensitive fault-settings on any circuit in which the magnetizing current difference is likely to appear. In the present arrangement, therefore, one triple-pole relay is provided which either will have fault settings sufficiently high to be clear of any magnetizing current disturbance or, as an alternative, may be provided with a suitable time-lag. This relay will be operative on the occurrence of faults between phases on the generator, transformer primary, or transformer secondary, windings. A further single-pole relay is provided which, as may be seen from the connections, will be tripped only by an earth fault on the generator or transformer windings. Neither of the relays will be directly affected by line or earth faults which may be fed by the plant protected. Both are provided with overload restraint in order to ensure immunity from operation, due to current transformer divergence. The earth-fault relay is not disturbed by The question of transformer design has already been gone into, but the author would emphasize that the whole point of using the biasing transformer and solid-core transformer resides in the fact that with such an arrangement (after making allowance for energy lost in the restraining windings) for any given primary earth-fault current the opposed-voltage system described in the paper will deliver into the pilot-wire circuit rather more than 50 times the volt-ampere output which can be given by the multi-gap type of transformer. These are actual test results, utilizing in each case transformers of similar rating. Inasmuch as for equivalent performance a heavier relay may be used in the one instance than in the other, it is maintained that this advantage alone more than outweighs any of the aspects of the arrangement which have been criticized.

Several speakers have discussed the question of simultaneous earth faults and their effect on this class

of protective gear. This has been dealt with in the paper and it would seem desirable to make more clear the relation between these operating conditions and the design of the opposed-voltage system. The opposed-voltage system as described can be made immune from incorrect operation due to through earth faults not limited by the value of the earthing resistance, with fault settings well below 100 amperes. The main advantages accruing from the particular form of circuit employed, i.e. with separate earth-fault and line-fault relays, is that it enables ring-core transformers to be employed without these operating on open circuit. This fact alone enables much more sensitive settings for earth faults to be obtained with a less sensitive relay, apart altogether from the question of the possible fault-setting in respect of stability.

Several speakers have drawn attention to the additional difficulties which are experienced in applying a differential system of protection to e.h.t. cable systems, in that, as mentioned by Mr. Clothier, the charging currents met with are a direct exception to the principle on which differential protection has been based. There are various obvious methods of meeting the difficulty, but at the present time it is impossible to say exactly which practical solution will be found to combine effective operation with the desirable simplicity of apparatus.

Mr. Biles describes an application of his diverter relay system to an opposed-voltage protective circuit. The diverter relay principle has already been dealt with. Mr. Biles's scheme may be analysed as follows: He has devised a modification of the protective circuit described in Fig. 24, in which only a 2-core pilot cable is installed. The circuit is interesting and possesses certain advantages, though it is doubted whether it will be possible fully to exploit the saving of one of the pilot cores, as pilot cables are so often installed before the protective gear is finally decided upon. In utilizing the one relay energized separately by earth faults and line faults, there is not the advantage residing in the arrangement described in the paper and having separate relays, in that in the latter the settings for earth faults and line faults may be adjusted independently, and, moreover, a definite indication is given as to which class of fault has occurred. A study of Mr. Biles's scheme appears to indicate that there is a critical value of simultaneous earth fault and line fault which would set up E.M.F.'s in opposition and might not prove operative. This is a remote case, however, and Mr. Biles is no doubt justified in ignoring it. Mr. Biles points out that the complete scheme has the same number of relays as the author's proposed scheme, but if biasing transformers were used there would only need to be two relays instead of four in Mr. Biles's scheme. Whilst, therefore, there is no reason whatever to suggest that Mr. Biles's proposals will not prove effective, it does not seem reasonable to claim that any arrangement of diverter relays is as simple or likely to prove as reliable as the arrangements described by the author, where the additional functions are performed with static gear.

Mr. Ross discusses the practical design and operation of the opposed-voltage circuit described. The difficulties envisaged by Mr. Ross do not, however, occur in practice.

Split-conductor system.—The author's proposal to embody overload restraint in a split-conductor transformer has met with a good deal of opposition on the lines which have already been mentioned in the reply. Such speakers have most emphatically declared that the split-conductor system is absolutely faultless in operation, whereas other speakers who have referred to split-conductor gear have mentioned cases where it has been found to trip on "through" faults. It is therefore again the fundamental question of balanced versus biased systems. With balanced systems it is no doubt possible to get a very large degree of success, but there are quite sufficient cases of failure to have been mentioned several times in the discussion. Thus it is felt by the author that the employment of a definite stabilizing influence, whereby certainty of successful operation —so far as immunity from tripping on "through" overload is concerned—is ensured, is by no means uncalled for.

Parallel-feeder systems.—Much has been said in the discussion as to the disadvantages of parallel-feeder protective systems in comparison with pilot-wire systems. This point has already been dealt with.

A most surprising feature of the discussion is the number of speakers who have indicated their impression that parallel-feeder systems in general are of no practical importance. As Mr. Trencham rightly points out, this view seems to be associated with a certain amount of insular prejudice, such systems having been used to a large extent abroad.

The author recently communicated with one of the principal designers of protective gear in the United States in respect of the general status of parallel-feeder protective gear in that country. He was advised that parallel-feeder systems are regarded as a standard method of protection for large networks and that there is at present no sign of their losing popularity, the experience gained with them being very satisfactory. The author's informant indicated that definite records are available of over 1 000 installations and that the actual number of equipments was several times this figure; this being the case, it is no doubt obvious that the attitude of certain speakers is hardly tenable.

The general criticism is that parallel-feeder gear is likely to be disturbed by load currents. This difficulty was no doubt experienced during the initial development of some systems of this nature, but this particular point and its effect on design is gone into very fully in the paper. If this be adequately studied, it will be seen that the difficulties mentioned by the various speakers are explained and carefully avoided.

Mr. Leeson describes a semi-automatic scheme for the protection of parallel feeders. This, however, is not directly comparable with any of the schemes described in the paper in which the maintenance of continuity of supply is considered to be an essential feature. Mr. Leeson's arrangement, on the other hand, does not prevent a shut-down. Moreover, a close study of Fig. D shows that a potential transformer is indicated in an inconspicuous manner, although this is not mentioned in the text. If the potential transformer is existing there is, of course, no reason why it should not be used; but having regard to the remarks of Mr. Clothier

and other speakers on the subject of potential transformers, it seems very doubtful whether their installation purely for the object indicated in the figure is justified.

Separate treatment of earth faults and line faults.—Mr. Trencham emphasizes some of the practical advantages of this principle, and shows how the extension of the same to the design of switchgear itself might lead to enormous reduction in the required rupturing capacity of oil circuit-breakers, and thus in their cost. Lieut.-Col. Edgcumbe also supports this principle but prefers leakage arrangements involving direct or primary core-balancing instead of arranging leakage connections in the secondary circuit of the current transformers. It is, however, purely a question of circumstances, and in a large number of practical cases it proves to be a convenience to energize the protective apparatus from current transformers installed in accordance with conventional cellular arrangements. We have, then, systems of protection which may, without modification, be applied to a new system without deranging the existing connections. Moreover, the trifurcating box is included in the protected zone. Where a core-balancing transformer is designed to embrace all three phases, it will either be installed on the cable itself—in which case it will not include the trifurcating box in the protected zone—or it will be necessary to bring three insulated primaries through one transformer beyond the cable box, where to a large extent present practice favours phase separation.

Another advantage of separate earth-fault and line-fault settings is brought to light in dealing with Mr. Howarth's query as to the question of tee loads. Wherever it is desired to put a small tee load on any feeder protected by a system in which separate earth-fault and line-fault settings are employed, no modification need be made to the protective circuit nor need extra transformers be installed. The line-fault setting may be sufficiently high not to be affected by the difference current represented by the small consumer. The earth-fault setting will not be affected by any load drawn from the line in this manner. The arrangement will, of course, clear faults originating in the tee connection, but will not be affected by any condition of load if the respective lines are sound.

Fault settings.—Several speakers have inquired as to the fault settings that may be obtained with the apparatus described. Utilizing in every case a relay of any desired pattern capable of operating with 0·5 volt-ampere, the following performance is being obtained *:—

For generator protection, faults of 5 per cent may be cleared. This figure could also be obtained with transformer protection if the primary and secondary windings are separately protected.

For overall protection of a transformer, in which magnetizing-current differences are met with, it will probably prove desirable not to employ such small settings. This depends to a large extent, however, on the nature of the system on which the transformer is installed, as magnetizing-current transients other than those occurring during switching are largely determined by disturbances in the system pressure.

With split-conductor systems there will be no appreciable change in the fault settings now being obtained, if the overload restraining feature be incorporated.

In both the balanced-current and balanced-power systems for the protection of parallel feeders, the relay will be operated by earth faults which set up difference currents equal to 20 per cent of the feeder rating. For line faults, as has been mentioned, higher settings exceeding normal loads are desirable.

In the case of the opposed-voltage system—this being definitely the most successful of any of the systems described in the paper—a special design of current transformer has been made to enable the best possible fault settings to be obtained. For an 11 000-volt system this transformer is about 7 inches in diameter and about 7 inches long, and fault settings of the order of 50 amperes may be obtained on feeders of average length.

Costs.—Mr. Woodhouse inquires as to the cost of protective gear of the nature described in the paper. It will no doubt be appreciated that it is very difficult to give definite figures of cost for different classes of protective arrangements, owing to the diversity of conditions met with. It may be definitely stated, however, that in none of the schemes described in the paper is it found that the total cost exceeds that of corresponding unstabilized protective gear.

The cost of the biasing transformer is not heavy, owing to the manner in which it peculiarly lends itself to standardization. This cost is amply balanced by savings in other directions, such as the avoidance of the use of expensive and highly sensitive relays, elimination of the anti-capacity sheaths in pilot conductors, and the avoidance of the necessity of balancing transformers. Moreover, the arrangements described lend themselves more easily to economy as regards spares and replacements, owing to the fact that standard transformers may be drawn from stock without having to be specially made and balanced.

* In every case, except the opposed-voltage circuit, the figures given refer to the use of standard current transformers.

THE RISE AND DISTRIBUTION OF TEMPERATURE IN SMALL ELECTRICAL MACHINES.*

By EDWARD HUGHES, B.Sc.(Eng.), Associate Member.

(*Paper first received* 31*st October*, 1923, *and in final form* 11*th January*, 1924.)

SUMMARY.

The paper deals with the factors influencing the shape of the heating and cooling curves of coils and electrical machines. The thermal conductivity of the insulation is calculated by alternative methods from the distribution of temperature in coils; and the effects of different temperature-rises and of different air velocities upon the thermal conductivity and upon the temperature-rise per watt are considered. A new arrangement for measuring the mean temperature-rise of field windings is described. The temperature-rise of the field windings is deduced in terms involving the speed and the armature loss for a number of different machines, and a comparison is made of the temperature-rise as measured by resistance with that measured by thermometer.

TABLE OF CONTENTS.

1. HEATING TIME-CONSTANT.

When heat is generated at a uniform rate in a coil, and the rate of heat dissipation is proportional to the rise of temperature above the surrounding medium, the temperature-rise after a time t is given by :—

$$\theta_t = \theta\{1 - \epsilon^{-t/T}\}$$

In coils used on electrical machines and apparatus, however, the rate of generation of heat seldom remains constant, it being usual to keep either the current or the voltage constant. In the former case, the rate of heat generation increases with time owing to the increase in the resistance of the copper; whilst in the latter case the rate of heat generation decreases. The effects of these changes will now be considered.

Heating equation when current is kept constant.—

Let H = energy in joules to raise temperature of coil 1 degree C.,

W_1 = initial power generated in coil,

β = final temperature that would have been reached if power remained at W_1,

and T = corresponding time-constant,

then $TW_1 = \beta H$

$$\therefore H = \frac{TW_1}{\beta}$$

If θ_t be the temperature-rise after a time t secs., the power generated in the coil at that instant

$$= W_1(1 + \alpha\theta_t)$$

where α = temperature coefficient of resistance.

If k = power dissipated by coil per degree C. rise of temperature, then

$$W_1(1 + \alpha\theta_t)dt = k\theta_t dt + Hd\theta$$

If θ be the steady temperature-rise of coil when current is maintained constant, then

$$W_1(1 + \alpha\theta)dt = k\theta dt$$

$$\therefore k = \frac{W_1(1 + \alpha\theta)}{\theta}$$

Substituting for k and H in the above equation we have :—

$$W_1(1 + \alpha\theta_t)dt = \frac{W_1(1 + \alpha\theta)}{\theta}\theta dt + \frac{TW_1}{\beta}d\theta$$

from which $$\frac{dt}{T} = \frac{\theta}{\beta} \times \frac{d\theta}{\theta - \theta_t}$$

$$\therefore \frac{t}{T} = -\frac{\theta}{\beta}\log_\epsilon(\theta - \theta_t) + A$$

When $t = 0,\ \theta_t = 0;\ \therefore A = \frac{\theta}{\beta}\log_\epsilon \theta$

Hence $$\frac{t}{T} = \frac{\theta}{\beta}\log_\epsilon \frac{\theta}{\theta - \theta_t}$$

$$\therefore \theta_t = \theta\{1 - \epsilon^{-(t/T)(\beta/\theta)}\}$$

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

But $\quad k\beta = W_1$

and $\quad k\theta = W_1(1 + a\theta)$

$$\therefore \frac{\theta}{\beta} = 1 + a\theta$$

Hence $\quad \theta_t = \theta\{1 - \epsilon^{-t/[T(1+a\theta)]}\}$

Consequently the effect of increase of resistance is to increase both the temperature-rise and the time-constant by $(1 + a\theta)$, but the shape of the curve is not affected.

Heating equation when voltage is kept constant.—Using the same symbols as before, we have for a temperature-rise θ_t, power generated in coil $= W_1/(1 + a\theta_t)$ and $k = W_1/[\theta(1 + a\theta)]$.

$$\therefore \frac{W_1}{1 + a\theta_t}dt = \frac{W_1}{\theta(1 + a\theta)}\theta_t dt + \frac{TW_1}{\beta}d\theta$$

from which $dt\left[\frac{(\theta - \theta_t)\{1 + a(\theta + \theta_t)\}}{1 + a(\theta + \theta_t) + a^2\theta\theta_t}\right] = \frac{\theta T}{\beta}d\theta$

Since $a^2\theta\theta_t$ is negligibly small in comparison with $\{1 + a(\theta + \theta_t)\}$ for the temperature-rise permissible in coils, we have :—

$$dt(\theta - \theta_t) = \frac{\theta T}{\beta}d\theta$$

$$\therefore \theta_t = \theta\{1 - \epsilon^{-(t/T)(\beta/\theta)}\}$$

But $\quad k\beta = W_1$

and $\quad k\theta = \frac{W_1}{1 + a\theta}$

$$\therefore \frac{\theta}{\beta} = \frac{1}{1 + a\theta}$$

and $\quad \theta_t = \theta\{1 - \epsilon^{-t(1+a\theta)/T}\}$

Hence the effect of increase of resistance is to decrease the temperature-rise and the time-constant by $1/(1 + a\theta)$, but not to alter the shape of the curve.

Predetermination of the heating time-constant.—If the effect of the insulating covering on the wire and of the air in the interstices be neglected, the value of T can be calculated thus :—

Let N = number of turns on coil,
l = mean length per turn in cm,
a = sectional area of wire in cm^2,
ρ = resistance per cm cube of copper at initial temperature,
s = specific heat of copper,
D = density of copper,
i = current density in amperes per mm^2,
and I = current in amperes.

Then power generated in coil $= I^2\frac{\rho Nl}{a}$

But $T \times$ initial power generated $= 4\cdot2 \times$ number of calories to raise the temperature by β deg. C.

that is, $\quad TI^2\frac{\rho Nl}{a} = 4\cdot2NlaDs\beta$

$$\therefore T = \frac{4\cdot2Ds\beta}{\rho}\left(\frac{a}{I}\right)^2$$

Taking the average initial temperature as, say, 16° C.,

$$\rho = 1\cdot6 \times 10^{-6}\{1 + 0\cdot0043 \times 16\}$$
$$= 1\cdot71 \times 10^{-6}$$

Also, $D = 8\cdot9$, and $s = 0\cdot094$,

$$\therefore T = \frac{4\cdot2 \times 8\cdot9 \times 0\cdot094}{1\cdot71}10^6\left(\frac{1}{100i}\right)^2\beta$$
$$= \frac{205\beta}{i^2} \text{ seconds}$$
$$= \frac{3\cdot42\beta}{i^2} \text{ minutes}$$

It is often more convenient, however, to determine

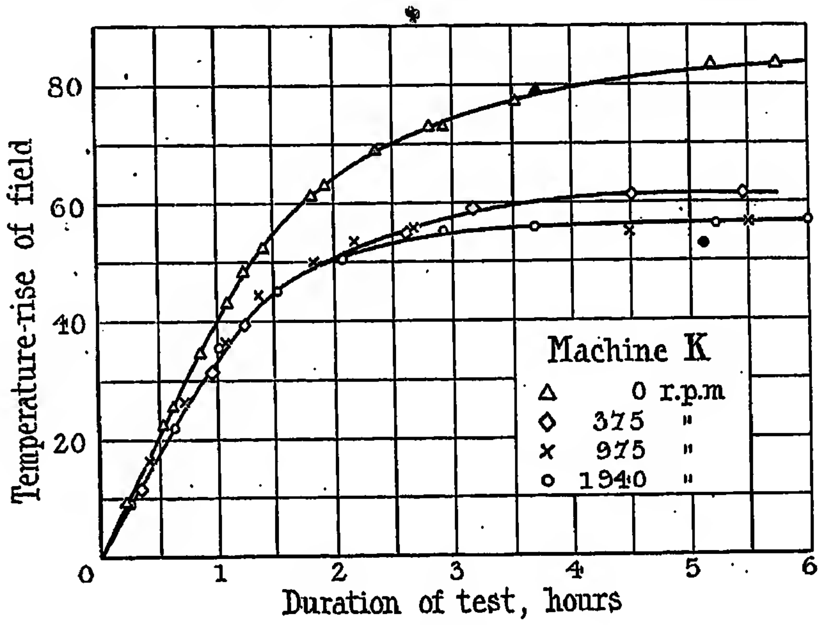

FIG. 1.

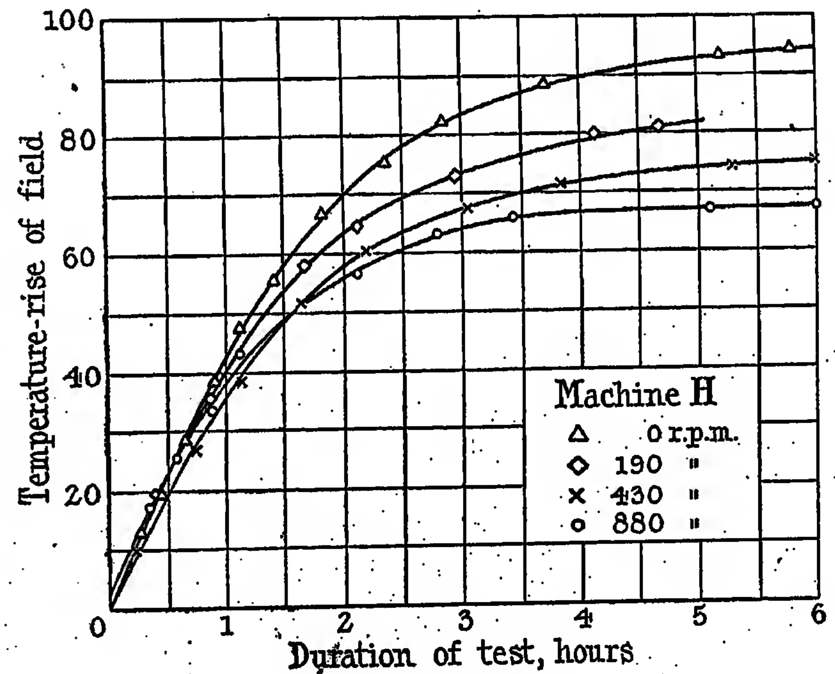

FIG. 2.

the temperature-rise per minute in terms of the current density; thus

$$\frac{\beta}{T} = \frac{i^2}{3\cdot42} = 0\cdot292i^2$$

If the current be maintained constant,

$$\beta = \frac{\theta}{1 + a\theta}$$

$$\therefore T(1 + a\theta) = \frac{3\cdot42\theta}{i^2}$$
$$= \frac{\theta}{\text{initial temp.-rise per min.}}$$

Similarly, if the voltage be maintained constant,

$$\beta = \theta(1 + a\theta)$$

$$\therefore \frac{T}{1 + a\theta} = \frac{3 \cdot 42\theta}{i^2}$$

$$= \frac{\theta}{\text{initial temp.-rise per min.}}$$

Comparison of test-results with the above expressions.—Tests were carried out on a number of coils, some being suspended in air and others being in position on the poles of d.c. machines. For convenience, the different coils have been designated A, B, etc., the particulars of the windings, etc., being given in the Appendix. It was found that fairly close agreement with the exponential law was obtained so long as the armatures were stationary. When the armatures were rotating, however, the shape of the heating curve for the field winding was modified very considerably. Typical cases of this effect are shown in Figs. 1 and 2.

The values of the actual heating time-constants for the coils have been determined from heating curves with armature stationary and compared with the values obtained from the above expressions, the results being incorporated in Table 1. The value of the time-constant was determined in each case by assuming values of θ and $T_{act.}$ and calculating the values of θ_t for different ratios of $t/T_{act.}$ in the equation $\theta_t = \theta\{1 - \epsilon^{-t/T_{act.}}\}$, the values of θ and $T_{act.}$ being varied to give values of θ_t as nearly as possible the same as those obtained from test. It was found impossible to get reliable and consistent results by drawing a tangent from the origin.

2. Cooling Tests on Field Coils.

Readings were taken of the resistances of field windings of machines F, G, H, I, J and K after the exciting currents had been switched off, the coils having attained steady temperatures. During the heating tests preceding these cooling tests, the armatures of all the machines were stationary. The resistances were measured at frequent intervals by a Post Office box, and the corresponding temperatures calculated. The difference of temperature between the coils and the air, after correction for any variation of the room temperature, has been plotted for each machine in Figs. 3, 4 and 5. It will be obvious that the cooling time-constant will not be affected by any variation in the resistance of the copper and may therefore be expected to agree with the value of T calculated in col. (10) of Table 1. On comparing the cooling curves with the nearest values obtainable from the expression

* Constant voltage. † Constant current.

$\theta_t = \theta\epsilon^{-t/T}$ it was found that agreement was fairly good during the first cooling period, but afterwards the divergence became comparatively large. The following figures for machines F and K are typical of the results obtained :—

Machine F (T = 67 mins.)			Machine K (T = 70 mins.)		
t	$\theta_t = \theta\epsilon^{-t/T}$	θ_t from curve	t	$\theta_t = \theta\epsilon^{-t/T}$	θ_t from curve

167·5	5·63	12·6	175	5·18	10·5

To show more visibly how the rate of cooling varies with the temperature, the upper curves in Figs. 3, 4 and 5 have been drawn, the points being calculated from the fall in temperature in 10 minutes and the average temperature above air during that interval. It will be noted that the rate of cooling is not proportional to the temperature except during the initial period—a period that may on the average be taken to be equal to the cooling time-constant. Afterwards the ratio falls rapidly to become approximately steady once more at the lower temperatures. This variation in the rate of cooling cannot be due to alteration in the thermal conductivity of the insulating covering on the wire (see page 632) ; it is to some extent accounted for by the variation in the heating coefficient referred to on pages 637 and 645, though, for machines F, G, H and I, the variation of the heating coefficient (Fig. 20) is much less than the variation of the rate of cooling shown in the above figures. It would therefore appear that the effect under consideration is partly, if not mainly, due to a redistribution of temperature in the field winding and pole-cores caused by the different temperatures of these parts, and by the different heat emissivities of the various cooling surfaces.

The results obtained from these cooling tests have been included in Table 1, from which it is seen that the values of T derived from the cooling curves agree fairly closely with the values of T given in col. (10) for the corresponding maximum temperature.

Principal conclusions from the above considerations.—

(*a*) The heating and cooling curves for field coils are approximately exponential when the armature is stationary.

(*b*) The heating curve for the field coils with the armature rotating may deviate considerably from the exponential law—the higher the speed, the more square-shouldered the curve.

(*c*) The actual heating time-constant may be from 20 to 90 per cent greater than that calculated for the copper alone, the percentage increase being greater the smaller the size of the wire, the thicker its covering, and the larger the adjacent winding (if any).

(*d*) The heating time-constant for a coil with constant current is greater than that for the same coil with

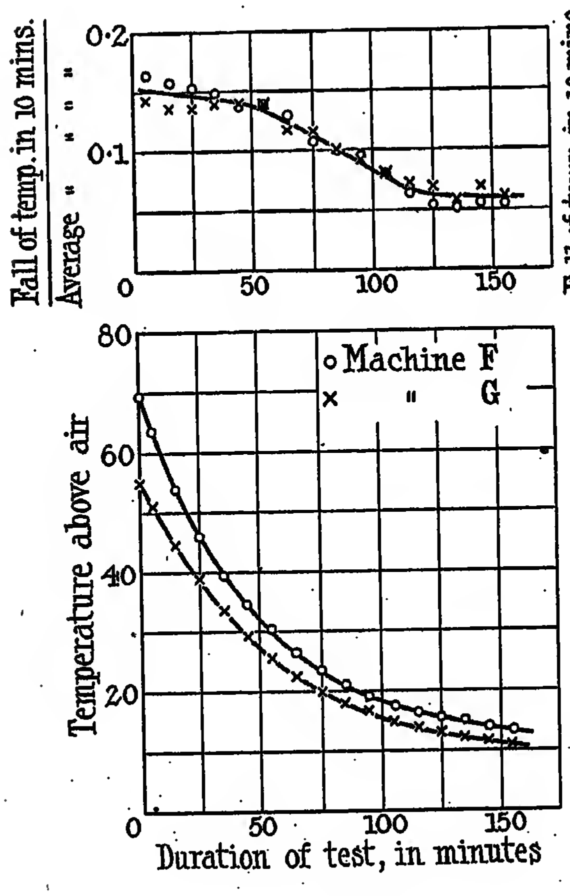

FIG. 3.

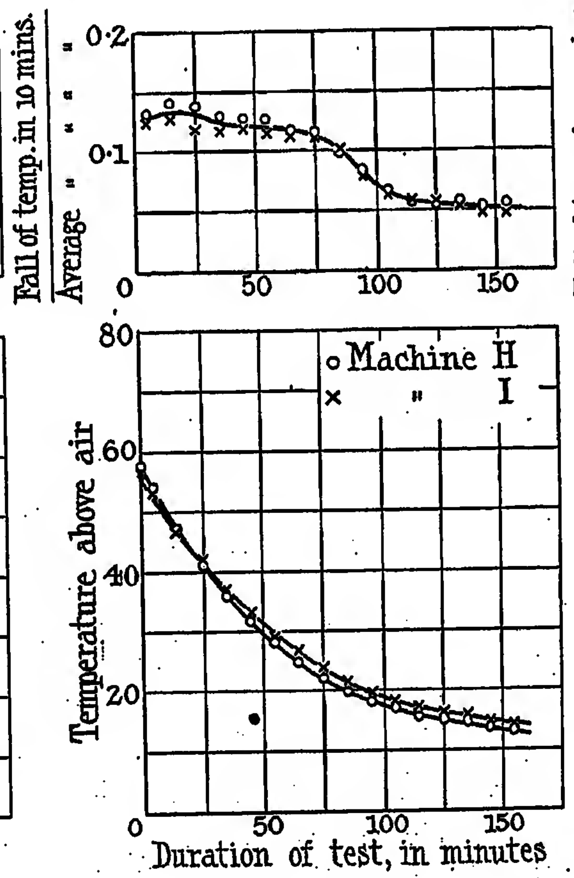

FIG. 4.

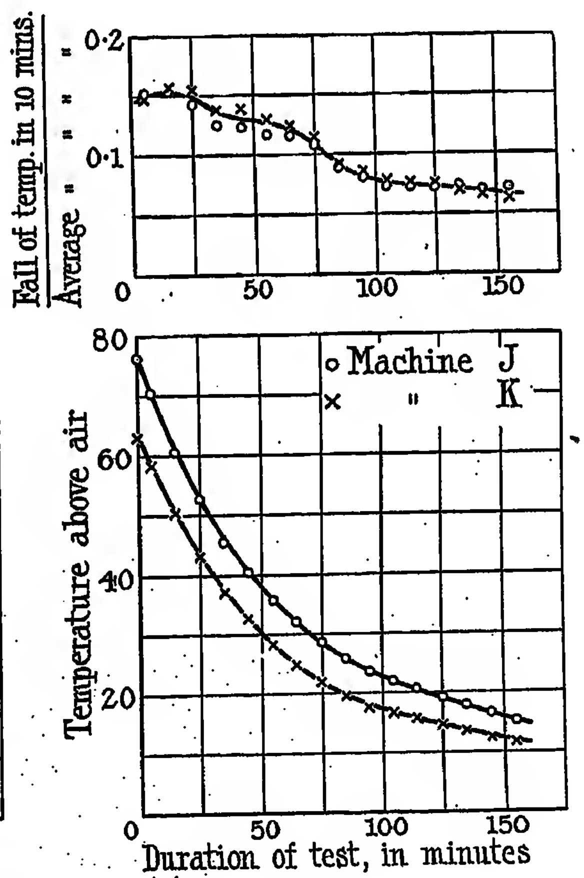

FIG. 5.

constant voltage, the difference being greater the higher the temperature-rise.

(*e*) The value of T, namely the time taken to attain steady temperature if the rate of heat generation remains at its initial value, is the same when calculated from constant-voltage and constant-current tests.

(*f*) The cooling time-constant is the same as the value of T calculated from the heating time-constant obtained from the constant-voltage or constant-current tests having roughly the same temperature-rise.

3. DISTRIBUTION OF TEMPERATURE IN A COIL.

A good deal of experimental work has already been done on this subject, but in most cases little appears to have been attempted except to give the bare results. In the discussion on Rayner's paper,* Sir Richard Glazebrook dealt fully with the theory of the subject and showed that the curves of temperature distribution should—on certain assumptions—follow the parabolic law; and curves from tests indicate that this is practically correct. He also made approximate calculations to determine various quantities affecting the temperature distribution. It was for the purpose of discovering if these factors could be determined more accurately and consistently that tests were made on coil A, which was fitted with five thermo-junctions of copper-constantan, two of the junctions being placed under and over the outer and inner layers respectively, and the other three junctions $\frac{1}{4}$, $\frac{1}{2}$ and $\frac{3}{4}$ of the distance along the section of the coil. The coil was impregnated after being wound the first time, but, owing to the junctions not having been properly placed, the coil had to be rewound. It was not re-impregnated, however. This probably accounts for the thermal conductivity of the insulation being of the same order as that of unimpregnated coils.

The coil was suspended in air and tested with different currents, and the temperatures of the junctions were measured by a calibrated galvanometer, each test being continued until the temperature became practically constant. The temperature-rise by resistance was also calculated, and in some cases the temperature-rise by thermometer was noted. Several of the tests were repeated to find how nearly the results agreed with each other. The temperature-rise per watt was calculated, and the results are given in Table 2.

The values of the temperature-rise per watt for the thermo-junctions have been plotted in Fig. 6, from

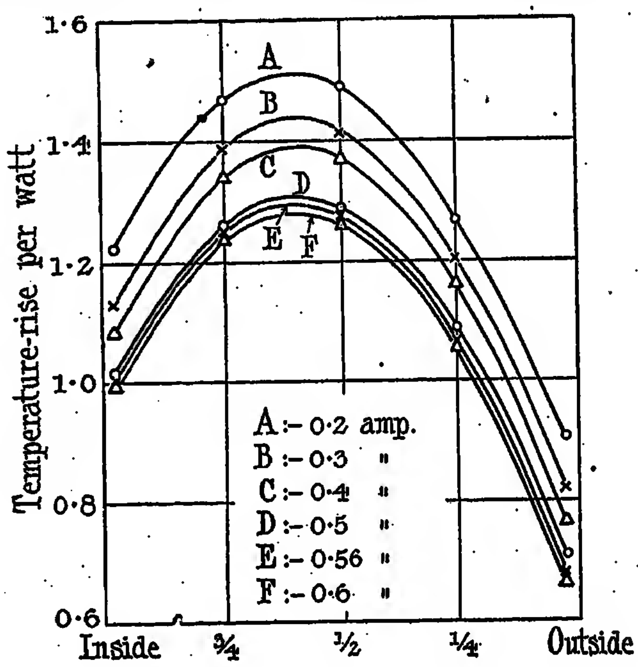

FIG. 6.

which it is evident that the temperature-rise per watt decreases appreciably with increasing values of the temperature-rise, but that the distribution of temperature and, therefore, the thermal conductivity of the insulation are almost independent of the temperature-rise.

The above results will now be analysed on the basis of Glazebrook's theory.

* *Journal I.E.E.*, 1905, vol. 34, p. 613.

If w = power in watts generated per cm³ of the coil,
W = total power generated in coil,
V = volume of coil in cm³,
θ_x = temperature-rise at distance x cm from the line of maximum temperature,
θ_m = maximum temperature-rise,
k = thermal conductivity of coil in watts per cm cube,
k_c = thermal conductivity of copper in watts per cm cube,
k_i = thermal conductivity of insulation in watts per cm cube,
a = depth of copper per cm depth of coil,

then
$$\frac{1}{k} = \frac{a}{k_c} + \frac{1-a}{k_i}$$
$$\therefore\ k_i = \frac{kk_c(1-a)}{k_c - ka} = k(1-a)$$
since ka is small compared with k_c, as shown below.

Thermal conductivity of copper $= k_c = 3\cdot 02$ watts per cm cube.

But the average value of k is about $0\cdot 004$, so that ka is obviously negligible compared with k_c.

By a trial-and-error method, a value of a giving the closest approximation to the values of θ_x/W in Table 2 can be determined for each value of the current. Table 3 gives results typical of those obtained, showing how very closely the test values agree with those calculated from the parabolic law.

It was thought that instead of allowing for the thickness of the insulation on the wire, more consistent values for the effective thermal conductivity might be obtained by taking account of the space factor; thus if

F_s = space factor of copper,
A = sectional area of coil,

and a_e = depth of copper per cm depth of coil for a square wire of equivalent area,

TABLE 3.

Junction	x	Current 0·6 amp.					Current 0·4 amp.				
		a	$\frac{\theta_m}{W}$	$\frac{\theta_m}{W} - ax^2$	θ_x/W by test	θ_x/W by Walker's expression	a	$\frac{\theta_m}{W}$	$\frac{\theta_m}{W} - ax^2$	θ_x/W by test	θ_x/W by Walker's expression
Outside	2·62	0·0911	1·28	0·655	0·662	0·663	0·0931	1·39	0·75	0·764	0·755
$\frac{1}{4}$	1·575	0·0911	1·28	1·053	1·054	1·050	0·0931	1·39	1·159	1·159	1·158
$\frac{1}{2}$	0·45	0·0911	1·28	1·261	1·259	1·26	0·0931	1·39	1·371	1·37	1·369

Inside	1·72	0·0911	1·28	1·01	0·996	1·0	0·0931	1·39	1·114	1·082	1·108

It was shown by Glazebrook that
$$\theta_m - \theta_x = \frac{w}{2k}x^2$$
$$= \frac{W}{2Vk}x^2 = bx^2$$
where
$$b = \frac{W}{2Vk}$$
or
$$\frac{\theta_m}{W} - \frac{\theta_x}{W} = \frac{x^2}{2Vk} = ax^2$$
where
$$a = \frac{1}{2Vk} = \frac{b}{W}$$

Hence $\theta_x = \theta_m - bx^2$, or $\theta_x/W = (\theta_m/W) - ax^2$.

For the coil under consideration:—

Average depth of coil .. .. = 4·5 cm,
Depth of line of maximum temperature from outside .. = 0·6 × depth of coil,
= 2·7 cm,
Volume of coil .. .. .. = 2 540 cm³,
Diameter of wire (bare) .. = 0·0545 cm,
Diameter of wire (d.c.c.) .. = 0·08 cm,
$$\therefore\ a = \frac{0\cdot 0545}{0\cdot 08} = 0\cdot 68.$$

then Aa_e^2 = total sectional area of copper,
$= F_sA$
$\therefore\ a_e = \sqrt{F_s}$

If k_{ie} = effective thermal conductivity of the insulation (including air space) in watts per cm cube,

then $k_{ie} = k(1 - a_e)$,
$= k(1 - \sqrt{F_s})$.

In order to check the values of the thermal conductivity obtained from coil A, all the curves given by Rayner * that appeared reliable were examined, and the value of $b(= aW)$ giving the nearest approximation to the whole curve was determined in each case.

The values obtained, together with the calculated values of k_i and k_{ie}, are given in Table 4. Rayner's coils are designated by the same figures as in his original paper.

The wires in all the above coils, except 4B, were double-cotton-covered, 4B being single-cotton-covered; and only 2A and 2B had been impregnated.

From the table it is seen that :—

(a) The values of the thermal conductivity of the insulation calculated from the space factor are more consistent than those obtained by simply allowing for the covering on the wire.

* *Loc. cit.*

(b) The value of the effective thermal conductivity of the insulation may be taken approximately as 0·001 for an unimpregnated coil and 0·002 for a coil that is impregnated. The space factor allows—at least to some extent—for the variation in the tightness with which coils may be wound.

The influence of different kinds of insulating coverings on the wire and of impregnation of the coil upon the distribution of temperature was dealt with by Rayner in the *Electrician* (1914, vol. 72, p. 702), but as no dimensions were given it was not possible to subject the results to the above analysis.

An alternative method of calculating the temperature at a distance x from the line of maximum temperature was given by Symons and Walker,* but the expression has been modified slightly in Miles Walker's "Diagnosing of Troubles in Electrical Machines" (page 62).

If θ_a be the air temperature, then using the same symbols as above we can write the expression in the form

$$(\theta_x + \theta_a + 235) = (\theta_m + \theta_a + 235) \cos px$$

where $p = I_x \sqrt{\left(\dfrac{1\cdot 6 \times 10^{-6} \times \sigma \times \beta}{k_i \times 235}\right)}$

σ = copper space-factor,

β = thickness of insulation per cm depth of winding,

$= 1 - \alpha$,

k_i = thermal conductivity of the insulation in watts per cm cube,

$I_x = i \sqrt{\left(\dfrac{l}{l+d}\right)}$

i = current density in amps. per cm^2,

l = length of bobbin in cm,

and d = depth of winding in cm.

The values of θ_x for a number of different coils were calculated from the most suitable values of p and θ_m for each case, and were found to be in close agreement with those given by the thermo-junctions. The figures for coil A with 0·6 and 0·4 amp. are given in Table 3. From the various values of p, the corresponding values of k_i have been calculated by means of the above expression and incorporated in Table 4. The expression,

* *Journal I.E.E.*, 1912, vol. 48, p. 694.

however, is much more cumbersome than that of Glazebrook.

The value of β may be determined (*a*) by allowing for the thickness of the covering on the wire, (*b*) by finding the total depth of copper from the number of layers and the diameter of the wire, or (*c*) by calculating the effective thickness of the insulation from the space factor of the copper as referred to on page 633. Unfortunately, these three methods when applied to the coils under consideration give inconsistent results, as will be seen from Table 5.

TABLE 5.

Values of β.

Coil	First method	Second method	Third method
A	0·32	0·516	0·518
B	0·216	0·269	0·345
2A and 2B	0·157	0·148	0·262
4B	0·129	0·232	0·326
5	0·10	0·106	0·222
7B and 7C	0·12	0·18	0·347
8A and 8B	0·116	0·288	0·293

The third method would be expected to give a larger value than those obtained from the first and second methods. The second method appears to be the least consistent; consequently the values of the thermal conductivity have been based on the first and third methods, i.e. the values of k_i in Table 4 are based upon the values of β given in the first column of Table 5, whilst those of k_{ie} are based upon the last column of Table 5.

A comparison of the values of k_i and k_{ie} given in Table 4 indicates that those for k_{ie} are more consistent than those for k_i. It also shows that the values of k_i calculated by the parabolic law are a little more consistent than those based upon the formula suggested by Miles Walker.

It follows from the above table that the temperature-rise at a distance x from the line of maximum temperature is given fairly closely by the expression

$$\theta_x = \theta_m - \frac{W}{2Vk}x^2$$

$$= \theta_m - \frac{W}{2V} \times \frac{1 - \sqrt{F_s}}{k_{ie}}x^2$$

where $k_{ie} = 0{\cdot}001$ for unimpregnated coils with cotton-covered wire,

$= 0{\cdot}002$ for impregnated coils with cotton-covered wire.

This expression may be still further simplified thus :—

$$\frac{W}{V} = \frac{I^2R}{lA} = \frac{I^2\rho lN}{a} \times \frac{F_s}{lNa}$$

$$= i^2\rho F_s$$

where l = mean length per turn,

i = current density in amps per cm^2,

ρ = specific resistance of copper at average temperature of coil, and may be taken as 2 microhms per cm cube.

Hence $\theta_x = \theta_m - \frac{1}{2}i^2 \times 2 \times 10^{-6}F_s \times \frac{1 - \sqrt{F_s}}{k_{ie}}x^2$

$= \theta_m - 10^{-3} \times i^2F_s(1 - \sqrt{F_s})x^2$ for unimpregnated coils with cotton-covered wire,

$= \theta_m - \frac{1}{2} \times 10^{-3}i^2F_s(1 - \sqrt{F_s})x^2$ for impregnated coils with cotton-covered wire.

4. Relation between the Maximum and the Mean Temperatures.

If the temperature distribution between the outside and inside of a coil be assumed parabolic, i.e. $\theta_x = \theta_m - bx^2$, and if d be the depth of the coil in cm, and x_1 and x_2 be the distances from the line of maximum temperature to the outside and inside respectively, then $d = x_1 + x_2$, and the average temperature across the section is given by :—

$$\theta_{av.} = \frac{1}{x_1 + x_2}\int_{-x_2}^{x_1}(\theta_m - bx^2)dx$$

$$= \theta_m - \frac{b}{3}\left(\frac{x_1^3 + x_2^3}{x_1 + x_2}\right)$$

$$\therefore \theta_m - \theta_{av.} = \frac{b}{3}\left(\frac{x_1^3 + x_2^3}{x_1 + x_2}\right) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

From this expression Table 6 has been calculated for the various coils already considered.

The majority of the values for $(\theta_m - \theta_{av.})$ calculated from the above expression are much smaller than those obtained by subtracting the temperature-rise by resistance from the maximum temperature-rise by thermo-couples. That this should be the case is evident from most of the curves given by Rayner for thermo-couples placed longitudinally along the line of maximum temperature. Most of the curves thus obtained were parabolic and indicate that some heat at least was being dissipated from the cheeks of the coils. They also showed that the difference of temperature between the centre and the ends of the coils depends to some extent upon the ratio of the length to the depth of the coil. To allow for this factor in some way, the calculated values of $(\theta_m - \theta_{av.})$ have been multiplied by $\sqrt{(l/d)}$ to give the figures in the last column of Table 6. Most of the values agree fairly well with the values deduced from the tests. It should be mentioned that there appeared to be a discrepancy in some of Rayner's readings for the temperature-rise by resistance.

It has been observed that in the majority of coils the line of maximum temperature is at about 0·6 of the depth from the outer surface, so that

$$\theta_m - \theta_{av.} = \frac{b}{3}0{\cdot}28d^2 = \frac{W}{2Vk} \times \frac{0{\cdot}28}{3}d^2$$

$$= 0{\cdot}0467\frac{W}{V} \times \frac{d^2(1 - \sqrt{F_s})}{k_{ie}} \quad . \quad . \quad (2)$$

But it has already been shown that

$$\frac{W}{V} = i^2 \rho F_s$$

$$\therefore\ \theta_m - \theta_{av.} = \tfrac{1}{2} i^2 \times 2 \times 10^{-6} F_s \frac{1 - \sqrt{F_s}}{k_{ie}} \times \frac{0 \cdot 28}{3} d^2$$

$$= 0 \cdot 1 \times 10^{-6} \frac{i^2 d^2 F_s (1 - \sqrt{F_s})}{k_{ie}} \quad . \quad . \quad (3)$$

To show how the values derived from Equations (1), (2) and (3) agree with each other, Table 7 has been compiled, mainly from the data in Rayner's paper.

A comparison of the different columns shows that the values calculated by the three expressions agree moderately well, and when multiplied by such a factor as $\sqrt{(l/d)}$ they give approximately the difference between the maximum temperature-rise and the temperature-rise measured by resistance. Since Equation (3) is undoubtedly the simplest to apply in the majority of cases, we can state that :—

Maximum temperature-rise — Average temperature-rise

$$= i^2 d^2 F_s (1 - \sqrt{F_s}) \sqrt{\frac{l}{d}} \times 10^{-4}$$

for unimpregnated coil with cotton-covered wire,

and $$= 0 \cdot 5 i^2 d^2 F_s (1 - \sqrt{F_s}) \sqrt{\frac{l}{d}} \times 10^{-4}$$

for impregnated coil with cotton-covered wire.

The factor 10^{-4} can be eliminated by expressing the current density in amperes per mm².

5. Variation of Temperature-rise per Watt with Temperature-rise.

The figures given in Table 2 show that the higher the temperature-rise, the lower the temperature-rise per watt. This result has also been observed by other experimenters. For instance, curves were given by Lister * for six different field coils, the temperature-rise being measured by resistance. Coils I, II, III and IV were suspended in air, whilst coils V and VI were on their machines, the armatures of which were stationary. These curves have been analysed and found to agree very closely with the expression:—

Temp.-rise per watt per dm² of total surface

$$= \frac{\theta A}{W} = \frac{c}{1 + a\theta}$$

where c and a have the following values :—

	Coils I and IV	Coils II and III	Coil V	Coil VI
c	17·5	19·55	16·25	20·2
a	0·0036	0·0038	0·0023	0·0033

The values of the temperature-rise per watt (by resistance) given in Table 2 have also been analysed in a similar way, and are found to be represented by

$$\frac{\theta}{W} = \frac{1 \cdot 35}{1 + 0 \cdot 005\theta} \quad . \quad . \quad . \quad . \quad . \quad (4)$$

or $$\frac{\theta A}{W} = \frac{22 \cdot 5}{1 + 0 \cdot 005\theta}$$

where A represents the total surface of the coil, namely, 16·7 dm².

On page 645 are given the results derived from tests on six different machines with their armatures stationary, for which the value of a in the above expression is found to vary from 0·0026 to as much as 0·03, the larger values being obtained for the open-type machines.

It is of interest to compare the above results with those obtained by other investigators. Let us first consider Stefan's law of radiation, viz. :—

Heat lost per sec. $\propto (T_2^4 - T_1^4)$

i.e. $$W = \frac{1}{k}(T_2 - T_1)(T_2 + T_1)(T_2^2 + T_1^2)$$

where T_2 = absolute temperature of the hot body,
T_1 = absolute temperature of the air,
and k = a constant for a given surface.

Then temperature-rise per watt

$$= \frac{\theta}{W} = \frac{T_2 - T_1}{W}$$

$$= \frac{k}{(T_2 + T_1)(T_2^2 + T_1^2)}$$

The best value of k for coil A is found to be 1·4; then taking the air temperature as 15° C. we have

$$\frac{\theta}{W} = \frac{1 \cdot 4}{(T_2 + 288)\{T_2^2 + (288)^2\}} \quad . \quad . \quad . \quad (5)$$

The values derived for coil A from this expression are given in Table 8. It is found, however, that these values are practically the same as those given by

$$\frac{\theta}{W} = \frac{1 \cdot 4}{1 + 0 \cdot 006\theta}$$

Flack, Griffiths and Hill,* in a paper on "Rate of Loss of Heat," gave the following expression for the cooling effect of still air :—

Watts per dm² of total surface

$$= 0 \cdot 027(1 + 0 \cdot 002\theta_a)\theta^{5/4}$$

where θ_a = air temperature,
and θ = temperature-rise.

The effect of θ_a can be neglected in the present discussion since the air temperature was always within the limits of 12° C. and 20° C.; hence this expression may be modified thus :—

$$\text{Temperature-rise per watt} = \frac{\theta}{W} = \frac{k_1}{\theta^{1/4}} \quad . \quad . \quad (6)$$

where k_1 is a constant for a given surface.

The results calculated from this expression after

* *Journal I.E.E.*, 1907, vol. 38, p. 399.

* See *Electrician*, 1915, vol. 76, p. 411.

having determined the best value of k_1 for coil A, namely 2·84, agree fairly closely with those obtained from test, as will be seen from Table 8.

In an article* on "Heat Losses in Heat Transmission," W. L. Cathcart refers to Peclet's empirical formulæ based on tests for temperature-rises between 25° C. and 65° C. with an average air temperature of 12° C. The heat loss due to contact of the air with surface of coil was found to be proportional to $\theta^{1\cdot 23}$, a result practically identical with the expression just dealt with. The loss of heat by radiation was found to be proportional to $(b^\theta - 1)$,

that is $$W = m(b^\theta - 1)$$

where b = a constant (1·0077 for metric units), m = a factor depending upon the nature of the surface.

This expression can be written thus :—

$$W = m\{(1 + 0\cdot 0077)^\theta - 1\}$$
$$= m\theta \times 0\cdot 0077[1 + \tfrac{1}{2}(\theta - 1)0\cdot 0077]$$

for the range of θ permissible in windings.

$$\therefore \frac{\theta}{W} = \frac{m_1}{1 + \frac{1}{2}(\theta - 1)0\cdot 0077}$$
$$\equiv \frac{m_1}{1 + 0\cdot 00385\theta}$$

This is obviously of the same form as Equation (4) above; and the coefficient 0·00385 agrees very closely with the values calculated for Lister's coils I to IV.

TABLE 8.

Values of θ/W.

θ° C.	From curve of test-results	From (4)	From (5)	From (6)
20·45	1·238	1·225	1·26	1·338
35·65	1·14	1·148	1·16	1·17
57·5	1·05	1·049	1·045	1·033
69·3	0·995	1·002	0·985	0·985
79·9	0·962	0·964	0·933	0·951

By comparing the figures deduced from the different expressions, it is seen that those based upon the simple expression

$$\frac{\theta}{W} = \frac{c}{1 + a\theta}$$

are nearer the actual values in the particular case considered, namely a coil suspended in air. The different values of a that have been observed for field coils in position on the poles is probably due to the heat being dissipated from a number of different surfaces, such as the external surfaces of the coil, the exposed surfaces of the poles and yoke, etc., all of which are at different temperatures. Also, the relative amounts of heat dissipated by these different surfaces vary with the type of machine.

* *Cassier's Magazine*, December, 1915.

6. Effect of Forced Draught upon Temperature-rise of a Coil.

Coil B was enclosed in a wooden box with holes, one at each end. A fan was fitted at one end to draw the air over and around the coil, the velocity of the air being measured at the input end by means of a Negretti and Zambra anemometer. A mesh was placed over the inner end of the inlet pipe to reduce any air eddies that might be formed.

The coil had 36 layers, and thermo-junctions were arranged: 1, 8, 9, 9, 8, 1. Temperature readings were taken for different air velocities, and the temperature-rise after 3 hours was determined in each case. The temperature-rise per watt was then calculated, the values being plotted in Fig. 7.

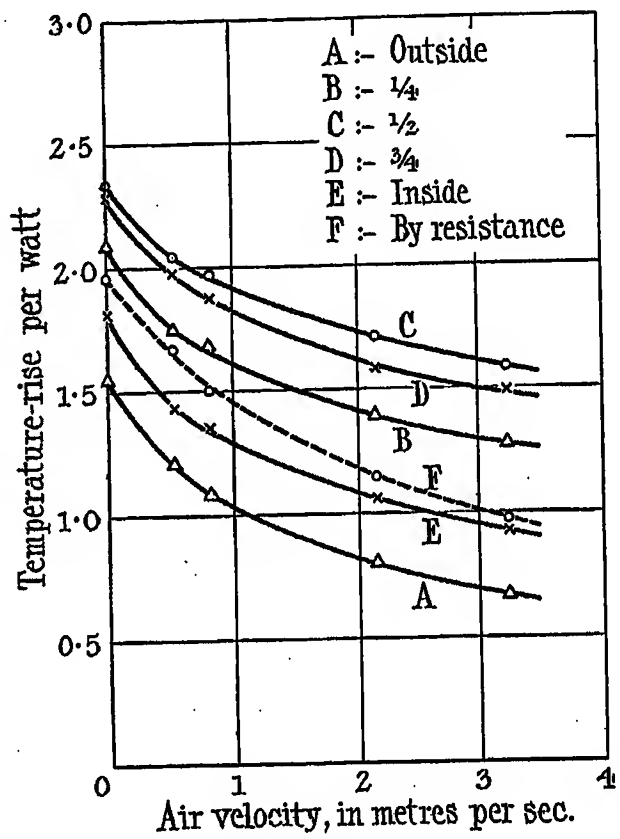

FIG. 7.

From the curve for temperature-rise by resistance it is found that

$$\frac{\theta}{W} = \frac{1\cdot 96}{1 + 0\cdot 325v}$$

where v = inlet velocity of air in m/sec.; and temperature-rise per watt per dm² $= \dfrac{\theta A}{W} = \dfrac{5\cdot 44}{1 + 0\cdot 325v}$, since $A = 2\cdot 78$ dm² for *external* cylindrical surface of coil.

For the outside thermo-junction we have.

$$\frac{\theta_0 A}{W} = \frac{4\cdot 28}{1 + 0\cdot 44v}$$

whilst for the centre of the coil the curve for $(\theta_m A)/W$ is intermediate between

$$6\cdot 56/(1 + 0\cdot 18v) \quad \text{and} \quad 6\cdot 56/(1 + 0\cdot 25\sqrt{v})$$

These results show that the temperature-rise of the

outside of a coil ventilated in the above manner is relatively much more affected than that of the centre of the coil.

An arrangement shown diagrammatically in Fig. 8 was next constructed, whereby the air could be made to impinge at a high velocity at four points on the surface of the coil, the velocity again being measured by an anemometer. The diameter of the tube where the velocity was measured was 7·5 cm in both of these experiments, so that the volume of air per second was 0·00442 × velocity in m/sec. As the total area of the nozzles was about 3·5 cm², the velocity of the air at the nozzles was 12·6 times that measured.

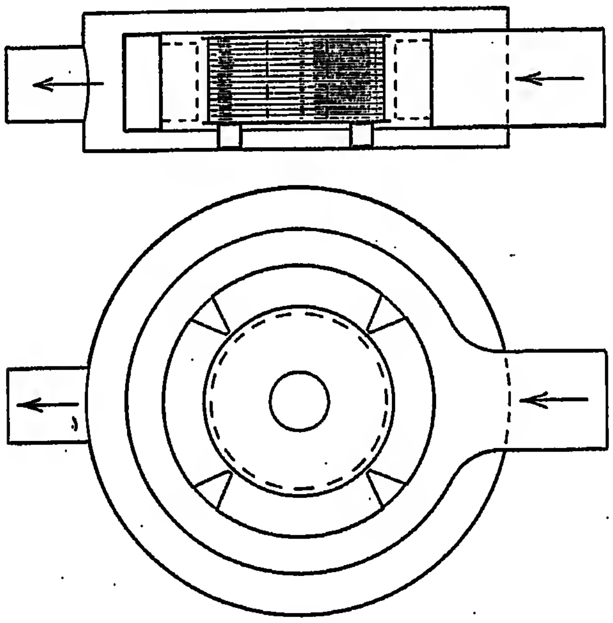

FIG. 8.

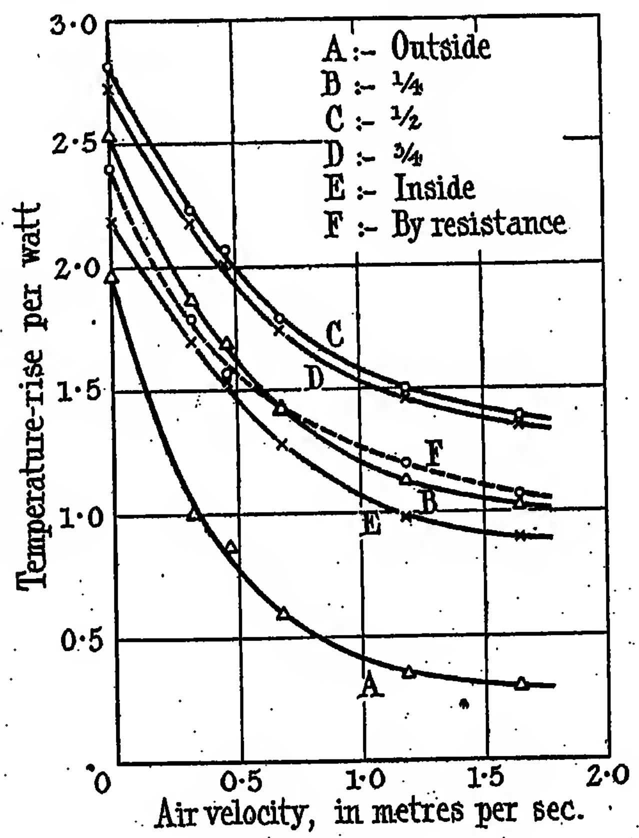

FIG. 9.

The results are plotted in Fig. 9, from which it is seen that for velocities up to about 1 m/sec. the temperature-rise per watt decreases very rapidly.

The curve for the temperature-rise by resistance is found to be intermediate between

$$\frac{\theta A}{W} = \frac{6\cdot67}{1 + 0\cdot86v} \quad \text{and} \quad \frac{\theta A}{W} = \frac{6\cdot67}{1 + 0\cdot935\sqrt{v}}$$

v being the velocity actually measured.

For the outside thermo-junction the temperature-rise agrees fairly closely with

$$\frac{\theta_0 A}{W} = \frac{5\cdot44}{1 + 4v^{1\cdot5}}$$

and the maximum temperature-rise is given approximately by

$$\frac{\theta_m A}{W} = \frac{7\cdot8}{1 + 0\cdot75v}$$

It may again be stated that A in the above expressions is the external cylindrical surface only.

A comparison of the results obtained in the above tests indicates the great improvement that may be effected by arranging for the air to impinge at a high velocity on the surface to be cooled, but that there is not much advantage in increasing the velocity beyond a certain value.

In the paper by Symons and Walker already referred to, curves are given for the temperature-rise of a coil and of a brass cylinder for different air velocities up to 3·5 m/sec., the results being expressed by

$$\frac{\theta A}{W} = \frac{9\cdot1}{1 + 0\cdot78v^2} \text{ (for brass cylinder)},$$

$$= \frac{9\cdot1}{1 + 0\cdot54v^2} \text{ (for coil of cotton-covered wire)}.$$

In these tests the air was blown on to the coil from two diametrically opposite sides; also the cylinder and coil were comparatively shallow.

On the other hand, Flack, Griffiths and Hill found the cooling effect of wind for velocities up to 15·6 m/sec. to be given by

$$\frac{\theta A}{W} = \frac{8\cdot8}{1 + 2\sqrt{v}}$$

whilst J. A. Hughes, in dealing with "Cooling of Cylinders in Stream of Air," * gives the loss of heat from different cylindrical tubes at 100° C. as proportional to v^n, where n varies between 0·55 for the smallest cylinder and 0·98 for the largest.

The above results are sufficient to show how the effect of air velocity may vary considerably with the manner in which the air impinges on a coil, and with the depth and the perimeter of the coil. It would appear that the only satisfactory method of deducing a reliable formula is from tests on a coil or a machine as similar as possible to the one under consideration.

7. A New Arrangement for Measuring the Average Temperature-rise of Field Windings.

The usual method of measuring the average temperature-rise of a winding is to determine by the voltammeter method or by a Post Office box the resistances

* *Philosophical Magazine*, 1916, ser. 6, vol. 31, p. 118.

R_1 and R_2 when cold and hot, respectively. Then if θ_1 and θ_2 be the initial and final temperatures respectively,

$$(\theta_2 - \theta_1) = (234 \cdot 5 + \theta_1)\frac{R_2 - R_1}{R_1}$$

The Post Office box method has the disadvantage that readings cannot be taken without stopping the machine, and even if this is done fairly quickly the temperature may have changed appreciably in the interval. Furthermore, there is always the liability of applying excessive voltage to the resistance box. The volt-ammeter method in the hands of an experienced person gives reasonably good results if the supply voltage is perfectly steady. If the voltage is fluctuating it is almost impossible to obtain reliable figures, and it was with the object of overcoming this difficulty that the author tried other arrangements and found the following method to work extremely satisfactorily.

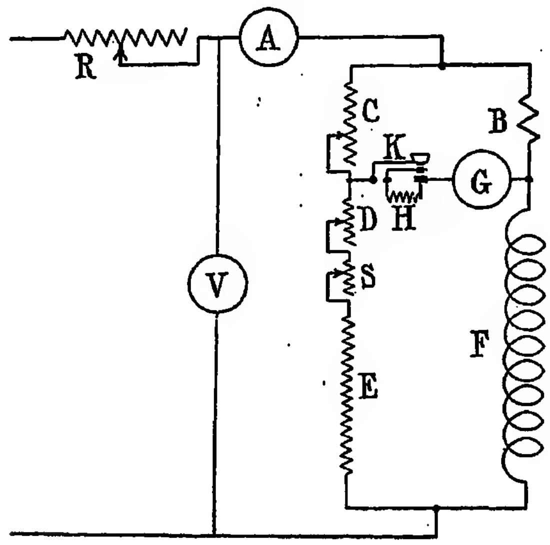

FIG. 10.

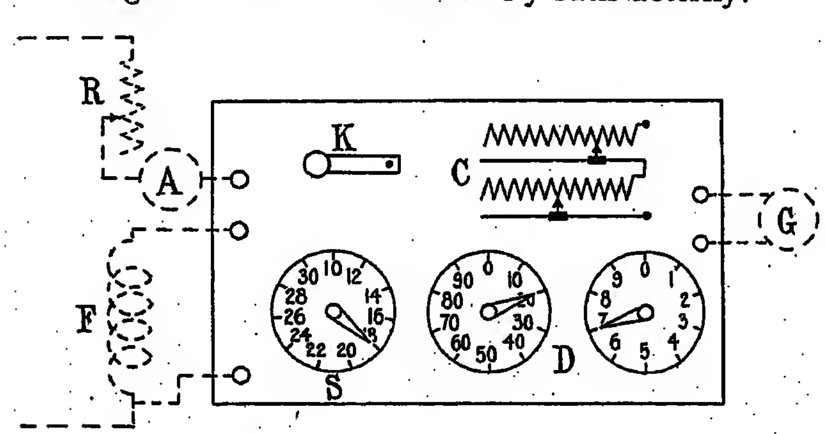

FIG. 11.

The connections are shown in Fig. 10, and Fig. 11 gives the appearance of the apparatus as constructed. F is the shunt winding and R the shunt regulator. E is a resistance of 3 000 ohms, B a shunt of about 0·5 ohm, C a variable resistance, and D a resistance arranged with two dials, the values of the steps being calculated so that the dials give the temperature-rise directly. S is a compensating resistance to allow for variations of the initial temperature. Dial S in Fig. 11 is arranged in steps of 2 degrees C. between 10° C. and 30° C. This subdivision reduces to quite a negligible amount any error due to variation in the initial temperature.

A table galvanometer G is controlled by a key K, H being merely a high resistance to protect G at the commencement of the test.

With D on zero, and S on the stud nearest to the air temperature, the supply is switched on and C adjusted to give zero reading on G. As the resistance of F increases due to rise of temperature, resistance is inserted at D to bring G back to zero.

$$\text{Then} \qquad \frac{R_1}{E+S} = \frac{B}{C} = \frac{R_2}{E+S+D}$$

$$\therefore \frac{R_2 - R_1}{R_1} = \frac{D}{E+S}$$

$$\text{But} \qquad \theta_2 - \theta_1 = (234 \cdot 5 + \theta_1)\frac{R_2 - R_1}{R_1}$$

$$= (234 \cdot 5 + \theta_1)\frac{D}{E+S}$$

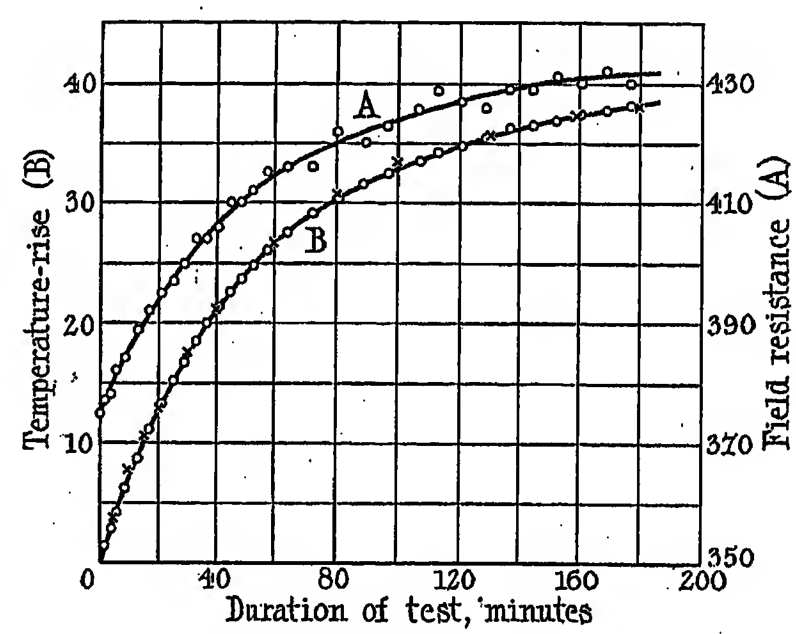

FIG. 12.

When $\theta_1 = 10°$ C., $S = 0$ (10° C. being the minimum air temperature allowed for); and if $\theta_2 - \theta_1 = 10°$ C. we have

$$D = \frac{3\,000 \times 10}{244 \cdot 5} = 122 \cdot 8 \text{ ohms}$$

Hence the resistance per degree C. = 12·28 ohms.

The resistances for dials D have been based on this figure.

In order that S may compensate for the different air temperatures at the commencement of the heating tests, we must have

$$\frac{234 \cdot 5 + \theta_1}{E+S} = \frac{244 \cdot 5}{E}$$

$$\therefore S = \frac{(\theta_1 - 10)E}{244 \cdot 5}$$

Since the dial of S has been arranged for steps of 2 degrees C., the resistance per step = 2 × 3 000/244·5 = 24·56 ohms.

Any variation in the air temperature during a test may be allowed for by moving S to the new air temperature or by correcting the temperature-rise indicated by D.

When the above method was first tried, an ordinary resistance box was used for D, the temperature-rise being calculated from the expression

$$\theta_2 - \theta_1 = \frac{(234 \cdot 5 + \theta_1)}{3\ 000} \times \text{resistance of D}$$

and the results were compared with those calculated from the volt-ammeter readings. Curve A in Fig. 12 shows how difficult it is to obtain consistent values of resistance, although the readings in this test were taken very carefully; the supply voltage, however, was fluctuating quite appreciably. The points marked with a cross on curve B were calculated from the curve drawn through the mean of the resistance points, whilst those indicated by a circle were calculated from the readings obtained by the bridge method just described. Had the temperature-rise been calculated from the actual resistances as measured by the volt-ammeter method, the results would have been much less consistent than the values of the resistance plotted in curve A.

outside thermo-junction (inserted under the outer layer of the coil) have been plotted against armature currents in Fig. 13, and the curves show clearly that the greater

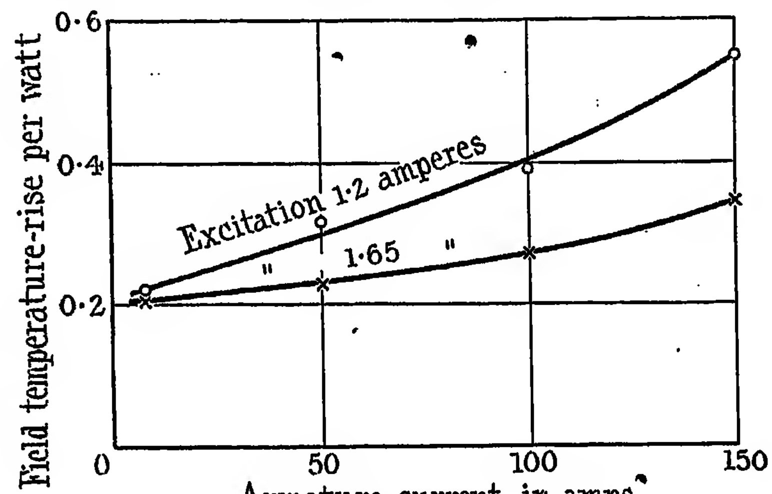

Fig. 13.

cooling effect of the higher speed is much more than counterbalanced by the heating effect of the armature losses, especially at low excitations. Since no data were given concerning the losses, it was not possible to proceed further with the analysis of these results.

Table 9.

Number of test	Peripheral speed	Field current	Armature current	Temperature of outside junction after 3 hours	Corresponding air temperature	Temperature-rise	Field watts	Temperature-rise per watt
	m/sec.	amps.	amps.	°C.	°C.	deg. C.		deg. C.
1	23·56	1·2	8	24·9	18·6	6·3	28·82	0·218
2	17·9	1·65	8	29·9	18·5	11·4	55·14	0·2065
4	23·56	1·2	50	30·5	21·2	9·3	29·43	0·316
5	17·9	1·65	50	34·0	21·0	13·0	56·87	0·2285
7	23·4	1·2	100	31·8	20·2	11·6	29·6	0·392
8	17·9	1·65	100	37·2	21·4	15·8	58·2	0·2715
9	22·9	1·2	150	33·4	17·1	16·3	29·8	0·547
10	17·9	1·65	150	37·1	17·1	20·0	58·2	0·344

It will now be realized that this bridge method enables the temperature-rise of the field to be determined while the machine is running, with a far greater degree of reliability than the usual method, and that its readings are not affected by a fluctuating supply voltage.

8. Heating Tests on Field Coils of Nine Different Machines.

In a paper on "Distribution and Rise of Temperature in Field Coils," * it was submitted that the higher the peripheral speed of the armature the greater the temperature-rise of the field. Such a conclusion was almost obviously wrong. Unfortunately, many of the figures given in Table 2 of the above paper do not agree with the curves, and Table 9 has accordingly been compiled from the data available.

The values of the temperature-rise per watt for the

* *Journal I.E.E.*, 1915, vol. 53, p. 526.

The results of further investigations on field coils by Maclean and Mackellar appeared in the *Electrician* (1917, vol. 79, pp. 465 and 500), the principal conclusions being :—

(*a*) The temperature-rise is given by

$$\theta = \frac{\theta_s}{1 + bv^n}$$

where θ_s = temperature-rise with armature stationary.

When $\theta_s = 29 \cdot 7$ for the machine tested, $b = 0 \cdot 451$ and $n = 0 \cdot 58$, and when $\theta_s = 14 \cdot 8$ for the machine tested, $b = 0 \cdot 644$ and $n = 0 \cdot 39$.

(*b*) The heating coefficient $K (= \theta A/W)$ increases a little with armature current, the effect being more pronounced with low field currents.

(*c*) The ratio (maximum temperature) : (mean temperature) is practically independent of the speed and of the armature current, whilst the ratio (mean tem-

perature) : (surface temperature) is independent of armature current for a given speed, but rises rapidly as the velocity is increased from standstill.

loss upon the field temperature was not realized, and consequently no record was made of the armature temperature. The machines were run on no load in

It was with the object of investigating this problem more completely and of comparing the results for different types of machines that the following tests were conducted. At the time, the effect of the armature loss upon the field temperature was not realized, and consequently no record was made of the armature temperature. The machines were run on no load in practically all the tests; and as the iron losses for the machines had been determined very carefully it has been found possible to take into account the effect of armature loss.

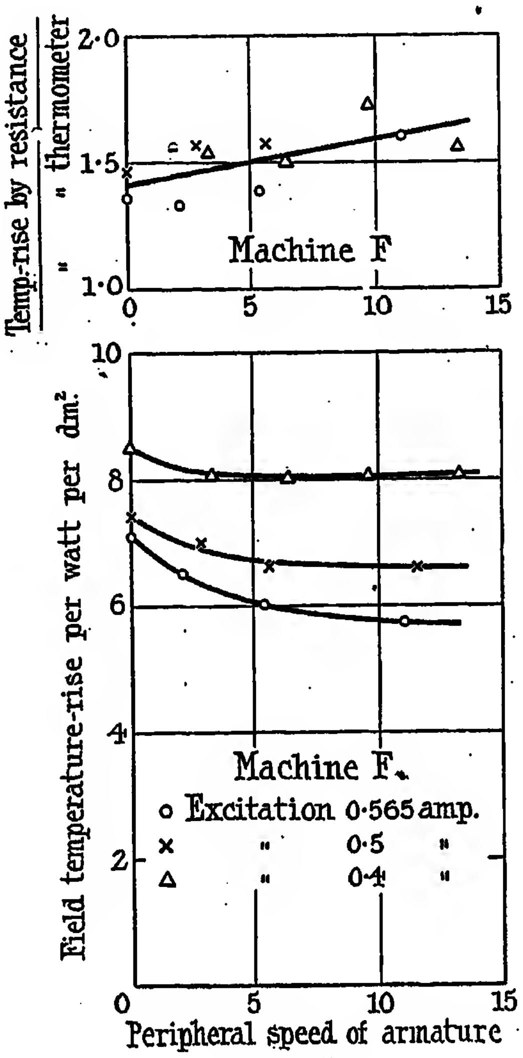

FIG. 14.

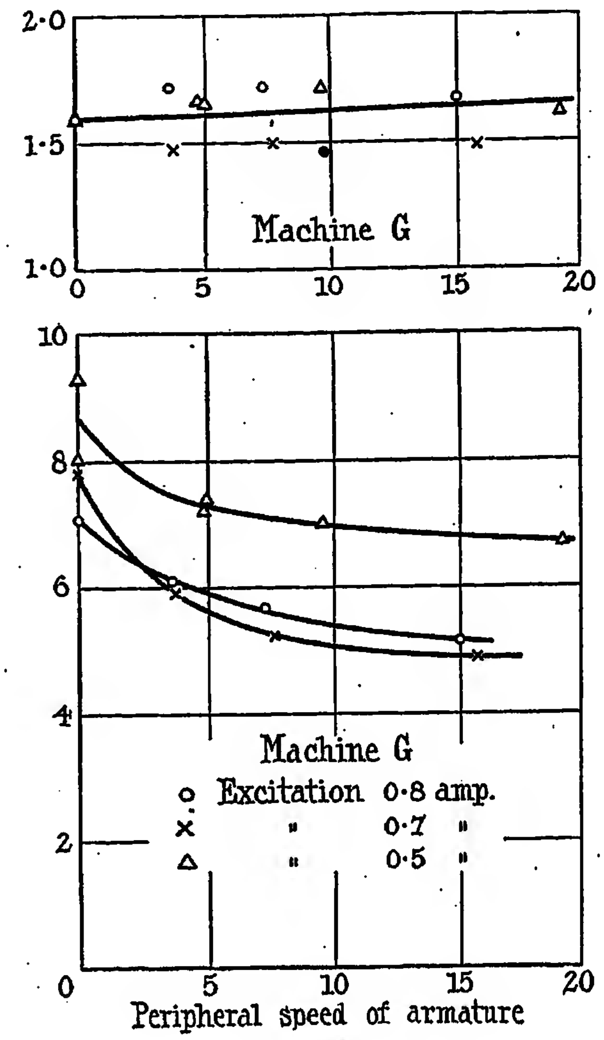

FIG. 15.

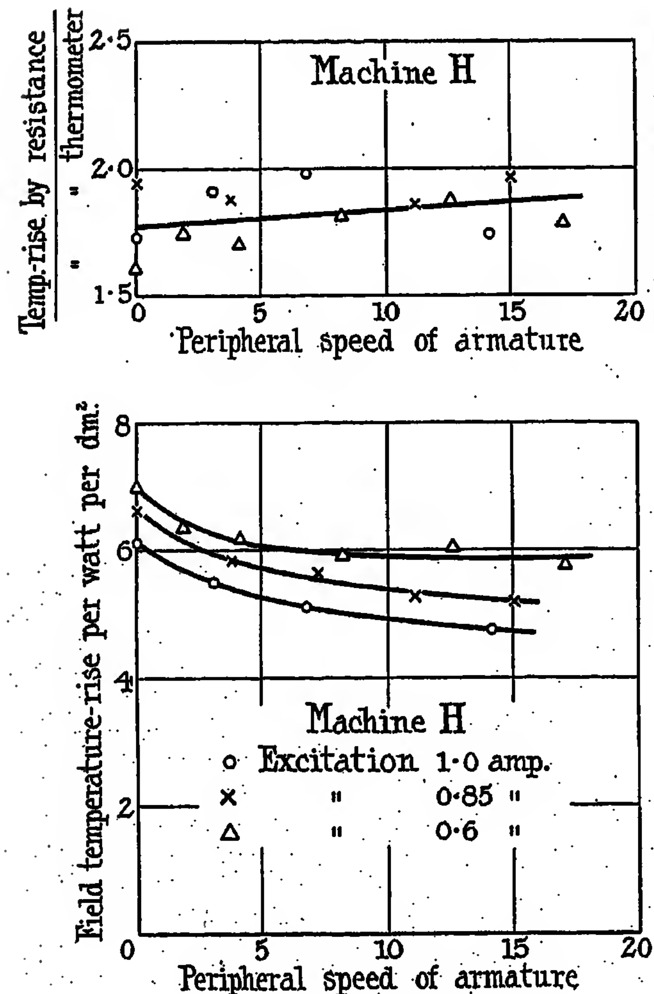

FIG. 16.

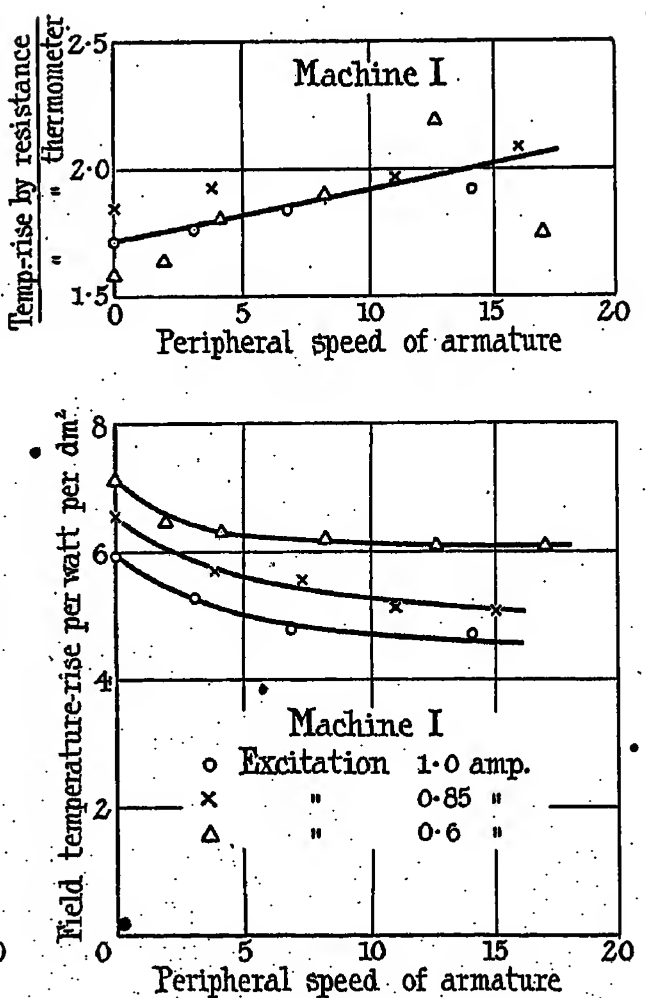

FIG. 17.

The temperature-rise of the field windings for all the machines except C, D and E was determined by the volt-ammeter method, but for these three machines the bridge method described on page 640 was employed. In most cases the final temperature-rise of the field coils on one of the upper poles was measured by a thermometer, the latter being placed on the surface facing another main pole or commutating pole and protected by cotton waste. All the thermometer readings were taken immediately after stopping the machines.

Table 10 gives the results obtained on these tests, and the curves in Figs. 14 to 19 show how the temperature-rise per watt per dm² varies with the speed for machines F to K. These curves were thought to be of the form represented by

$$\frac{\theta_f A_f}{W_f} = \frac{k}{1 + a\sqrt{v}} \text{ (where } k \text{ and } a \text{ are constants),}$$

but a closer inspection of the curves—especially those for machines J and K—indicated that the effect of the armature loss must not be neglected, and that the temperature-rise of the field is more correctly represented by

$$\frac{\theta_f A_f}{W_f} = \frac{l(1 + mW_a/A_a)}{1 + nv}$$

where l, m and n are constants for a given machine, v is the peripheral speed of armature in m/sec., and W_a/A_a is the armature loss in watts per dm² of armature surface.

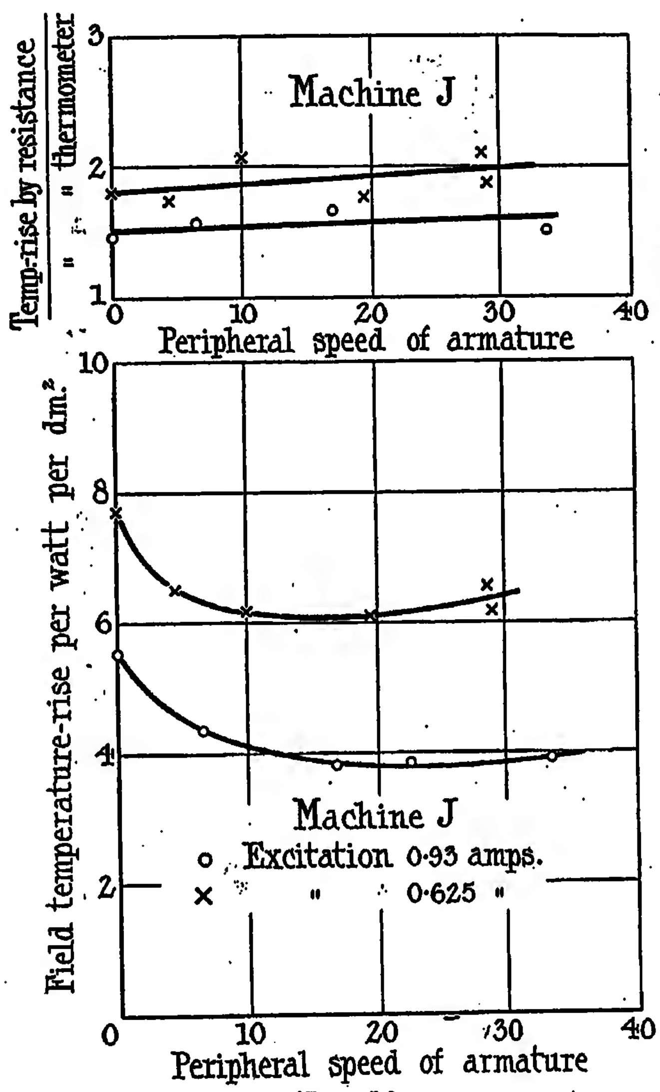

Fig. 18.

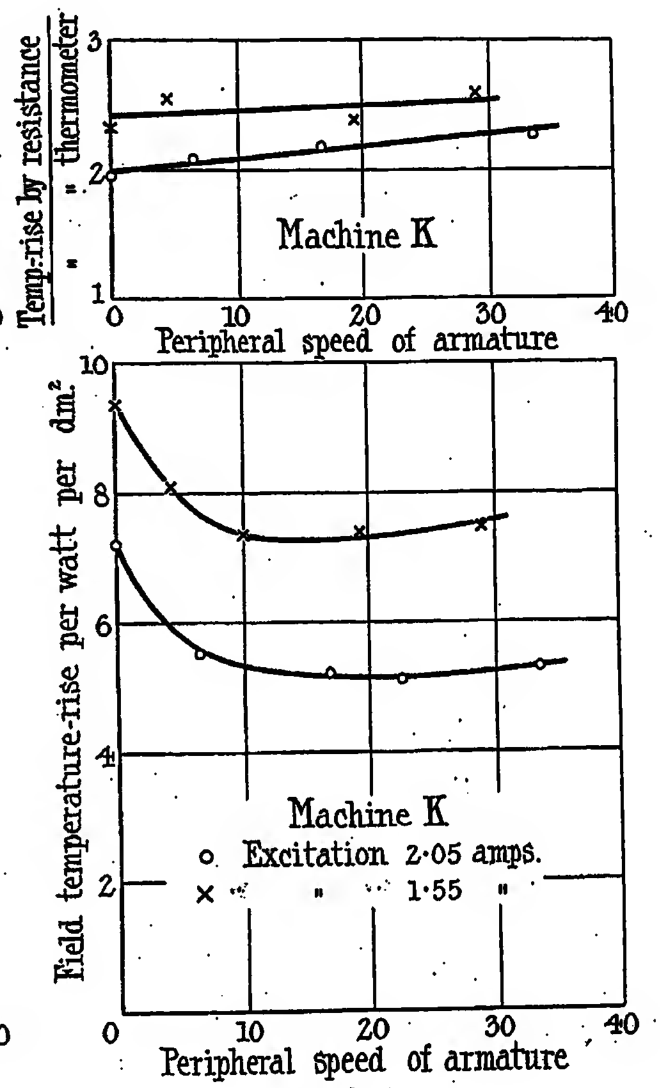

Fig. 19.

The values of l, m and n for the various machines are given in Table 10; and col. (13) shows how closely the values calculated from this expression agree with the values in col. (7) deduced from the test-results.

In order to show how the value of l varies for different machines and for different temperature-rises of a given machine, the curves in Fig. 20 have been drawn. On page 637 it was shown that the temperature-rise per watt per dm² for stationary coils could be expressed in the form

$$\frac{\theta A}{W} = \frac{c}{1 + a\theta}.$$

Applying this expression to the curves in Fig. 20 we have the results given in Table 11.

Table 11.

Machine	c	a
F	11·0	0·00855
G	10·4	0·00546
H	7·76	0·00263
I	8·23	0·00438
J	15·15	0·0242
K	25·5	0·0306

The average value of a for protected-type machines may be taken as 0·005, which is the same as that given

on page 637. For the open-type machines, J and K, the values of a appear to be unduly high, and the values of c are in consequence also very high. The comparatively high values of l for machine K are probably due to the fact that this machine was fitted with a compensating winding which shielded the shunt winding to some extent.

The values of m and n in Table 11 depend upon the

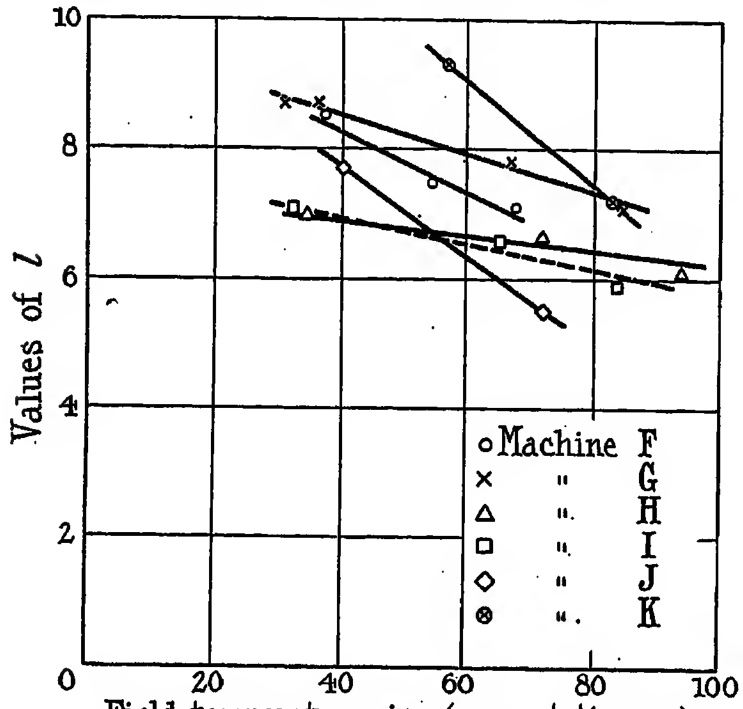

FIG. 20.

arrangement and ventilation of the armature winding, the presence of a fan on the armature, the proximity of the field winding to the armature, the relative temperatures of the field and armature windings, etc. In order to trace the variation of m and n for the different conditions, the ratio m/n has been calculated in Table 10

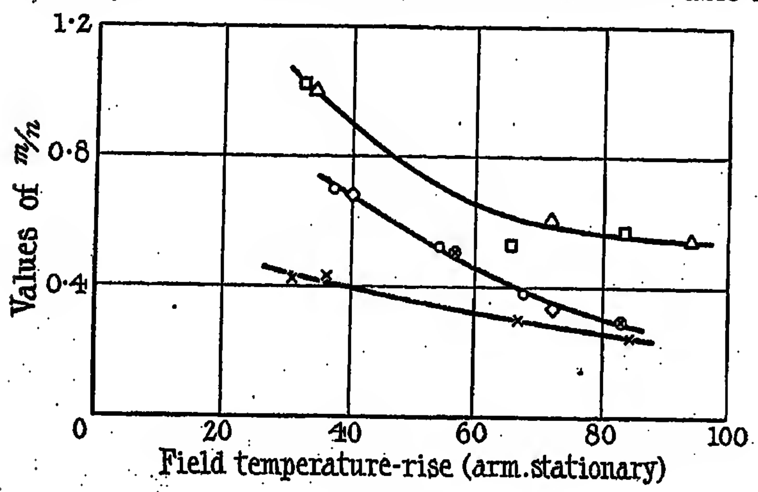

FIG. 21.

and plotted against field temperature-rise in Fig. 21. From these curves it is seen that:—

(a) The lower the temperature-rise of the field, the greater the effect of armature loss in comparison with that of speed.

(b) The effect of fitting an armature with a fan as in machine G is to reduce the ratio m/n, i.e. to make the speed relatively more important than the armature loss. Also, with the open-type machines J and K the ratio is much smaller than for the protected-type machines H and I by the same makers.

(c) The influence of the proximity of the field coils to the armature is very evident by comparing the ratios for m/n given in Table 10 for machines C and D. Each of these machines has a series winding of approximately the same size as the shunt, but in machine D the shunt winding is the nearer to the armature, whilst in the other machine the series winding is the nearer.

(d) The temperature-rise per watt per dm^2 of the field winding of protected-type machines is given approximately by

$$\frac{\theta_f A_f}{W_f} = \frac{7 \cdot 5(1 + 0 \cdot 03 W_a / A_a)}{1 + 0 \cdot 05 v}$$

9. COMPARISON OF TEMPERATURE-RISES BY RESISTANCE AND BY THERMOMETER.

The ratio of temperature-rise by resistance to that by thermometer has been calculated wherever possible in Table 10, and has been plotted in Figs. 14 to 19. There is a certain amount of inconsistency noticeable in some cases, due mainly to the difficulty of taking reliable thermometer readings. The ratio in most cases shows an inclination to increase with increase of speed, probably due to the greater temperature gradient produced in the outer half of the coil by the greater ventilation. The ratio for machine K is decidedly higher than for the other machines, and this may be due to heavier insulation on the field coils owing to the compensating winding being in close proximity. It is not due to an abnormally high temperature gradient in the winding, because it has been shown on page 630 that the effect of the insulating covering on the wire of these coils is much less than in any of the other coils. Also, the coils are shallower than those of machines H, I and J, and all these coils had been thoroughly impregnated (see page 648).

Table 12 has been compiled to show that the ratios obtained above are not abnormally high for coils wound with d.c.c. wire. The data for coils numbered 2A to 8B have been taken from Rayner's paper,* whilst the values for coils R1 to R5 were given by Rayner in the *Electrician*.*

The above figures for the relation between the mean temperature-rise and the temperature-rise measured by thermometer are sufficient to demonstrate the unreliability of the thermometer reading as an indication of either the mean or the maximum temperature-rise of a field winding, though the thermometer method alone is recommended by the British Engineering Standards Association (B.S.S. No. 168). The results given above also indicate that unless the temperature-rise by resistance for taped coils is allowed to be at least 70 per cent greater than that by thermometer, the resistance method is handicapped in comparison with the thermometer method.

The author desires to express his thanks to Prof. F. G. Baily for permission to carry out the tests on coil A and on machines F to K at the Heriot-Watt College, Edinburgh. The tests on coil B and on machines C, D and E were performed at the Brighton Technical College, and the author's thanks are due to Mr. H. A. Ashdown, B.Sc.(Eng.), who did most of the observational work.

† R and C signify "rectangular" and "circular" respectively.

ADDITIONAL PARTICULARS.

(A) Coil wound on a press-spahn former and taped half-lap. Five thermo-junctions were inserted in the positions described on page 632.

(B) Coil wound on a brass former with leatheroid insulation and varnished on the outside. Five thermo-junctions also inserted in the coil in the positions described on page 638.

(C) 5 kW dynamo. Machine has a series field winding of nearly the same size as the shunt, the series winding being side by side with the shunt but nearer the armature.

(D) 3·5 kW dynamo. This machine also has a series field winding of approximately the same dimensions as the shunt, but the series winding in this case is the further away from the armature.

(E) 3·5 kVA three-phase alternator with revolving armature.

(F) 10 b.h.p. shunt interpolar motor. The field coils are impregnated.

(G) 15 b.h.p. shunt interpolar protected-type motor, fitted with a fan at the back of the armature. The field coils are wound with untreated wire, dried in a vacuum and impregnated, after which they are taped and varnished.

(H) 20 b.h.p. shunt interpolar motor direct coupled to a non-interpolar generator I. The field windings are similar except that machine I has a series winding of 32 turns of 3·43 × 3·43 mm wire in two layers on top of the shunt. The makers state that "the field coils are all impregnated *in vacuo*, being placed in a vacuum chamber for 12 hours at a temperature of 180° F. They are then impregnated under a pressure of 35–40 lb. with standard black solid compound, the coils then being completely covered with flexible mica cloth and waterproof tape."

(J) 60 b.h.p. shunt interpolar motor direct coupled to a shunt interpolar generator K. The field coils of both machines were subjected to the same treatment as were H and I. Machine K is fitted with a compensating winding.

DISCUSSION ON "THE CHARACTERISTICS OF A D.C. SERIES MACHINE SELF-EXCITED BY RECTIFIED CURRENT FOR PURPOSES OF REGENERATIVE CONTROL." *

SCOTTISH CENTRE, AT DUNDEE, 25 APRIL, 1924.

Mr. D. H. Bishop: The paper describes a very ingenious method by which a series motor can be transformed at a moment's notice into what is virtually a shunt motor. It has occurred to me that a certain amount of saving in energy consumption would be possible, in connection with tramway work, if, having started up the car by means of motors connected as series motors, they could then be converted into shunt motors. If it is required to run at a constant speed, that could no doubt be done without wasting power in resistance. This would mean that some form of speed regulation would be required, and that is also necessary if the full benefit of regenerative control is to be obtained. I should like to ask the author whether he would put a rheostat in the primary circuit of the transformer or whether he would try to alter the ratio of the latter. Table 1 shows some results obtained with the brushes in various positions. Is there any practical objection to keeping the brushes in, say, position 5, independent of the direction of rotation? I fancy that the difference of potential between the two segments of the rectifier is only a matter of 10 volts at the maximum, and is therefore not likely to be a source of trouble on account of short-circuits across the insulation between segments. There is a very low voltage at the rectifier, and the author mentions that he had to use a considerable pressure on the brushes. I take it that the reason is that the rectifier would not otherwise excite. Does this mean that carbon brushes cannot be used? The use of metal brushes on slip-rings is to be avoided if possible.

Dr. S. Parker Smith: The author has worked out a very ingenious method and has proved the method to be a success. As he would tell us himself, this is by no means the first device that has been developed for regenerating energy from traction motors. Perhaps it would be well to examine very briefly the position of the matter as it stands at the present day, rather than to discuss technical details which the author has already put clearly before us. We are stopping electric trains and tramcars innumerable times a day, and why is it that we waste all the energy? Why is it also that regeneration in regard to main-line work is going out of use? It was introduced and it was thought that a great improvement in efficiency would result. What do we find? In many countries where the conditions are specially suitable for the regeneration of energy the regenerative apparatus has been discarded, because the return was not worth the trouble. The French welcomed regeneration with great enthusiasm; the Italians before them did the same, likewise the Swiss. What has happened? Very often when they got the energy they did not know what to do with it, for there was not a train climbing when another was descending. In many cases the complication and cost are scarcely justified with water power, apart from the practical difficulty of securing some use for the energy. In America better results are claimed—but even there the results are not altogether perfect. Regenerative energy can be bought at too dear a price. To prevent wear and tear on the tyres, on the brake shoes and on the rails, a simple alternative is rheostatic braking, and that is what many people are adopting. Coming to the case of the motor coach, which is starting and stopping every mile or so, and where the cost of energy is a large part of the working cost, a strong case can be made out for regeneration, for even a few per cent in the cost is a good reduction. Here, however, restrictions imposed by the limits of space available render the installation of the essential equipment difficult. As soon as a motor is made to regenerate, the machine may be overloaded. In other words, the motors cannot work also as generators without overheating. That is

* Paper by Dr. R. D. Archibald (see page 288).

one great reason why none of these schemes has come into use on the suburban railways. On the tramcars rheostatic braking is used, and the motors could here be made to regenerate; but it is not needed only when a tramcar descends a hill. The great saving would ensue if the energy could be regenerated while the tramcar is being brought to rest. My criticisms are not directed against the device, but are simply intended to point out some of the practical difficulties to be overcome in adopting regenerative methods.

Mr. A. P. Robertson: Regarding the connections for this method of regeneration, it seems to me that there would be a great many contacts on the controller, which would consequently be much more complicated than it is at present. In practical working, would the motor run as a series motor with the rectifier and transformer always in circuit, or would the field switch be opened at starting, which would make it a plain series motor? I take it that, after the motor is up to speed, the rectifier switch is closed and the field built up as a shunt from the armature, and that the end of the series field is then disconnected from the line and put direct on the brushes of the armature. If that is so, this alone will result in a considerable number of extra contacts. Then, again, the brushes are shown in the neutral position, which is not the best place. The best place is a little in advance, and, as the machine has to run in both directions, the position of the brushes requires to be altered according to the direction of the motor. All this has to be done with one handle, and may call for mechanical connections from the controller to the brush gear. On page 234 the current density on brush 5 is given as 47 amperes per sq. in. at full load (17·5 amperes). That figure was taken on a 5 h.p. motor at 400 volts. On a 600-volt circuit and a 40-h.p. motor, the current would be about 40 amperes, and much larger brushes would be required. The brush pressure is given as 14 lb./sq. in. This is rather high; the usual pressure is nearer 5 lb./sq. in. I think that metal brushes will have to be used to get the requisite current density. The difficulty with the metal brush is lubrication, and there are many methods of oiling. So far we have found that the best method is hand lubrication, but that method could not be applied to the brushes of a tramway motor. I had thought that railways would be ideal for regenerative control because of the long gradients, but from Dr. Parker Smith's remarks it appears that, due to the infrequency of running, regenerative control is not so suitable as on tramways. With tramways there is a large amount of town work. Cars in busy streets move for only a short distance at a time and that very slowly, and the regeneration, to be of any use, would require to be effective at a low speed. On the other hand, on long runs where there are gradients some use might be made of it. What is the lowest speed at which regeneration would be effective by this method?

Mr. W. B. Hird: It appears to be largely a question of the complications necessarily added to the equipment in order to obtain a satisfactory regenerative control. It is difficult to believe that the extensive additions to the equipment proposed in the paper are the simplest and easiest solution of the problem. I do not think that a practical tramway engineer would agree to the proposal that he should add slip-rings and an additional set of brush gear to his motors. I have had a considerable experience of another class of motors, namely coal-cutter motors, where there are very severe restrictions on the space available, and I am therefore fully able to realize the difficulties involved and the sacrifice of existing useful properties which would be involved in finding room for slip-rings and an additional set of brush gear. The complications required are not confined to the motor. The switching arrangements also must be added to, and if it became also necessary to make arrangements for shifting the brushes it appears that the advantages to be gained from regenerative control would be more than outweighed by the complications added to the equipment and the sacrifices required to find space for these additions. Mr. Robertson asked how far the speed could be reduced by means of regenerative control. It is obvious from the speed curves given in the paper that the speed could not be brought down to very low limits by this means, and that the chief gains to be derived from the return of energy to the line would be obtained not at stops but when coasting down hills of some length and of a considerable gradient. In this connection I think that the difference between a tramway service and a railway service has not been sufficiently emphasized. On a railway, it would generally be possible to coast down the hills uninterrupted by any traffic stops; in a tramway system, however, even with considerable gradients in the different routes, free coasting is liable to constant traffic interruptions and therefore loses much of its value. Take, for example, the Glasgow system, which has considerable hills. How often would a car be able in a day's work to run down Renfield-street without several traffic stops interfering with the regenerative process? In spite of the advantages of railways over tramways in this respect, Dr. Parker Smith has told us that regenerative control has been abandoned on several railways where it had been originally used, because the gain was not worth the added complications. Although the author's method is very ingenious, I feel that regenerative control has little, if any, future before it, and it is especially doubtful whether a tramway system would ever derive much benefit from this or any other system.

Dr. R. D. Archibald (*in reply*): In reply to Mr. Bishop, the question of whether the speed should be controlled by a rheostat in the primary or by varying the ratio of the transformer depends on whether a fine adjustment or large range of speed is required. I am of the opinion that for many purposes two speeds, obtained by varying the ratio, would be sufficient, but a combination of both methods could be used with advantage if not too complicated. The brush position 5 in Table 1 is the proper running position and gave good results in both directions. I may say that a more accurate method of setting the brushes, which was employed later, indicated that the brush settings given in Table 1 were half a mica-width further back than shown and that the tests were really performed on a setting between 4 and 5. There is, of course, no question of shifting the brushes on reversing the direction of

rotation. The tests in different positions were taken merely to show the effect on the characteristics. There was no danger from short-circuits between the segments, as the voltage was from 5 to 10 volts and the segments were 0·1 in. apart, which is much wider than in an ordinary commutator. Copper brushes were used for 4, 4′, in Fig. 1 as they were handy, but the slight extra drop incurred by using graphite brushes would not have made any appreciable difference. Excitation was easily obtained at normal brush pressure of $1\frac{1}{2}$ to 2 lb. when the commutator ran true. The contact resistance of a carbon brush increases with pressure up to 4 or 5 lb. per sq. in., after which further increase of pressure makes little or no difference. It is therefore essential to use a pressure of not less than about 5 lb. per sq. in. In the tests higher pressures were used, as the commutator developed a slight wobble, and the 14 lb. pressure mentioned in Table 6 was adopted to ensure that no sparking could be attributed to jumping of the brushes.

Dr. Smith has given us a very good statement of the general position of regenerative control at the present time, and I agree with him that it cannot be assumed that regenerative control would necessarily be any benefit in all cases where rheostatic braking is employed. In tramcars and even in battery vehicles, however, it seems to me that much could be done with a device such as this which can be adapted to a standard outfit without interfering with the series-parallel control.

I did not intend to touch on the question of control, but as Mr. Robertson has raised it I may say that I would not suggest any alteration of the standard controller, as this would be a fatal objection to any device for regeneration. It is quite feasible, as shown in the concluding paragraphs of the paper, to start up the motor as a series machine and change its characteristic from series to shunt by closing the transformer primary circuit and the rectifier circuit. A double-pole switch is sufficient for this purpose. The result, then, is that the rectifier boosts up the motor field-current and causes the motor armature to generate current which passes back through the rectifier to the line. This scheme worked quite satisfactorily and gave a large range of speed with one setting of the transformer ratio, and could be used for slowing down cars on the level by returning current to the line. With the same setting of the transformer ratio, greater braking effect can be obtained by changing over the armature connection from the field to the line, giving the ordinary connections used in these tests. This would be done preferably with some resistance in the controller, which would then be cut out gradually to obtain full regenerative effect. It is not difficult to devise a switch not only to perform these changes but also to return everything to normal series-parallel control when the controller handle is moved to the off position, so that in an emergency the rheostatic brake can be brought into action in the ordinary way. Alternatively, stronger regenerative effect can be obtained by reducing the ratio of the transformer, instead of by changing over the armature connection. The switching arrangements would then be very simple indeed. The size of brush required for 40 amperes is only a little more than double the size used in these tests.

The position as regards running at low speeds is quite the reverse of what Mr. Hird imagines it to be. The motor was run as a regenerator at much lower speeds than those given in the tests, but the transformer used had not tappings suitable for making tests at these speeds. They were obtained by using low tappings in the primary, as higher tappings in the secondary circuit were not available. This made the magnetizing current as high as 7 or 8 amperes, and as this current had a demagnetizing effect on the motor field it made the speeds higher than they would have been with suitable tappings, and therefore gave false results. The lowest speed obtainable depends on the saturation point of the motor field, and there is no more difficulty in saturating the field with the rectified current than there is in rheostatic braking. The speed can therefore be brought practically as low as with the rheostatic brake. Although I agree with Mr. Hird that it is not easy to fit slip-rings and brushes in a restricted space, I do not share his point of view. The problem of collecting a small alternating current in this way has scarcely ever arisen, and it involves as much departure from conventional design as the coal-cutter motor does for its success. The space in this motor is less than in many tramway motors, yet no trouble has ensued. Stretched flexible cable was used for collecting the current, but this was merely to save making brush gear and not because brush gear could not have been fitted. My own experience of Renfield-street is that ever since the accident occurred (in which the driver forgot that he had a rheostatic brake) I have observed that many drivers are in the habit of using rheostatic braking in preference to mechanical braking. The question thus arises: Why not regenerative braking?

INSTITUTION NOTES.

Robert Blair Fellowships.

The London County Council have founded two Fellowships, each of the value of £450 and tenable for one year, to enable British students of at least 21 years of age to pursue a course of advanced study or research in Applied Science and Technology in the Dominions, the United States or other foreign countries. The Fellowships are open to suitable candidates who have been trained in Applied Science and Technology, but in making the awards preference will be given to engineering science and to those who have completed a course of study in London institutions or who have been identified with the London teaching service.

Applications for the Fellowships should be made on a prescribed form obtainable from the Education Officer, London County Council, The County Hall, London, S.E. 1, on or before the 30th June in each year.

Current Loading of Paper Cables.

The British Electrical and Allied Industries Research Association have issued in booklet form (Ref. F/T14) the tables of Permissible Current Loading of British Standard Impregnated Paper-Insulated Electric Cables included in the Second Report on the Research on the Heating of Buried Cables which was published in Vol. 61 (1923) of the *Journal*.

Copies of the booklet can be obtained by members of the Institution on application to the Secretary of the Electrical Research Association, 19, Tothill-street, Westminster, S.W., at the reduced price of 9d. per copy.

The Benevolent Fund.

The following is a list of the Donations and Annual Subscriptions received during the period 26 May–25 June, 1924 :—

TRANSMISSION MAINTENANCE OF TELEPHONE SYSTEMS.

By P. E. Erikson, Member, and R. A. Mack, Associate Member.

(*Paper first received* 8*th December*, 1923, *and in final form* 15*th February*, 1924; *read before* The Institution 6*th March*, 1924.)

Summary.

This paper is divided into two parts. The first part deals with the broad aspects of modern telephone transmission maintenance, the economic justification for good maintenance, and the general lines upon which it should be carried out. The second part gives the theoretical considerations leading up to the development of a series of testing instruments, by means of which transmission losses in any part of the telephone system can easily be measured. This part also contains brief descriptions of the instruments and their use.

Table of Contents.

Part I.

GENERAL ASPECT.

During the last three years no less than six important papers * dealing with various telephone problems have been presented before the Institution. The discussions in connection with these papers have clearly shown the interest which an ever-increasing number of the members are taking in the development of the art of

* Sir W. Noble: "The Long-Distance Telephone System of the United Kingdom," *Journal I.E.E.*, 1921, vol. 59, p. 389.
E. S. Byng: "Telephone Line Work in the United States," *ibid.*, 1922, vol. 60, p. 85.
J. G. Hill: "Phantom Telephone Circuits and Combined Telegraph and Telephone Circuits," *ibid.*, 1922, vol. 60, p. 675.
F. Gill: "Inaugural Address," *ibid.*, 1923, vol. 61, p. 1.
F. G. C. Baldwin: "The Progress and Potentialities of the Telephone in the United Kingdom," *ibid.*, 1923, vol. 61, p. 24.
J. A. Fleming: The Fourteenth Kelvin Lecture: "Problems in Telephony Solved and Unsolved," *ibid.*, 1923, vol. 61, p. 613.

telephonic communication. The importance of this subject is accentuated by the fact that it was made the theme of the Presidential Address in 1922–23 and of the Fourteenth Kelvin Lecture (*loc. cit.*).

A study of the papers and addresses mentioned reveals the fact that, broadly speaking, they all deal with development, design or construction of telephone plant. The transmission maintenance question is referred to by some of the authors, but, as we shall endeavour to show, this phase of the subject is so vital as to warrant a separate study and discussion.

What do we mean by transmission maintenance? In its broadest sense we interpret it to mean not only the upkeep of telephone lines and apparatus from a purely physical standpoint, but the provision of methods and apparatus to guard against the introduction of factors which are detrimental to a satisfactory transmission of speech. The designer of the better class of equipment which goes into a modern telephone system works to certain standards, and this enables the telephone administration to furnish satisfactory transmission of speech. If correctly installed, such a system should therefore theoretically be 100 per cent perfect. Now, it is common experience among telephone engineers that while the plant may be nearly perfect when first installed, deterioration, due to a number of causes, inevitably occurs in time. By way of illustration let us consider a non-loaded long-distance open-wire line 500 miles long with conductors weighing 600 lb. to the mile throughout in its construction. The transmission equivalent of this circuit, between test-boards, would then be about 13 miles of standard cable (measured at a frequency of 800 periods per second). For the purpose of this illustration let it be assumed that the combined losses due to the extensions through the exchanges to the subscribers' premises at each end, amount to a total of 16 miles of standard cable. The total equivalent is therefore 29 standard miles, which may be regarded as satisfactory.

The transmission-equivalent of the open-wire line presupposes normal conditions, that is to say, high insulation, freedom from external influence (such as noise by induction), good conductivity and absence of bridged connections (accidental or otherwise). Now it is to be expected that, in time, any one or all of the conditions mentioned will change and that losses will gradually creep in.

Faulty insulators, an error in the transposition of the line wires during changes or repairs, defective joints or some apparatus or instrument subsequently placed across the circuit at an intermediate point—any one or all of these causes may result in an appreciable increase in the transmission-equivalent. The losses thus introduced may easily aggregate 5 to 10 standard miles.

Furthermore, in the exchanges there are a number of points at which losses may accidentally be introduced. Poor contacts on protector springs, a faulty coil or incorrect wiring have been found to cause losses of as much as 10 to 15 standard miles, with an average of about 2 standard miles or even higher.

If we take the losses which by accident may occur in the open-wire line proper to be of the order of 7 standard miles, and the losses due to defects in the extension lines at each end to be equivalent to 4 standard miles (based on the average of 2 miles cited above), we then have to add 11 standard miles to the original 29 miles for overall transmission. In other words, more than one-third has been added to the original figure, which now becomes 40 standard miles. This, as telephone engineers know, may be regarded as uncommercial speech transmission.

The factors which contribute to this abnormal condition will be dealt with more fully in this paper, but, before taking up the purely technical side of the problem, it will be useful to demonstrate what these losses may mean from an economical standpoint. In the ordinary way, losses which are encountered in commercial life may be expressed in some monetary value and, while in this case such expression is difficult, it is nevertheless possible, by means of an example, to give a fair idea of the considerable sums of money involved.

If, to compensate for losses occurring in a correctly designed plant, it is assumed that the efficiency of some portion of it has to be improved, the cost of such improvement can be taken as a measure of the money value of the losses which were present.

The following example, taken from a paper by Captain J. G. Hines read before the Institution of Post Office Electrical Engineers on 13th November, 1923, illustrates this method:

"It may be stated that in the case of an exchange of moderate size such as Willesden, which is about 7½ miles from the Trunk Exchange, a reduction of one mile S.C.E. in the local line allowance can only be made up on the existing trunk junctions by an additional capital expenditure of approximately £6 600. As there are 100 exchanges of various sizes in the London area, it will be seen that the total expenditure that would be involved by a general reduction of the loss by one mile is very large."

It should be noted that the capital expenditure referred to above could not fully compensate for losses occurring between subscribers' stations and the end of the trunk junctions. The above example is, therefore, more indicative of the money value of losses occurring in plant used only during trunk connections.

A further example serves to indicate the money value of losses occurring in two important items of local plant, namely, "A" position cords and "B" position cords, and illustrates the order of the expenditure necessary to compensate for losses which can be eliminated by the carrying out of transmission maintenance tests.

The figures given below are based upon actual experience of the losses in "A" and "B" cord circuits, which can be detected by the use of a simple transmission measuring-set of a type referred to in this paper. Tests made upon several modern telephone systems have shown that, until detected, approximately 10 per cent of all "A" and "B" cords have abnormal losses. Measurement has also shown that the average abnormal loss upon such cords is of the order of 4 miles of standard cable.

Taking what may be regarded as an average telephone connection involving the use of at least two cords, it follows from the above data that the average accidental

loss, assuming 2-cord circuits involved, would amount to $2 \times 4 \times \frac{10}{100} = 0 \cdot 8$ m.s.c.

The estimation of the value of this loss involves an economic study of some length, but such a study based upon a large telephone system indicates that an average loss of 0·8 mile of standard cable upon the average connection involves an annual loss of approximately 3·2 pence for every subscriber's station in the system.

Taking the round figures of 1 000 000 subscribers' stations for the United Kingdom, this represents an annual loss of about £13 000. Assuming that interest, depreciation and maintenance can be taken at 12·5 per cent of the capital involved, the capital amount corresponding to the above annual loss is £104 000.

When it is remembered that this example takes into account only the losses which are known to occur on but two items of the plant, the saving which can be effected by proper transmission maintenance upon all items can be well appreciated.

We now propose to deal with the transmission maintenance of modern telephone plant. For this purpose we may select as an illustration a telephone system in any progressive country, since the general principles of construction and design are everywhere the same. We have, however, largely taken the American practice as a basis, chiefly for the following two reasons:

(*a*) The telephone development in that country is the highest in the world.

(*b*) We have had an opportunity of studying more intimately the transmission maintenance practices in that country.

We have already briefly referred to the abnormal transmission losses which may develop in a telephone system, impairing its efficiency to a greater or less extent. Before discussing these losses and their causes in detail, it will be advisable to consider the normal condition, that is to say the grade of transmission which should be given in a well-designed system.

For convenience in discussing this broad subject, which, in fact, comprises all of the equipment germane to a telephone plant, we may divide it into two main parts:

I. The exchange area system.
II. The long lines system.

As it would lead us too far afield if we were to consider every piece of apparatus and every circuit in the system, we have confined our study to representative types. The principles are substantially the same for similar portions in the whole system.

I. The Exchange Area System.

In dealing with this part of the telephone system—as distinct from the long lines plant—it is necessary to indicate what elements we are including under this heading. An exchange area, as we are considering it from a transmission maintenance standpoint, is understood to include telephone exchange equipment, used for long-distance operation, for junction working and for local traffic. The losses which occur in the long-distance switchboard circuits, the "A" and "B" cord circuits and associated apparatus (telephone operator's sets, etc.) are dealt with as types, and so are the losses in the circuits of private branch exchanges.

It should be noted that, although we have here described transmission maintenance practices as applicable to manual switchboard equipment, these practices are equally important for machine-switching equipment. Space will not permit a description of their application to the latter, but since the principles are essentially the same for both, a consideration of the manual equipment will, we believe, be sufficient for purposes of illustration.

When operating conditions so demand, telephone repeater equipment is sometimes installed in long-distance telephone-exchange buildings. This type of equipment is not ordinarily classed with exchange apparatus, and, since it requires special maintenance tests, these are described in the part of this paper which deals with long lines. The lines connecting the local exchanges and those extending to the subscribers' premises are, however, included in our study of exchange areas.

It is not intended to describe here the operating features of the equipment involved, as this is well known to telephone engineers, but for the sake of reference the main items of which we are considering the transmission features are further subdivided under two headings: A. Internal equipment. B. External wire plant (local lines).

A. Internal Equipment.

1. Exchange Equipment.

Long Distance Switchboard | "A" Board | "B" Board | Private Branch Exchange

(*a*) Cord Circuits | (*b*) Telephone Operator's Circuit | (*c*) Line Termination Apparatus | (*d*) Protection

2. Subscribers' Instruments (including protection).

(*a and b*) *Cord circuits and telephone operators' circuits.*—All of the above items constitute circuit elements which introduce what might be termed "normal transmission losses" into the exchange area. From various causes, such as mistakes in wiring of the apparatus, faults developing in service (short-circuit of winding or other defects in the apparatus), losses are introduced which, if allowed to remain, would seriously interfere with efficient operation of the circuit. The ordinary maintenance of an exchange area does not provide means for detecting all such losses, and it is necessary to provide instruments for measuring in a rapid routine fashion such parts of the equipment as experience has shown to be subject to defects.

Considering the large number of elements involved, it will perhaps be advisable to select some representative cases indicating normal transmission losses, and illus-

The examples given in Table 1 are the results of actual measurements and demonstrate, beyond any doubt, the importance and need of careful transmission maintenance upon circuits of these types. Testing apparatus is now available which enables tests to be made in a routine manner for the location and elimination of defects which have accidentally developed.

(*c*) *Line termination apparatus.*—The importance of correctly terminating a loaded cable in exchange areas was early recognized. The impedance of a loaded cable circuit is so much greater than that of the non-loaded circuits to which it is connected in service that, unless special precautions are taken, transition losses will occur at the junction.

Repeating coils, having suitable impedance values in their primary and secondary windings, are therefore inserted between the two types of line, with the result

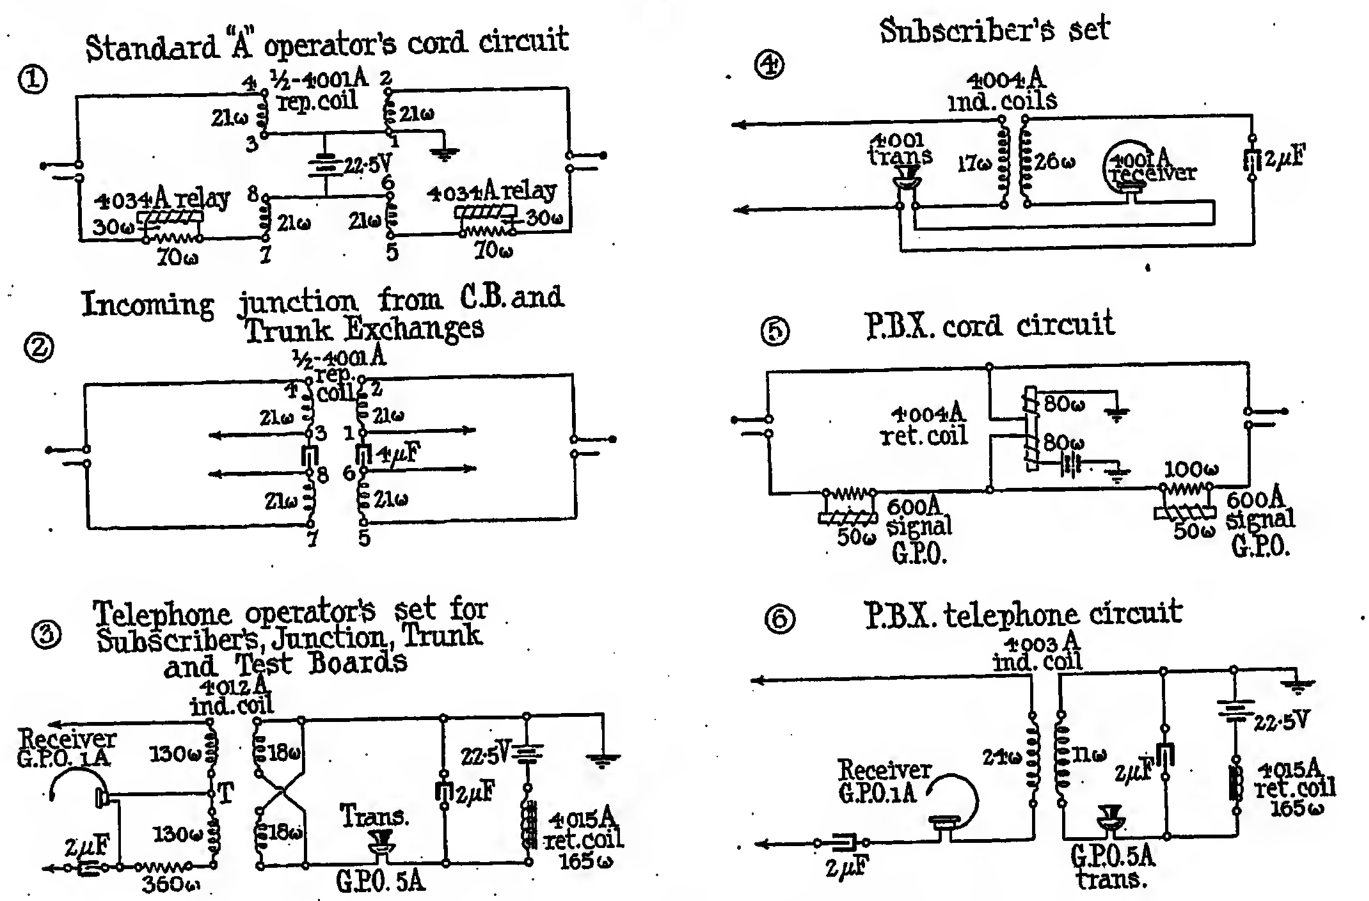

FIG. 1.—Typical transmission circuits in exchange areas.

trate the effects which the defects above mentioned have upon the system as a whole.

In Fig. 1 are shown in diagrammatic form representative manual types of cord circuits for trunk and local switchboards, as well as operators' telephone sets for the same type of equipment. Under normal operating conditions the transmission loss in any one of the circuits shown is bound to vary, but having obtained sufficient test data it has been possible to establish an average value and also a maximum (limiting) value, the latter being intended to indicate the point beyond which abnormal losses may be suspected. As a matter of interest Table 1 gives the values for the circuit shown, the figures being arranged in three columns. The first column shows the average loss, the second column the limiting value, and the third column abnormal loss, the cause of which is recorded in the column headed "Remarks."

that the transition losses are materially reduced. It follows that if, by mistake, a repeating coil of incorrect impedance ratio is inserted, this loss may be materially increased.

For the purpose of illustration let us take the case of a cable circuit, loaded at intervals of 1⅝ miles with coils having an inductance of 175 millihenrys. Assume that this cable terminates in a non-loaded loop of 20-lb. conductor, say 1½ miles in length. With the proper type of repeating coil, the total transition loss will amount to about 0·7 mile of standard cable. Now suppose an ordinary repeating coil, having a unit impedance ratio (1 : 1), is placed in the circuit. The total losses would then amount to 1·8 miles of standard cable. Thus a loss of 1·1 miles of standard cable has accidentally been added to the circuit.

Again, take the case of a loaded cable circuit which is designed for long-distance operation with telephone

repeaters. If, as frequently happens, the cable has to enter a repeater station through a repeating coil, then it is necessary (in 2-wire operation) to insert a coil of similar characteristics on the corresponding " network " side of the circuit in order to obtain the necessary balancing condition. The " line " coil and the " network " coil must have the same electrical characteristics, within very close limits, otherwise the gain obtainable by means of the repeater is seriously affected.

(*d*) *Protection.*—In regard to protection apparatus, more particularly that installed in a telephone exchange, experience has shown that trouble is caused by excessive contact resistance between the heat-coil contact surfaces and the protector springs, as well as between the protector springs and their assembly bolts. Trouble from this source usually appears as line noise, which is detrimental to transmission, but it may also result in a direct transmission loss, which can economically be eliminated.

Where the length and importance of the junction cable circuits warrant it, their transmission efficiency may be improved by loading.

(1) Grade of Transmission.

Before discussing the broad aspects of the maintenance of this part of the exchange area plant, brief references will be made to some considerations governing the transmission standards which should be aimed at in a well-designed system.

The circuits to be considered are:

(*a*) Subscribers' lines (to the local exchange).
(*b*) Junction circuits (connecting ordinary exchanges).
(*c*) Trunk switching circuits.
(*d*) Order wire circuits.

(*a*) *Subscribers' lines.*—The choice of conductors for this class of circuit is necessarily based on the limiting loop resistance for each exchange area, as determined

Table 1.

Ref. No. in Fig. 1	Description of circuit	Average loss	Limiting loss	Abnormal loss	Remarks (Cause of abnormal loss)
		Miles of standard cable			
1	Standard " A " operator's cord circuit	1·4	2·0	5·4	Non-inductive relay winding disconnected
2	Incoming junction circuit	0·7	1·4	11·5	4-μF condenser disconnected
3	Telephone operator's set	3·5	4·8	5·0	350-ohm resistance short-circuited
4	Subscriber's set *	4·0	4·5	8·9 8·7	17-ohm winding reversed 26-ohm winding reversed
5	Private branch exchange cord circuit	1·2	1·5	4·1	Non-inductive relay winding disconnected
6	Private branch exchange telephone circuit	1·2	1·5	7·3	Induction coil windings interchanged

* Transmitting loss.

Note.—1, 2, 3, 5 and 6 are measured as bridge losses in the circuit.

The winding of the heat coil, which is in series with the line, is designed to have a resistance of the order of 3 to 4 ohms. A poor contact may add 1 ohm, or more, to this resistance and it is quite evident that a loss due to this cause should be prevented.

(2) Subscribers' Instruments.

Considerable attention has recently been given to this part of the local line plant, and it is believed that development work now in progress will result in simple and inexpensive means being provided for checking the efficiencies of subscribers' transmitters and receivers after the latter have been put into service.

B. External Wire Plant in an Exchange Area.

The circuits which connect the subscriber with his local exchange (usually referred to as " the subscribers' loop "), as well as those interconnecting the various exchanges in a modern telephone system, are usually carried in lead-covered cables (aerial or underground).

by a fundamental plan study. Different lengths of subscribers' loops require different sizes of conductors in the cable, but, generally speaking, it has been found economical to standardize the sizes of conductors in a cable and, ordinarily, 3 sizes of conductors are used, namely:

British Standard (nominal weight of conductor per mile)	American Wire Gauge (B. & S.)	Diameter, in mm.
20 lb.	No. 19	0·91
10 lb.	No. 22	0·64
6½ lb.	No. 24	0·51

The use of a still smaller size, namely, No. 27 B. & S. or 3¼ lb. conductor (0·36 mm), has been considered for short subscribers' loops in congested areas. In some instances it has been found economical to combine two

sizes of conductor in the same subscriber's loop. On account of the circuit density near exchanges, and the consequent duct congestion, the smaller size has usually been placed at the exchange end of the loop.

For reasons inherent in the size of the exchange area or the natural growth of a community, it happens that a few loops exceed the limiting resistance contemplated in the fundamental study. Special methods may have to be resorted to, such as the use of auxiliary batteries on the subscriber's premises, parallel working of pairs where spares are available, etc.

In order to give some idea of the magnitude of the normal losses in subscribers' lines it may be stated that from 4 to 5·5 miles equivalent in standard cable may be regarded as good practice. The loss, as stated, represents the mean value of the sending and receiving losses when referred to a circuit, using a standard common-battery instrument and zero subscriber's loop.

These subscriber's line losses can be related to the resistance of the subscriber's loop in accordance with the following table:

transition losses at the exchange end can be materially reduced by means of suitable transformers.

(*c*) *Trunk switching circuit.*—Strictly speaking, this circuit is part of the long-distance (trunk) plant and, as such, it is therefore important that the transmission losses should be reduced to as low a value as it is economically possible to produce.

The standard of transmission which has been found desirable is such that the equivalent of the circuit should be from 1·5 to 3 miles of standard cable. Where the circuit is of sufficient length, it may be loaded, the conditions in this respect being substantially the same as for the long junction circuits.

(*d*) *Order-wire circuits.*—Good transmission over order-wire circuits is important for maintenance of proper standards of service. For example, although the telephone operators using these circuits are trained listeners, the passing of a wrong number may occur because of reduced efficiency of the line. Repetition and consequent waste of operating time follow, to the detriment of the service.

TABLE 2.

Type of cable used			Subscriber's line losses	
Conductor	Mutual capacity		4 standard miles	5·5 standard miles
	μF per mile	μF per km		
20-lb. (0·91 mm)	0·085	0·053	170 ohms	240 ohms
10-lb. (0·64 mm)	0·083	0·050	190 ohms	280 ohms
6½-lb. (0·51 mm)	0·078	0·048	220 ohms	325 ohms

The question of loading subscribers' loops to improve transmission has been considered. The improvement obtainable by this means is not very great, chiefly because the impedance of the subscriber's set and the repeating coil both have a positive reactance. Furthermore, no gain is secured by this method in the battery supply, which forms a major part of the loss in long subscribers' loops.

(*b*) *Junction circuits.*—Junction circuits are less in number and generally longer than subscribers' loops, and can therefore economically justify a higher grade of construction. Cable conductors up to 40 lb. per mile in weight have been used, while 20-lb. conductor circuits are quite generally used. Under certain circumstances loaded 10-lb. conductors are used, as described below.

The allowable transmission loss in junction circuits in a well-designed exchange area may fall between 7 and 10 miles of standard cable, and should not exceed the latter figure. These values are, however, not to be regarded as absolute figures, as they are dependent on other factors, notably the limiting loop resistance and the general standard of transmission adopted for the system.

It has been found economical to load junction circuits in the case of long 20-lb. and 10-lb. conductors. The

During busy hours it frequently happens that 4, and in some cases as many as 6, "A" operators come in simultaneously on an order wire. In the former case the added loss in transmission is about 9 miles of standard cable; in the latter case about 12 miles of standard cable are added to the loss in the order-wire.

The total equivalent of any order-wire, from operator to operator, should not exceed 20 miles of standard cable. Experience has shown that with this allowance very little trouble is caused, but as soon as it is exceeded complaints are quickly forthcoming.

(2) TRANSMISSION MAINTENANCE.

The upkeep of junction and subscribers' lines for the purpose of ensuring good transmission differs only in degree from that required for the long lines.

(*a*) *Direct-current tests.*—In all cases where a cable has been installed it is customary to make tests for insulation resistance and direct-current resistance and so to establish records of the condition of the circuits. The results of these tests, and particulars of the size (or sizes) of conductors, number of pairs, etc., are usually entered on cards which are kept for reference at the exchange.

Periodic tests are then made for the purpose of

checking the above results. The insulation test is particularly useful as an indicator of the general condition of the cable. Changes noted in this respect during successive tests may enable incipient troubles to be detected and corrected before the cable becomes commercially unfit for service.

(*b*) *Tests on loaded circuits.*—In addition to the above-noted tests, it is good practice to ascertain from time to time the condition of the loading coils. A means to this end is the line impedance bridge described on page 676 and shown in Fig. 17.

(*c*) *Transmission tests.*—The transmission-equivalents of a junction circuit can best be measured from the main distributing frame. The No. 1-B transmission set described on page 671 provides a rapid and reasonably accurate means for this test. If great accuracy is desired, tests may be made, using the No. 3-A transmission measuring set. The former method necessitates the looping of the circuit and consequently a " triangulation " test, in order to obtain correct values for the individual circuits.

II. THE LONG LINES SYSTEM.

General.

The first telephone line was the best telegraph line of the day, consisting of a single iron wire with an earth return. It soon became evident that this type of line was unsuitable for telephone operation, partly on account of the disturbances which arose from the earth connection and partly on account of the inferior transmission qualities of iron wire.

The introduction of the double-wire copper circuit eliminated to a considerable extent both of these defects. Early investigators showed the way to the elimination of mutual interference when several telephone circuits were placed on the same pole line. The various systems of transposing telephone wires have all been developed as a means not only for the prevention of cross-talk between telephone circuits, but also to reduce interference from neighbouring telegraph and power circuits.

In recent years the construction of high-tension power lines for industrial and railway purposes has necessitated further precautions to safeguard the communication circuits against external disturbances. In this connection we may mention the important work carried out in California on behalf of the California Railroad Commission by a Joint Committee of power and communication engineering experts. The investigation lasted nearly five years and the recommendations of the Committee are contained in a series of technical reports subsequently issued by the Railroad Commission of the State of California on 1st April, 1919 (California State Printing Office, Sacramento, 1919).

The history and development of the phantom telephone circuit formed part of the subject of a recent paper before the Institution.* The successful operation of the phantom circuit is rendered possible only by a careful maintenance of balanced line conditions and suitable transpositions of the wires.

Then we have Pupin's epoch-making invention which, with the work of G. A. Campbell and others, gave the telephone engineer a practical solution of Heaviside's theory of the need of increased inductance in telephone circuits for the improvement of transmission. The application of the loading coil to open-wire telephone lines extended the talking range of this class of circuit to a distance of 2 200 miles (New York–Denver), the longest non-loaded open-wire line up to that time (1912) being about 1 000 miles.

Paper-insulated telephone cables had been in use several years before the loading coil was commercially developed, but the distances which they could cover from a telephone transmission standpoint were necessarily limited. To-day, the loading of cables for long-distance telephony is being adopted in all countries where the service justifies it, because the development of balanced cables and loading coils has long been recognized as a commercial success.

The latest stage of development is, of course, the introduction of the telephone repeater into the long-distance telephone plant. In their paper on " Telephone Repeaters " before the American Institute of Electrical Engineers, Messrs. Gherardi and Jewett give an excellent account of the subject. Sir William Noble in his paper before the Institution on " The Long-Distance Telephone System of the United Kingdom " illustrates the economies to be expected as a result of the adoption of the telephonic repeater in the cable system of the British Post Office. Mr. Gill in his Inaugural Address points the way to the solution of the international telephony problem, the solution being largely founded on the judicious use of the telephone repeater.

The outside line plant of a large telephone system represents by far the greatest proportion of the capital investment, and it is therefore not surprising that every effort is made to utilize it to the utmost of its capacity.

One of the latest achievements in this respect is the successful adaptation of the principle of carrier-current transmission, which enables several telephone conversations to be carried over the same metallic circuit. This subject is covered in a very comprehensive paper read in 1921 before the American Institute of Electrical Engineers by Colpitts and Blackwell.* Mention should also be made of two prominent papers presented to the American Institute in August 1922, namely, " Telephone Transmission over Long Cable Circuits," by A. B. Clark, and " The Philadelphia–Pittsburgh Section of the New York–Chicago Cable," by J. J. Pilliod.†

This brief survey of the development of the long lines transmission problems gives, we believe, a fair idea of the need for means to fulfil the more and more exacting requirements in regard to the proper maintenance of the transmission service. It has been shown that ever greater distances are being conquered, with consequent greater demand on a widely separated staff responsible for the operation of a complicated system.

If we consider a country-wide telephone system such as that represented by the long lines in the United States or Great Britain, we find all the industrial and commercial centres linked up by important telephone

* J. G. Hill: "Phantom Telephone Circuits, and Combined Telegraph and Telephone Circuits, worked at Audio Frequencies," *Journal I.E.E.*, 1922, vol. 60, p. 675.

* *Transactions of the American Institute of Electrical Engineers*, 1921, vol. 40, p. 205.

† *Ibid.*, 1922, vol. 41, p. 446.

lines. By far the greater portion of these lines are, as yet, made up of open-wire construction, although long-distance cables with their greater immunity against "breakdowns" are rapidly coming into use, where economic considerations demand it.

The weight of the copper wires in overhead lines economically limits the distance over which commercial speech can be carried.

A glance at Table 3 shows the limitations in this respect. For the purpose of this illustration a 15-mile equivalent (between test-boards) has been assumed.

tion of the system as a whole. The control of the circuit as a working unit, and the responsibility for securing a specified transmission-equivalent, must rest with one station selected for that purpose.

It may be of interest to outline the procedure which is followed in this respect, taking as an example a section of the transcontinental line above referred to. This circuit passes through Chicago on its way west, and between the two cities, New York and Chicago, there are three repeater stations, indicated by crosses in the diagram below.

Chicago		Beaver Dam		Brushton		Harrisburg		New York
O	295 miles	X	248 miles	X	207 miles	X	181 miles	□

It is to be noted that the lines referred to are not loaded. In the United States the greatest weight of open-wire lines which it has been found economical to improve by loading consists of about 175-lb. conductors. The problem of maintaining a sufficiently high insulation on large open-wire conductors has confined the loading to gauges below the one just mentioned.

Furthermore, it was found that when repeaters were installed on loaded open-wire lines some difficulties were experienced in maintaining, at all times, a sufficiently close balance between the loaded line and its network.

TABLE 3.

Non-loaded Open-wire Circuits.

Weight of copper wire in aerial construction	Diameter of conductor	Maximum distance between test-boards	
lb.	mm	miles	km
800	5·68	720	1 160
600	4·92	570	920
400	4·02	410	660
300	3·48	325	525
200	2·84	230	370
100	2·01	130	210

The loading of a circuit also reduces the speed of propagation and limits the frequency-spectrum, which, in turn, affects the quality of the speech. It has therefore been found more desirable to limit the use of loading coils on open-wire lines and to obtain the desired grade of transmission by means of repeaters alone.

In fact, the transcontinental line (New York–San Francisco) which was originally loaded and so operated with repeaters has since been "unloaded," and repeaters have been installed at more frequent intervals.

We may therefore regard the long-distance system as sections of high-grade lines, located between repeater stations or connecting the latter with terminal cities.

UNITY OF CONTROL.

It would obviously not be practicable to depend solely on the maintenance of the individual sections (i.e. between repeater stations) for the successful opera-

(1) *Repeater gain test.*—The control station (Chicago) makes a roll call and requests the repeater stations to measure the repeater gains, to make vacuum-tube rejection tests (described on page 662) and to report the results at the expiration of 5 minutes. The control station then obtains the reports, starting with Beaver Dam. No record is made of this report; the repeater stations merely state that everything is in order, or, if not, they state briefly the apparent nature of the trouble.

(2) *Balancing test* ("21-*test*").—The control station requests New York to terminate the circuit at the measuring unit with a non-inductive resistance, equivalent to the impedance of the circuit. Brushton is instructed to turn both potentiometers on the repeater set to zero, and Harrisburg is told to make an impedance unbalance test (described on page 663 as "21-test") in both directions. Beaver Dam is likewise instructed to make the same test, the circuit at Chicago having meanwhile been closed through a suitable impedance. Five minutes is allowed for these tests, at the expiration of which Beaver Dam reports. Brushton is then requested to restore the circuit to normal and to obtain the test result from Harrisburg. In turn, New York, Brushton and Chicago then make impedance unbalance tests, for which a time interval of 5 minutes is allowed. The circuit is then restored to normal condition and the results of the last-mentioned tests are reported to the control station.

(3) *Talking test.*—An overall talking test is made between Chicago and New York, using standard subscribers' sets at both ends.

(4) *Transmission test.*—Using a frequency of 1 000 cycles per second the transmission equivalent of the circuit between Chicago and New York is measured. The repeaters at the intermediate stations are set at their specified gains and the circuit is tested on the "straight away" basis, i.e. using the transmission measuring sets described on page 672.

(5) *Ringing test.*—The last test to be made is a ringing test between New York and Chicago. This test is made in both directions, so as to ensure that the signalling apparatus is working properly.

The attenuation loss in each line section is a fixed quantity, and its magnitude is determined from purely economic considerations. In aggregate, these losses are quite considerable when several sections are used in

tandem for long built-up connections. The function of the repeater is, of course, to reduce these losses and bring the transmission circuit down to an equivalent which will permit of commercial speech.

In his Inaugural Address Mr. Gill gave a striking example of the condition which will arise if the gains obtainable by means of repeaters are not maintained at their specified values. As the example which he gives has an important bearing on the question of long lines transmission maintenance, we quote it below *in extenso*:

"When repeaters are in operation, they must maintain constant the gains to be given out or there will be serious effect on the speech. If we assume a 4-wire circuit between Rotterdam and Milan, 500 miles (810 km) long and having five repeaters in it, operating at gains of 23, 30, 30, 30 and 23 standard miles (S.M.) respectively, say an average of 27·2 each, we need only consider what will happen if the gains fall off, since the gains will originally have been set to be as high as safely allowable. Assume, then, that the line without repeaters has a net equivalent of 148 S.M. from which we deduct the repeater gains, 5 × 27·2 = 136, leaving the net loss = 12 S.M. Now suppose the gain at each repeater station for any reason at all falls off by 2 per cent; this will represent 0·54 S.M. each, or 2·7 S.M. for the five stations, and the net result will then be increased from 12 to 14·7 S.M., an increase of 23 per cent in the loss in the line. Should the gain on each repeater fall by 7·5 per cent the total additional loss will be 10·1 S.M., and the final net loss will be increased from 12 to 22·1 S.M.—an increase of 84·5 per cent. In this case the loss would be so great that probably the line would become unworkable. I have chosen these examples to show the importance of uniformity of construction, uniformity of maintenance, and uniformity of operation; it will be seen afterwards what is their particular application. The examples are rather understated than exaggerated; it would have been quite reasonable to have taken a case with 20 repeater stations in tandem, and, furthermore, the gain given by a repeater would not in fact be one definite figure for all frequencies."

The problem of long lines transmission maintenance may therefore be separated under two headings:

(A) Repeater station maintenance.
(B) Repeater line section maintenance.

In practice, all the tests required for both (A) and (B) are carried out either from the repeater station or from a terminal station. It will therefore be convenient to describe briefly the nature of these tests and the practical methods used in applying them to the system as a whole.

(A) Repeater Station Maintenance.

In order to ensure at all times efficient and reliable service, it is very important that a definitely established maintenance routine should be carried out, and periodic tests made upon the various elements which go to make up a repeater station.

For this purpose certain testing equipment is always included in repeater stations, consisting of suitable voltmeters and ammeters for the purpose of checking the normal operating voltages and currents in the repeater circuits. The testing equipment also includes means for determining the transmission gain which the repeater gives in service. There are also separate testing circuits for the signalling operations, which have to be verified from time to time.

The tests which have to be made may be grouped under the following five headings:—

(1) A daily test of the battery circuits to check the proper values of currents and potentials.
(2) A periodical test to ascertain that the ringing and switching relays in the various circuits work properly.
(3) A monitoring test upon commercial calls. Such tests should also be made periodically on through line repeatered circuits.
(4) A transmission test on the repeater should be made at least once a week, to ensure that it is giving the desired transmission gain.
Further and more complete gain tests should be made periodically on all repeater units.
(5) The vacuum tubes should be periodically tested, so that they may be replaced when they show any signs of ageing.

(1) *Battery test.*—The change in the actual gain of a repeater is due to the battery variations, and, in order that the repeater gain may be kept constant, definite limits have to be placed on the voltages of the three batteries.

In regard to the tests of the batteries in repeater stations, suitable instruments are provided on the power switchboards associated therewith. It is therefore an easy matter to check the voltages of (*a*) the battery which supplies the current to the filaments of the repeaters; (*b*) the battery which supplies the anode potential to the vacuum tubes; and (*c*) the battery which supplies the grid potential to the vacuum tubes.

In addition to these tests a further check is obtained by measuring the filament current, the space current and the grid potential, on instruments mounted on a separate panel on racks conveniently located in regard to those supporting the repeater panels proper.

In the latest type of vacuum tube using oxide-coated filaments the current under normal operation should be 0·97 ampere. This current is allowed to vary between 0·94 and 1·0 ampere. Fig. 2, which applies to a typical tube, indicates how the gain of the repeater is practically independent of the filament current, except for values outside the above limits.

The voltage of the plate battery is normally made 130 volts positive to the negative end of the filament. Small changes in this voltage do not affect the operation of the repeater to any great extent. A serious variation would, however, result in a considerable change in the gain. The limits are therefore fixed at 125 volts minimum and 135 volts maximum.

The grid is maintained at 9 volts negative to the negative end of the filament. The limits imposed on the grid battery are such that the grid voltage does not

vary by more than $\pm \frac{1}{2}$ volt from the mean value 9 (volts).

If the grid voltage falls below its correct value the gain and space-current are increased, and this may be accompanied by a sacrifice in quality.

The three effects enumerated above may be cumulative and it is therefore necessary, in placing operating limits on repeater station batteries, to consider all three cases simultaneously. This consideration results in imposing narrower limits on the batteries than are required by an individual case. It is this consideration which fixes the lower limit of filament current at 0·94 ampere.

It will be noted that, in fact, very little change in gain occurs until the filament current falls below 0·9 ampere. When the current falls below 0·85 ampere the gain decreases very rapidly.

The upper limit of the filament current is imposed

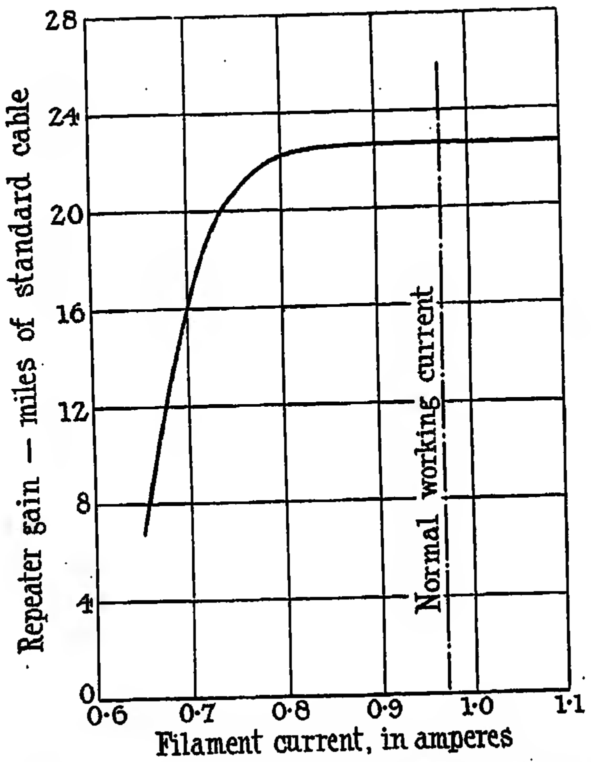

Fig. 2.—Characteristics of vacuum tube having oxide-coated filament.

for a different reason. As may be seen from the curve, the tubes would work well with a much higher filament current but the life would be considerably shortened. For example, at 1·25 amperes the life is reduced by something like 80 per cent. From these considerations an upper limit of 1 ampere is therefore fixed.

(2) *Ringing tests.*—These should be made under actual operating conditions, that is to say, outgoing signals intended for the distant station should be supplied on the line jacks on the toll switchboard, and incoming signals from a distant station should be received in the same manner as for an ordinary long-distance call.

The low-frequency (16 or 20 cycles) signalling apparatus for the repeater circuit is generally so arranged that during the ringing interval the telephone repeater is rendered inoperative. When 135-cycle frequency signalling is used, the ringing current is, when necessary, allowed to pass through the vacuum tube in order that it may be amplified before being allowed to pass through the repeater station. When testing the low-frequency signalling, the repeater attendant should listen-in on the repeater circuit during the ringing interval, when the changes in the repeater circuit, caused by the operation of the signalling relays, can be heard in the receiver. In this way the proper operation can easily be verified. If it is found that the signals do not come through in the proper manner, the relays associated with the signalling equipment should, of course, be adjusted.

(3) *Monitoring tests.*—These need no further comment, except that the equipment which is used by the repeater attendant should be so designed as to introduce a minimum transmission loss when in operation. It is customary, therefore, to arrange the coils, by means of which the test is carried on, so that they take off a very small portion of the amplified output of the repeater unit.

(4) *Transmission tests.*—In order to measure the gain which the repeater is giving, a special gain-measuring set is included in the modern telephone repeater station. Gains varying from zero up to 46 miles of standard cable can be measured with a set with a precision of $\pm \frac{1}{4}$ mile. A description of the measuring set may be of interest and is therefore given on page 674.

The normal gains which repeaters are required to give should be specified as determined by the circuit lay-out work when the repeaters are installed. These repeater gains should never be changed by the local repeater attendant except on instructions from the office which has control of the transmission efficiencies of the trunk circuits on which the repeaters are operated. Tests should be made weekly for both the "East" and "West" amplifier circuits at the working potentiometer steps.

Gain calibration should be made on all repeaters periodically, and these calibrations should be used to check the weekly gain measurements. These calibration measurements are made to ensure that the gain-frequency characteristic of the repeater is correct, and to check the functioning of the filters.

Measurements should be taken at least every six months and should be made preferably at the normal working steps at the following frequencies: 200, 1 000, 2 000, 2 500 and 3 300 cycles.

The single-frequency measurements made weekly at 1 000 cycles and checked by the half-yearly figures are used in connection with line-balance tests and also as an indication of any incipient trouble in the apparatus or vacuum tubes.

(5) *Vacuum-tube rejection tests.*—In order to determine whether or not a vacuum tube is defective, a direct measurement of the repeater gain should be made by means of the precision-gain measuring apparatus. Tubes are taken out of service when the variation in gain between the allowable current-limits stated above is greater than one mile of standard cable.

(B) Repeater Line Section Maintenance.

The well-known type of telephone repeater designed for ordinary 2-wire circuits depends for its proper operation on an accurate balance between the line section and its equivalent network. So long as the

network impedance simulates that of the line with sufficient accuracy, the repeater will give the desired gain. Well-designed networks may, in general, be depended upon to maintain their original constants, but the line is subject to changes from various causes, with resultant changes in its impedance. Variation of insulation on open-wire lines, or a faulty loading coil in a cable—to mention two instances—will affect the impedance of the line and cause sufficient variation to prevent the repeater from being operated at its desired efficiency. Means for detecting such irregularities have been developed and will be briefly referred to.

The tests described below refer specifically to loaded cable sections, although they apply, in general, to open-wire lines as well. The requirements relating to insulation tests would necessarily be somewhat modified to meet special conditions.

(1) *Insulation-resistance and continuity tests.*—Although these tests and their object are well known to telephone engineers, their importance warrants a reference to their application on loaded cable (repeater) sections. Generally speaking, if a high insulation resistance is maintained at all times, fault location is greatly facilitated. Also, continuous vigilance in this respect will have its reward, since even a slight decrease in insulation resistance is a danger signal which gives the attendant an opportunity of investigating any incipient trouble before the cable circuit becomes unfit for service.

Good maintenance practice demands that the following routine be observed in regard to the two types of test mentioned :—

The standard voltmeter-deflection method is recommended and the test can most conveniently be carried out from the test-board at the repeater or terminal station.

The insulation resistance should be tested between cable pairs and between each wire of a pair and earth. This test should be made daily on all pairs not in service, and fortnightly on all cable pairs in service.

The continuity test should be made once a week on all cable pairs not in service. This test is not necessary on cable pairs in service, but can, if desired, be made during the fortnightly test for insulation.

(2) *Line impedance test.*—The most obvious method of determining the condition of a line section is, of course, to measure its impedance over a suitable range of frequencies. The apparatus required for this purpose may conveniently take the form of an alternating-current Wheatstone bridge, the operation of which is well known.

This method, although very accurate, has the disadvantage that it is rather slow. To test one circuit over a range of frequencies from 200 to 3 000 cycles per second in steps of, say, 60 cycles takes up the best part of an hour and, if a large number of circuits have to be so tested, considerable time is consumed.

More rapid tests have been devised which enable the operator to determine, with a fair approximation, the condition of the line. These tests in no sense replace the impedance/frequency test, which yields valuable information, particularly in the location of line irregularities. One of these tests, known as the "singing point test" (or 21-test), will be described, as it possesses several advantages.

(3) *Singing point test (21-test).*—As is well known, the operation of a 2-element 2-wire repeater is only made possible by balancing the line in the two directions by a network, which simulates the impedance of the line at all essential voice frequencies.

If the repeater is a 21, or 2-way 1-element type, the degree of balance between the line and its balancing network can be expressed in terms of the gain necessary to make the repeater sing. This gain is the actual effective gain given by a 21-type unit to a circuit, and is equal to the calibrated gain as measured on a gain-measuring set. As shown in Fig. 3, this gain g is equal to the actual gain of the element G minus the loss due to two divisions of energy at the output transformer. This latter loss is $2 \times 3{\cdot}2$ standard miles $= 6{\cdot}4$ standard miles plus the actual coil loss, the total being approximately 7 standard miles. Hence $g = G - 7$. With coils as actually used, the inherent loss is about $0{\cdot}6$ standard mile.

For singing to occur, the gain G must equal the

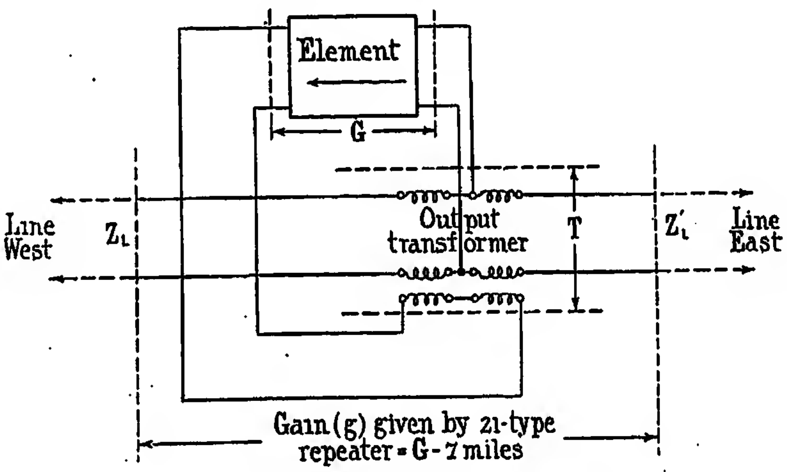

Fig. 3.—Diagram of "21" type repeater circuit.

transmission loss T due to imperfect balance between line "east" and line "west,"

$$\text{i.e. } G = T, \quad \text{or} \quad g = T - 7$$

From this a new definition of singing point is obtained, namely, the transmission loss across a 3-winding transformer minus 7 S.M.

If this result is applied to a 22-type circuit when arranged for a singing point test as given below, it will be found that $T - 7$ is equal to the sum of the calibrated gains of the two potentiometer settings plus 7.

Fig. 4 is a simplified diagram of the "22" type repeater circuit. In describing the method of procedure of making the "21" circuit test, reference will be made to this figure.

To test the balance existing between the east line and its balancing network, the repeater is disconnected from the west line by placing a short-circuit plug in the repeater "line jacks west" and the west network is removed by inserting an open-circuit plug in the repeater "drop jacks west." It will now be seen that the output transformer is so arranged that it will operate as an ordinary repeating coil. This connects the output of repeater No. 2 to the input of repeater

No. 1, forming a "21" circuit involving both repeaters. The singing point should now be determined by monitoring on the repeater set and increasing the gain, step by step, until singing occurs.

The dials of the two potentiometers should be moved up alternately so that they are always within one step of each other, and preferably on corresponding steps. When singing occurs, the readings on both dials are noted. The reading found in this manner has arbitrarily been called "plus poling."

The test is then repeated with the position of the plugs interchanged as regards their positions in the "west" line and "drop" jacks. This latter reading is called "negative poling."

The lower of the two readings obtained as described above is the more representative one, and is used in all cases.

When the unbalance current returns to the input terminals of the 3-winding transformer, it may or may not be in phase with the original current entry. When this return current is directly in phase, the cumulative result will be greater than when it is out of phase. For this reason two polings are taken, one of which will bring the return current more nearly in phase with the original current than the other, and will therefore give a lower singing-point reading.

The calibrated gains used in obtaining the singing-point are obtained from the weekly tests mentioned in a previous section of this paper.

(4) *Impedance unbalance test.*—In the "21" test the singing point is observed at the particular frequency at which the repeater system sings most readily, i.e. the frequency at which the impedance unbalance between the line and its network is greatest.

A method has, however, been developed which enables the singing point to be accurately determined at any desired frequency. This method and the particular testing designed for these purposes are described later in this paper.

(5) *Overall transmission test.*—These measurements should be made from test-board to test-board between the two terminals of the circuit, either on a loop or direct measurement (i.e. without the aid of a return loop) basis as discussed below.

(*a*) *Direct measurement of transmission.*—The circuit which it is desired to test should be connected to transmission measuring sets at both terminals. The terminal office in charge of the test can make arrangements with the distant terminal over the regular traffic channels. Measurements should be made in both directions, one station sending while the other receives, and vice versa. At the sending station the impedance of the sending element should be adjusted to fit the impedance, at that station, of the line which is being measured. At the receiving station the impedance of the receiving element should be adjusted to fit the impedance of the receiving end of the line, and also the impedance of the sending element should be adjusted to match the impedance at the sending end of the line in order that the receiving set may be properly calibrated to take account of differences of impedance, if any, between the two ends of the line. A more detailed description of this test, and the apparatus therefor, is given later in the paper.

(*b*) *Loop transmission testing.*—Where there is no transmission testing equipment at the distant office, it will be necessary to make measurements by looping the circuits back at these offices. Measurements should be made in both directions over the loop with the impedances in the sending and receiving elements of the measuring set adjusted to fit the impedance of the line being tested.

The measurements thus made will give an equivalent for the loop which involves two circuits. In order to obtain the value of each individual circuit it will be necessary to make three loop measurements on three circuits and to compute the value for each circuit from this triangulation.

Of the two methods described above, the first is by far the simpler to handle from both a testing and a traffic point of view. Fewer measurements are involved, and only the circuit under test has to be given up by the traffic department.

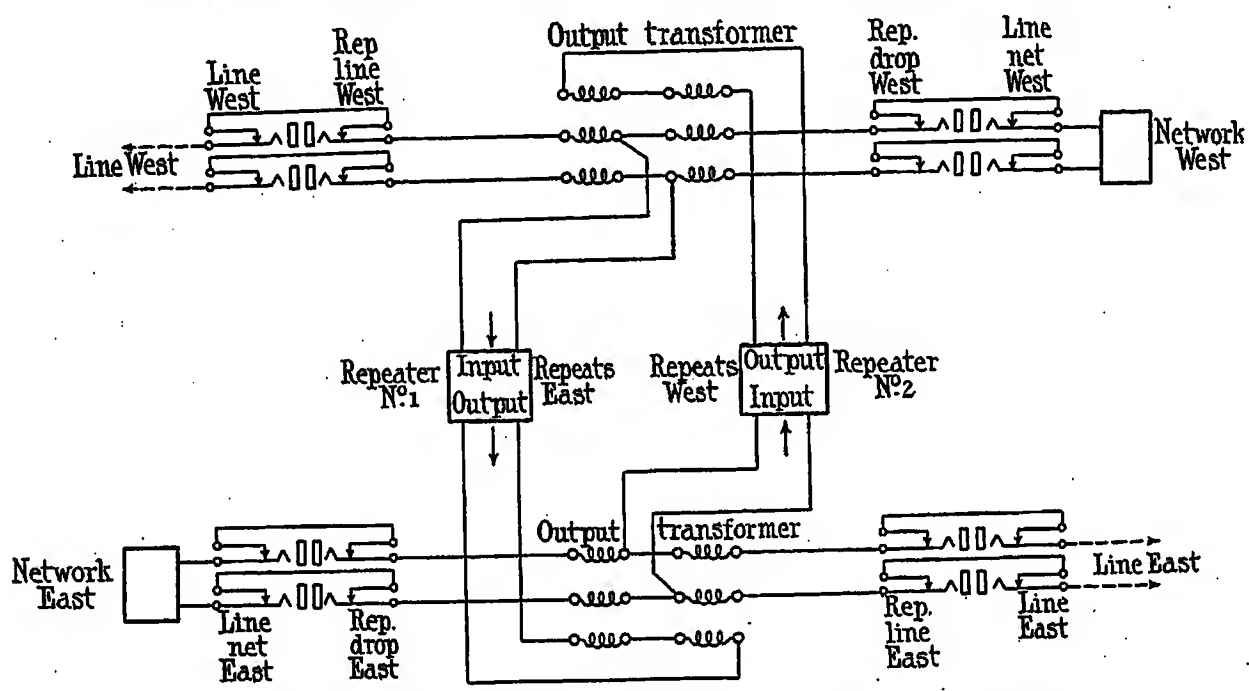

FIG. 4.—"22" type telephone repeater circuit, simplified diagram.

Part II.

METHODS AND MEANS.

The foregoing section has dealt with the more or less general aspect of modern transmission maintenance. The economic justification for good maintenance has been emphasized and the general lines upon which such maintenance is to-day provided for have been indicated. The present section deals particularly with the various factors affecting transmission efficiency in the various portions of the plant, and the methods and means for measuring the influence of these.

The last few years have seen considerable advances in the development of precision sets for telephone transmission measurement, and it is proposed to refer here to the application of such sets to the maintenance problem, in order that telephone engineers may better realize the ease with which such measurements can now be made.

Experience of the last decade in measurements of this kind has culminated in the development of precision measuring sets in such forms that they can be

Telephone transmission efficiency can be defined in terms of "intelligibility," or the ability of a system (the word system as used here comprises the items of telephone plant in service during a conversation between two subscribers) to transmit ideas correctly. Intelligibility can, in turn, be expressed in terms of "articulation," which can be defined as the ability of the system correctly to transmit sounds.

The chief factors determining the transmission efficiency of a system are shown diagrammatically in Fig. 5, which has been drawn up with particular reference to the viewpoint of transmission maintenance. Definitions for the less well-known terms used are given in this figure.

The five factors determining articulation, and therefore transmission efficiency, are :—

(A) Non-linear distortion.
(B) Noise conditions.
(C) Cross-talk.
(D) Echoes and transient effects.
(E) Frequency response.

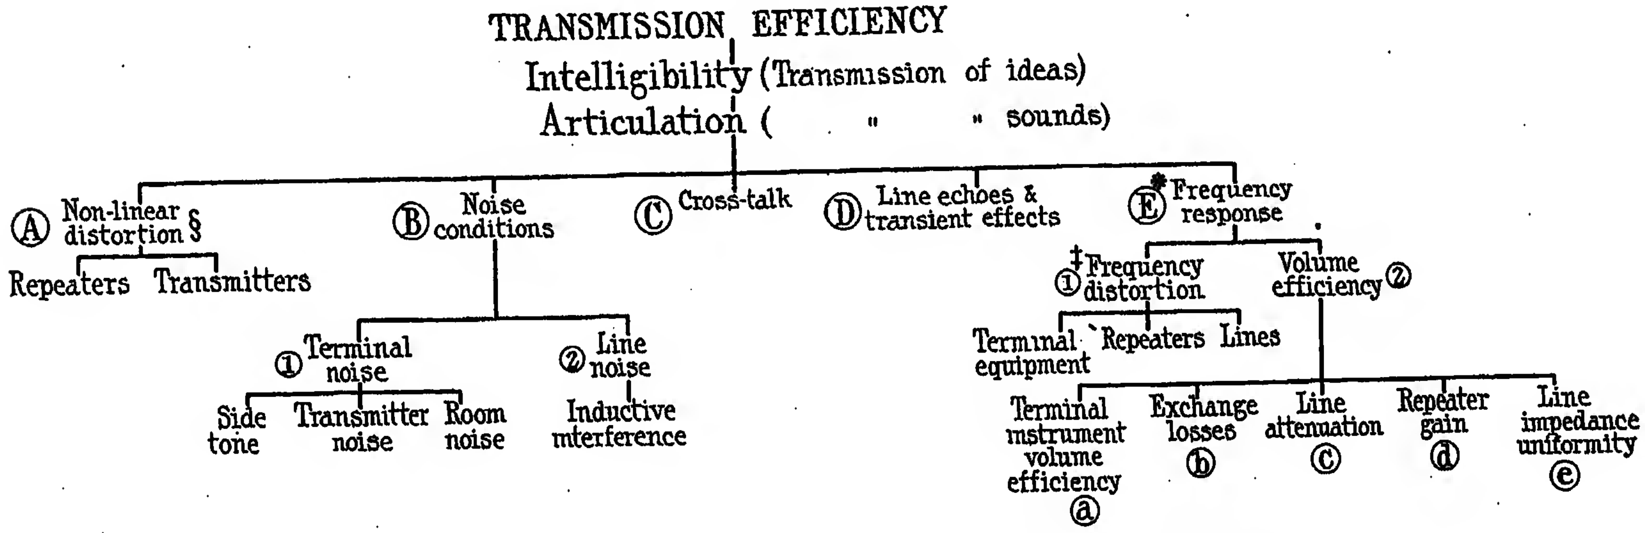

FIG. 5.—Diagram showing factors affecting transmission efficiency.

* The frequency response of a system is defined by its attenuation/frequency characteristic.
‡ The frequency distortion of a system is the distortion due to unequal attenuation of the different frequencies.
§ Non-linear distortion is caused by the output energy of a system not being directly proportional to the input energy, and results in the production of overtones not present in the original wave.

operated reliably by the more skilled members of the regular maintenance staff. By the use of such instruments the very considerable economy resulting from good transmission maintenance can be realized.

A number of the instruments described in this paper differ to some degree as to precision, range and portability. For the sake of identification and ready reference, type numbers have been used throughout in the description of the instruments.

In proceeding to a description of the various measuring sets, it is well to review some of the essentially theoretical aspects of the subject. So far, only the more practical aspects have been dealt with.

As the transmission efficiency of any portion of the telephone plant depends upon a large number of factors, it is well here to consider these in their relation to one another, as this will, of course, determine the care and cost which can justifiably be expended in maintenance tests upon each.

(A) NON-LINEAR DISTORTION.

Non-linear or asymmetric distortion is the least important of these. It occurs chiefly in repeaters and in transmitters when these are handling energy in excess of the value for which they have been designed.

In the case of repeaters it may be brought about if, by the imperfect control of repeater gains upon a long line, the power handled by a vacuum tube in the repeater is greater than it should be. In practice this is guarded against by a proper observation at each repeater station of the "transmission level," or in other words the voltage upon the circuit.

In the case of ordinary transmitters, non-linear distortion is greatly increased during loud speaking or shouting, particularly when this is close to the instrument.

The next two factors influencing transmission efficiency, namely, noise conditions and frequency response, are interdependent in that it is the difference between

the volume of reproduced speech and the volume of noise present which influences the articulation.

Both these factors are therefore of great importance.

(B) Noise Conditions.

The study of the influence of noise conditions upon transmission efficiency has only of recent years received

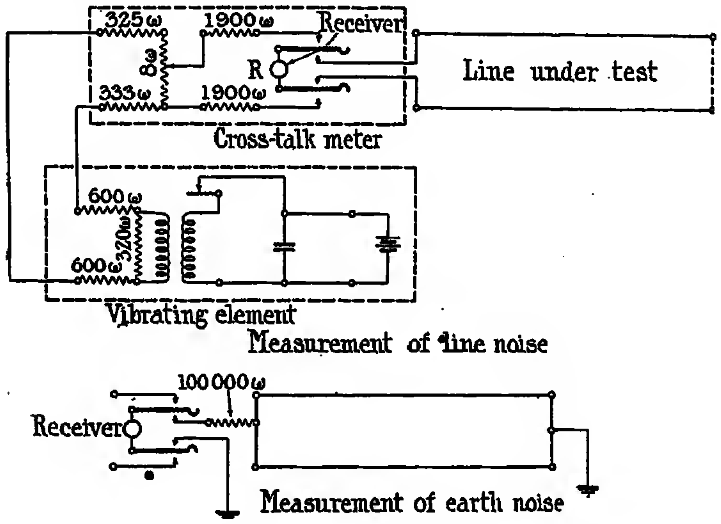

Fig. 6.—Circuit of noise-measuring set.

the attention which it deserves, and, although modern plant is now planned and constructed taking full account of the noise conditions to which the system might be subjected, it is necessary to be on the alert lest the increase in the noise condition of the circuits reaches such values that the transmission efficiency is impaired to an appreciable extent.

(1) *Terminal noise.*—This calls for little comment. Its presence at the sending end is due to the side tone of the terminal instrument, which is determined by the design of the latter and is therefore not likely to vary from time to time. Should it happen that under conditions of repair an incorrect connection is made within the set, leading to excessive side tone, this should be immediately observed and therefore corrected at once. Terminal noise is due chiefly to room noise which, except to the degree that its effects are worse when side tone is excessive, can obviously only be diminished by the subscriber. The most serious effect of room noise is due to side tone when receiving; it can be reduced by covering the transmitter mouthpiece with the hand. When subscribers' sets of the anti-side tone type are used, the effects of room noise are avoided. In cases where the transmitters employed are of a type unsuited to the circuits in which they are used, terminal noise may be caused by transmitter burning.

(2) *Line noise.*

(*a*) *Inductive interference.*—Line noise is generally due to inductive interference from external power circuits.

The important part which noise plays in determining the transmission efficiency of an average commercial telephone connection can be realized from the following example, based on known data regarding the influence of noise and other factors upon intelligibility.

Assuming a connection under average plant conditions between two subscribers each provided with central battery sets on 1-mile loops (20-lb. conductor) and connected by aerial lines equivalent to 30 miles of standard cable, the average line noise present upon such a connection is responsible for a decrease in intelligibility equivalent to the decrease in intelligibility which would be caused by increasing the equivalent cable length to about 45 miles, with the circuit absolutely quiet. (The increase in distortion with an increase in equivalent cable length has here been neglected.)

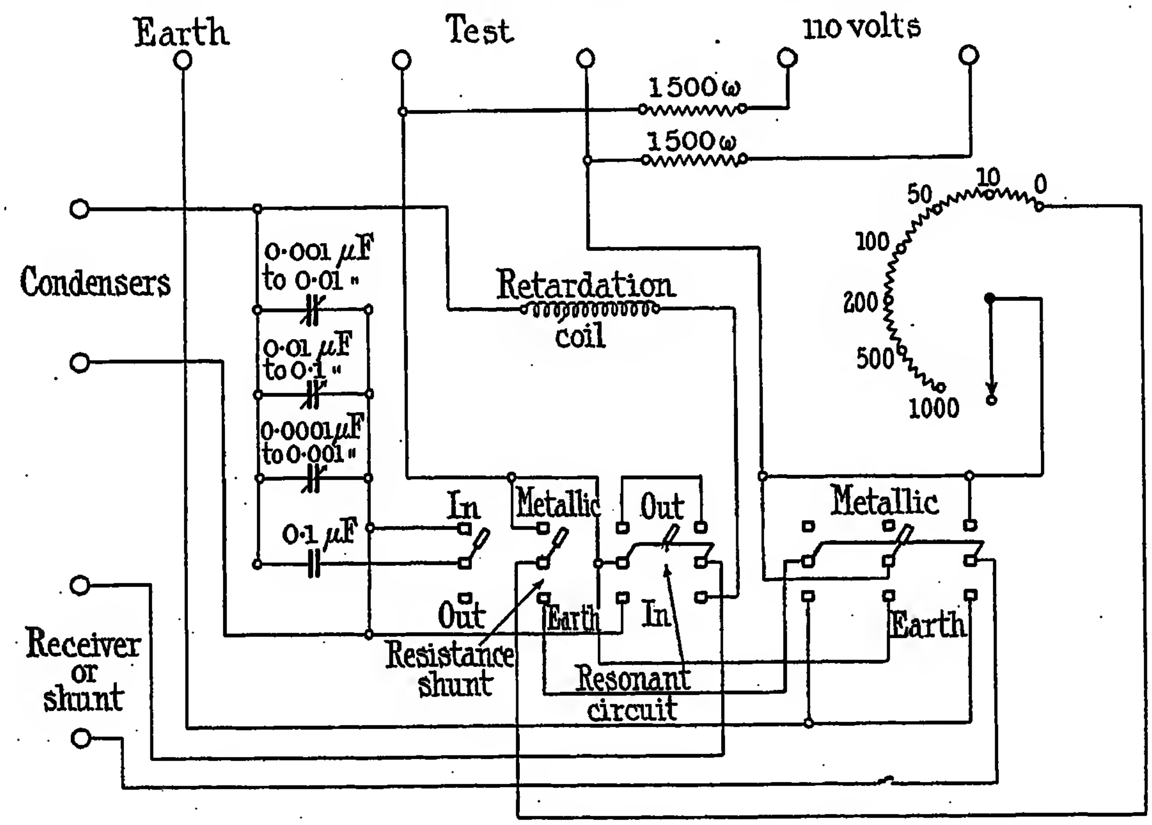

Fig. 7.—Circuit of "2-A" noise-analysing set.

The noise upon any circuit can be directly measured by means of a "1-A noise-measuring set" in terms

of an arbitrary noise unit. The effect upon transmission efficiency of various amounts of noise has been closely studied, so that an estimate can now be made of the reduction in intelligibility in any given case due to the presence of a given amount of noise.

The circuit of the noise-measuring set referred to above is illustrated in Fig. 6. It is a portable instru- calibrated to read in millionths of the output current from the source.

The circuit arrangements used for noise measurements are shown in Fig. 6. In measuring noise to earth, the two wires of a circuit within the cable under test (being subjected to the inducing influence) are connected to earth through a high resistance in series with the noise-

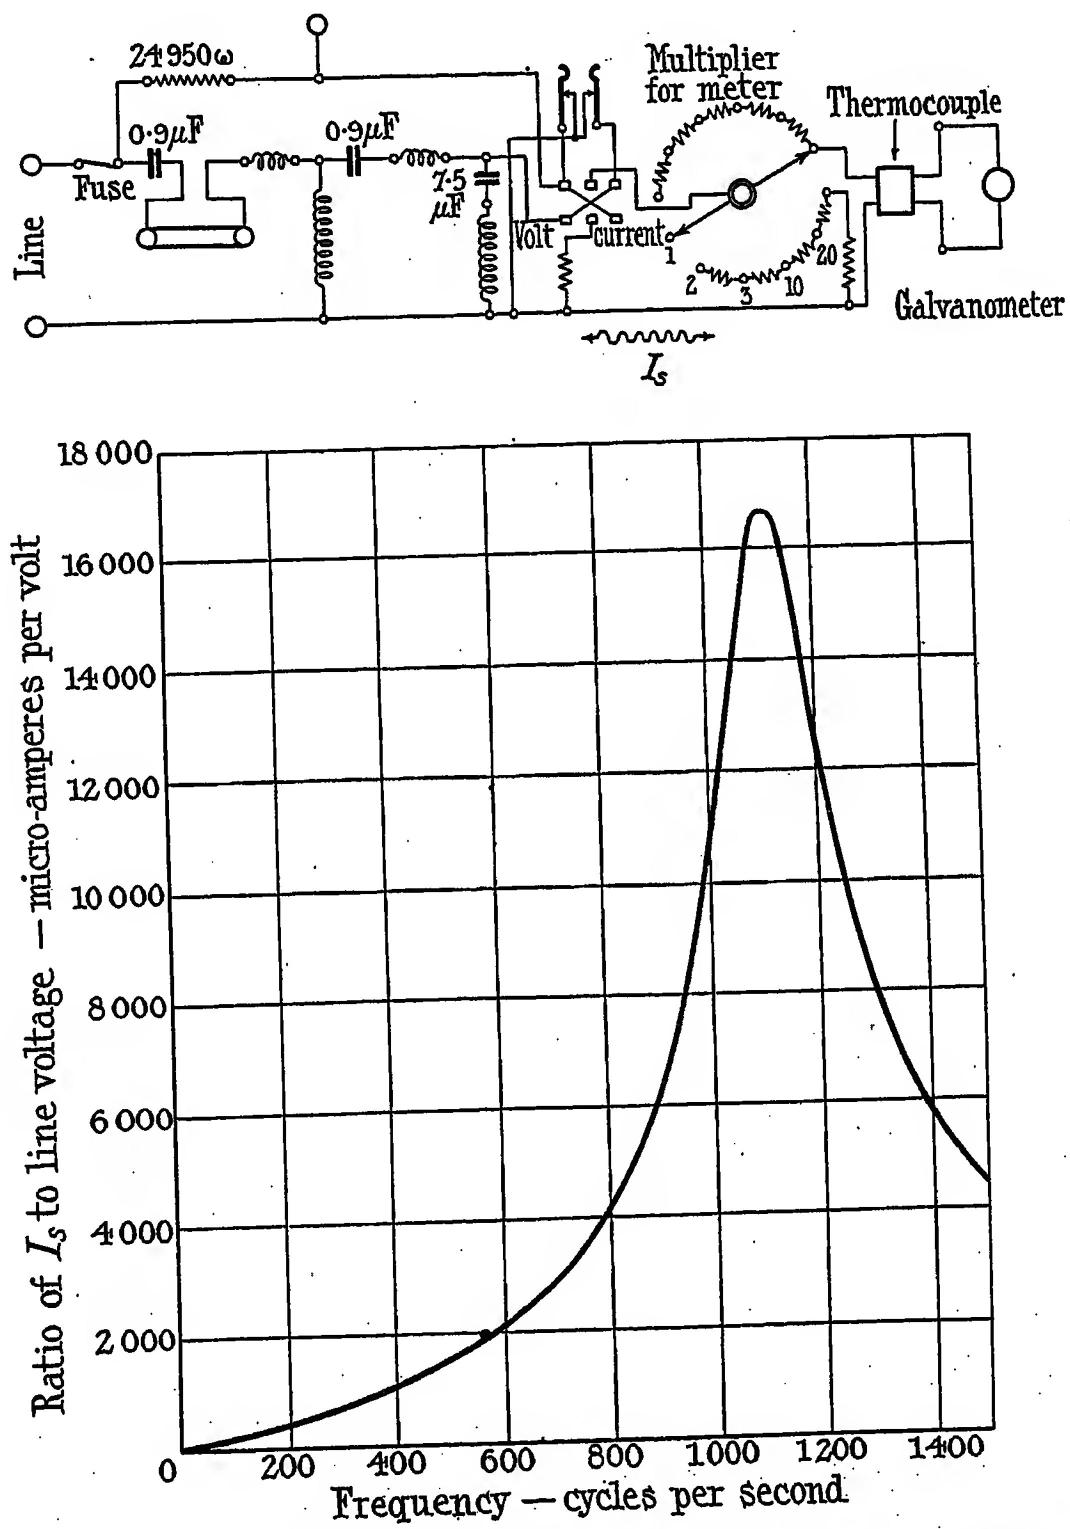

FIG. 8.—Circuit and calibration curve of telephone interference-factor measuring set.

ment including a standardized vibrating element or noise standard generating a noise of comparatively low fundamental tone very rich in harmonics. It is used in conjunction with a potentiometer, the noise upon the circuit under test being observed in a receiver and measured by adjusting the potentiometer setting until the noise in the receiver, when connected alternately to line and standard, is judged to cause the same interference with conversation. The potentiometer scale is measuring receiver and the noise units present in the receiver measured by comparison with the noise standard. This quantity can be regarded as a measure of the voltage to earth induced by the disturbing influences and tending to cause noise upon the circuit due to unbalances.

The number of noise units present in the receiver when connected across the two lines of the circuit is then measured. This quantity can be regarded as a

measure of the noise induced upon the circuit. The ratio of the noise to earth to the noise in the metallic circuit so measured may be taken as a rough index of the balance to earth of the cable under test from the viewpoint of freedom from inductive interference.

Two further instruments used in connection with noise investigations may be mentioned here.

The 2-*A noise-analysing set*, the circuit for which is shown in Fig. 7, is used for determining the frequencies of the different overtones present in a noise and, in conjunction with the 1-A noise-measuring set, may be used for obtaining an approximate estimate of the relative magnitudes of the different overtones.

The *telephone interference factor meter*, the circuit for between telephone circuits in millionths of the current which flows from a standard talking set into a universal shunt having about the same impedance as a long non-loaded open-wire circuit, say about 600 ohms.

The fundamental criterion of cross-talk between two circuits is the amount of the energy transferred from a sending end of one circuit to the receiving end of another and, as it may happen that the characteristic impedances of these circuits are different, it is necessary that this fact should be allowed for in measuring cross-talk.

In most cases it is necessary to make allowance for this fact in correcting cross-talk readings as actually made with a measuring set by multiplying by a factor $\sqrt{(z_2/z_1)}$, where z_1 and z_2 are the characteristic impedances of the disturbing circuit and the disturbed circuit respectively.

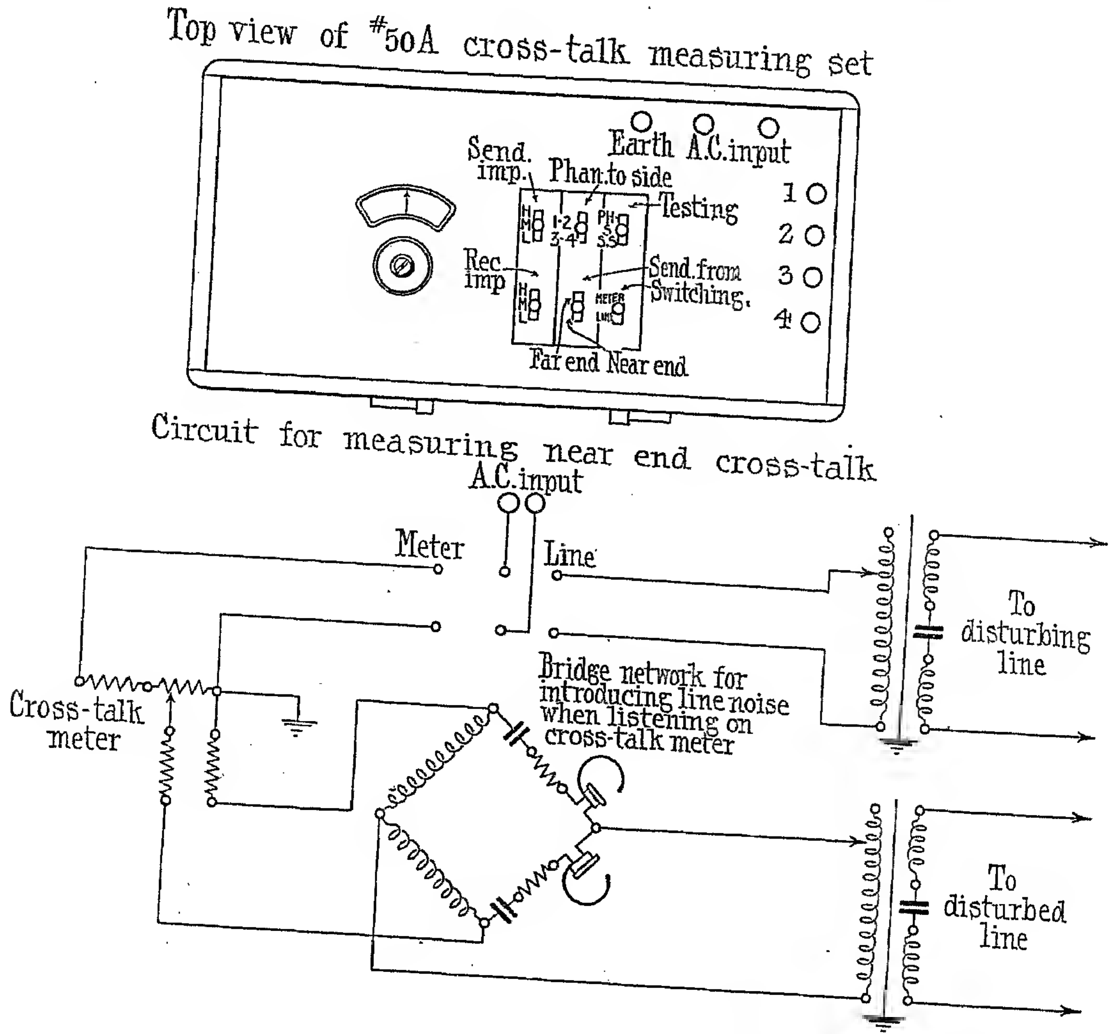

FIG. 9.

which is shown in Fig. 8, is used to measure the telephone interference factor of the wave-form of any electrical machine or system, this factor being an approximate measure of the relative tendency which the electrical plant involved will have to cause noise in a telephone circuit, other conditions remaining constant.

These two instruments are used in association with investigational work rather than with regular transmission maintenance, and do not therefore call for more detailed description.

(C) Cross-talk.

The ordinary methods for the measurement of cross-talk upon a circuit by means of a cross-talk meter are now well known to telephone engineers. Until recently it was found convenient to express the cross-talk

In making cross-talk measurements upon noisy lines, difficulty is experienced in obtaining a good balance between the cross-talk current in the testing receiver when connected alternately to the disturbed line under test and to the cross-talk meter. This practical difficulty is eliminated in the cross-talk measuring set indicated in Fig. 9 in which two balanced receiving circuits are used to connect together the receivers, the "listen" terminals of the cross-talk meter and the disturbed line, in such a manner that the line noise will be heard at all times in the receivers while the presence of the disturbed line will not affect the current flowing into the receivers from the cross-talk meter, and vice versa. This is, of course, an application of the Wheatstone bridge principle.

This set is arranged to measure the current in the disturbed circuit in millionths of the current passing in the receiving circuit, assuming that these circuits are of the same impedance. It is, of course, important in making such tests that the circuits under test are terminated with impedances of the same order as those of the circuits. In the cross-talk measuring set referred to, the circuit under test can be terminated by impedances approximately corresponding to 1 800, 1 200 or 600 ohms, repeating coils (transformers) with variable ratios of transformation obtained by means of tapping being employed. These values have been chosen to cover the range of normal impedance values occurring in a modern telephone system, namely, "heavy" loaded, "medium" loaded and non-loaded cable circuits.

A balanced retardation coil is provided in the testing circuit to enable cross-talk tests to be made between the phantom and side circuits of a group of four wires.

For the termination of the distant ends of the circuit under test it is usual to employ a resistance box, from which resistance values corresponding to the three

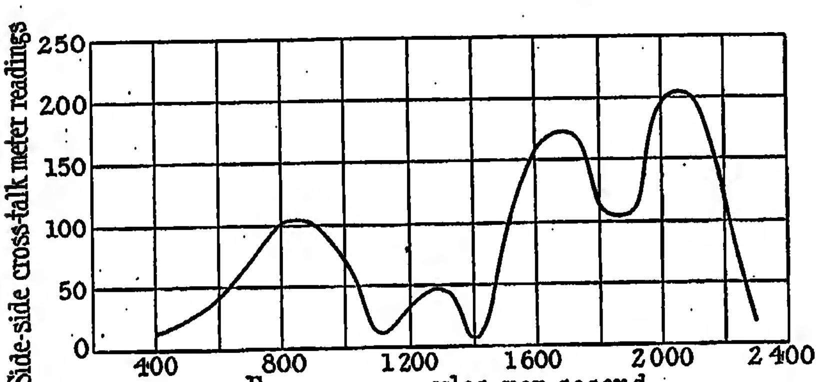

FIG. 10.—Curve showing variation of cross-talk with frequency.

From tests made on a quad of 1·0 mm conductors in cable, 22·2 km long, loaded every 2 km with 0·177-henry coils in the side circuits and 0·107-henry coils in the phantom side. The far end was terminated with pure resistance equal to the characteristic impedance.

impedances given above can be obtained. For convenience of making phantom circuit to side circuit measurements, the resistances for terminating the side circuits are of the balanced type, the mid-points being used for taking off the phantom taps.

It is, of course, of vital importance that cross-talk measuring apparatus such as that described above is carefully balanced and itself free from cross-talk.

In making cross-talk tests upon circuits, it is important that a source of testing current be employed which gives results comparable with those obtained if actual speech were employed.

When cross-talk frequency curves are obtained from measurements on loaded cable circuits, it is frequently found that these are not smooth and regular but are of an undulatory nature. Fig. 10 shows a typical curve of this kind. The undulations may be due to a variety of causes, one of which, and probably the most important, being that the cross-talk as measured is the summed-up effect of a number of sources of cross-talk which combine in different ways, depending upon the frequency. If there are two sources of cross-talk not close together and the cross-talk due to each as measured at the end of the line is known, the two values must be combined at an angle, depending on the frequency, to obtain the total cross-talk. The cross-talk due to each source alone varies approximately as the frequency, but that due to two sources may vary more rapidly, owing to the variation of the angle between them.

From the above, it is evident that since a small change in value of a single frequency might cause a change from a high to a low value of cross-talk, single-frequency cross-talk tests cannot in general be relied upon to give an indication of the cross-talk condition of the plant.

A source of power has been developed which gives results comparable with those of speech. It consists of an electrically driven vibrator, giving a low-frequency tone rich in harmonics. In using this source of power for cross-talk measurement or loaded circuits, a network is inserted in the circuit to limit the current passing and to terminate properly the sending circuit.

(D) Line Echoes and Transient Effects.

These effects are inherent in long-distance circuits involving loading and repeaters, and are taken into account in the design and planning of such circuits. They are dependent on the type of loading employed and the number and location of the repeaters, also upon the transmission gains at which the repeaters are operated and the degree of unbalance between balancing networks and lines. If under service conditions these effects are found to be appreciable, they must be diminished by a reduction of repeater gains or by an improvement in the degree of balance between lines and balancing networks.

The instruments used for the measurement of repeater gain and line impedance balance are referred to later.

(E) Frequency Response Characteristic.

The last of the five chief factors determining the transmission efficiency of the system remains to be dealt with.

This factor has been referred to earlier as the frequency response characteristic of the system, and involves the volume transmission efficiency of the system for all individual frequencies occurring in the sounds which it is desired to transmit.

The frequency response characteristic of a system is usually represented by a curve plotted between response (vertically) and frequency (horizontally), the values of response being in terms of the total attenuation occurring in the system at each individual frequency.

It will be seen from Fig. 5 that the influence of frequency response upon the transmission efficiency can be regarded as due to two separate considerations, namely, frequency distortion and volume efficiency.

(1) *Frequency distortion* is, of course, the distortion due to various single frequencies in the telephone range being attenuated differently. The term "volvme efficiency," as used here, involves the idea not of the volume efficiency at one frequency but the effective volume efficiency due to all the frequencies being transmitted, the volume efficiency for each individual frequency being weighted in accordance with its importance.

Dealing first with the frequency distortion factor for the system, this will depend on the frequency distortion occurring in the terminal equipment, comprising the telephone instruments and the exchange equipment, the frequency distortion in the lines themselves and also in the repeater. The frequency distortion occurring in the terminal equipment and in the lines is determined at the time the system is planned and constructed.

In the case of repeaters of the 2-wire type, the frequency distortion present may vary from time to time, depending upon the margin existing between the gain at which the repeater is operating and the singing point between the lines and balancing networks between which the repeater is working. Ordinarily, repeaters of this type are so designed and adjusted that the gains given at various frequencies are those required when the lines and networks with which they are used are balanced for impedance within certain well-defined limits. Should it happen that, owing to line troubles, the standard of impedance balance between the line and network is lowered, and that at the same time the repeater gain is not reduced by a corresponding amount, the gain given by the repeater at different frequencies will depart from the normal values.

This effect is well illustrated by Fig. 11, which shows the transmission frequency characteristic of a repeatered loaded cable circuit under two conditions: first, when the gain given by the repeater almost brings the system to a singing condition; and, secondly, when the repeater gain has been lowered from its previous value by about 4 miles of standard cable.

It is evident, therefore, that the varying effect of frequency distortion in repeaters of the 2-wire type will have to be guarded against by ensuring that line-impedance uniformity is maintained to a certain standard, and that repeater gains are maintained uniform at certain predetermined values.

Considerations of volume efficiency for the system demand the same requirements, and the means which are employed for the maintenance of these conditions are dealt with below under "Volume Efficiency."

It is necessary to point out here that in the case of repeaters of the 4-wire type the above considerations do not apply, as the gain which such repeaters can give is not so dependent on the impedance balance of the lines to which they are connected.

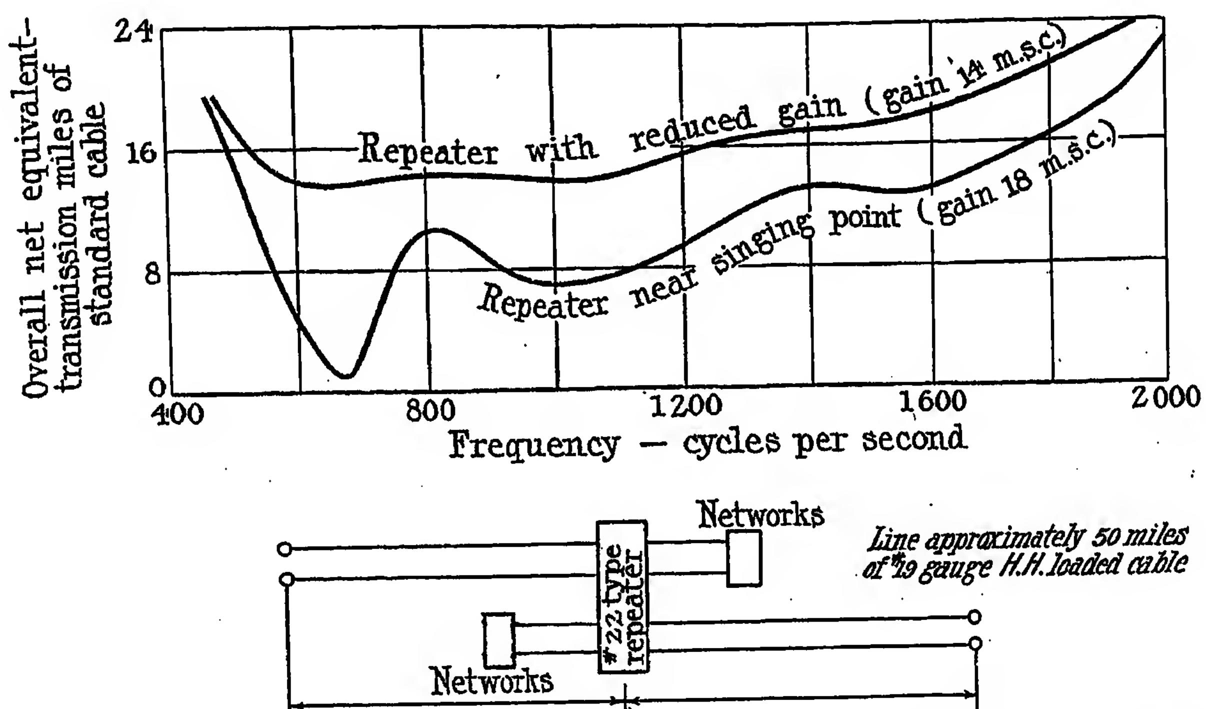

FIG. 11.—" 22 " type repeaters. Effect of lowered line singing point upon attenuation characteristic of circuit.

(2) Volume Efficiency.

We turn now to the second factor contributing to the frequency response characteristic of the system, namely, volume efficiency. From the viewpoint of transmission maintenance, this is without doubt the most important of any single factor bearing upon transmission efficiency. In the early days of telephone transmission engineering it was the only factor to which serious attention was given by engineers, and a tendency remains to-day in some countries to judge the transmission efficiency of a system from the attenuation values of its component parts, with entire disregard of noise condition, or even of distortion.

The volume efficiency of a system depends upon the volume efficiency of the component parts, terminal equipment lines and repeaters, etc., at all frequencies. It also depends upon the transition losses, which are liable to occur at the junction between the various plant items.

Of these various factors, all, with the exception of transition losses, are controlled by routine transmission maintenance. Ordinarily, in planning the system, care is taken that the impedances of the various circuit elements, which are or might be used in conjunction one with the other, are sufficiently similar in impedance characteristics to cause inappreciable losses. In the matching of the impedance values of various parts of the plant, repeating coils and transformers with "inequality ratio" windings play an important part, and it is, of course, important in new construction or

in extension work that transformers of the proper impedance ratio should always be employed.

The remaining factors, as will be seen from Fig. 5, are resolved into the following items :—

(a) Terminal-instrument volume efficiency.
(b) Exchange losses.
(c) Line attenuation.
(d) Repeater gain.
(e) Line impedance uniformity.

The means and methods available for the measurement of these items will now be described.

(a) *Terminal-instrument volume efficiency.*—Until recently it has been almost general practice with telephone administrations to assume that a telephone set when once put into service retains its original efficiency. In cases where obvious defects have arisen in subscribers' sets, it has been left to the regular maintenance staff to effect such repairs as were clearly necessary, without an accurate check on the efficiency of the telephone set being made. Undoubtedly the explanation of this has been the difficulty and cost of making efficiency tests, due to the necessity of making actual speech tests under more or less laboratory conditions, the volume efficiency of the instrument under test being carefully compared with standard instruments of known efficiency.

The institution of repair and recovery workshops, where defective instruments are corrected by a specially trained staff, and the development of rapid routine methods for making volume efficiency tests, have overcome this difficulty.

(b) *Exchange losses.*—In the earlier part of this paper (page 659), reference was made to the necessity of providing an instrument for measuring in a rapid routine manner such parts of the exchange equipment as experience has shown to be subject to defects. Such an instrument is the 1-B transmission measuring set, the circuit of which is given in Fig. 12. It has been primarily designed for measuring with a 1 000-cycle alternating current the transmission losses caused by telephone apparatus and exchange equipment under regular operating conditions. It can also be used for measuring the loss in junction, trunk lines, etc., provided that the two ends of the circuit or equipment to be tested can be made available at the testing point. The set is arranged to measure losses from 0 to 46 miles of standard cable in steps of half a mile. It is constructed in a portable form and weighs approximately 13 lb.

While we can use any source of single-frequency current giving suitable wave-form and approximately the correct frequency, a special single-frequency source to give current of a frequency of 1 000 cycles per second has been designed for use with the set. This oscillator consists essentially of a generator element and a filter circuit. The generating element consists of a carbon button and two specially-wound receiver spools coupled by means of a tuned metallic reed. The system operates off three dry cells, which are mounted in the same carrying case as the generating element proper.

The circuit of this measuring set is made up of two artificial line branches, which are permanently bridged together, at the end of which the alternating-current source is connected so that the same alternating potential is impressed on both branches. These two branches are similar, except that the apparatus or circuit of which the transmission loss is to be measured is connected into the upper one, while the lower one consists of an arrangement of variable resistances both in series and in shunt, constituting a variable artificial line.

In using the set, the variable artificial line in the lower branch of the circuit is adjusted so that the same volume of transmission is received over each of the two branches at the receiving ends, and the loss in the apparatus under test is known directly from the

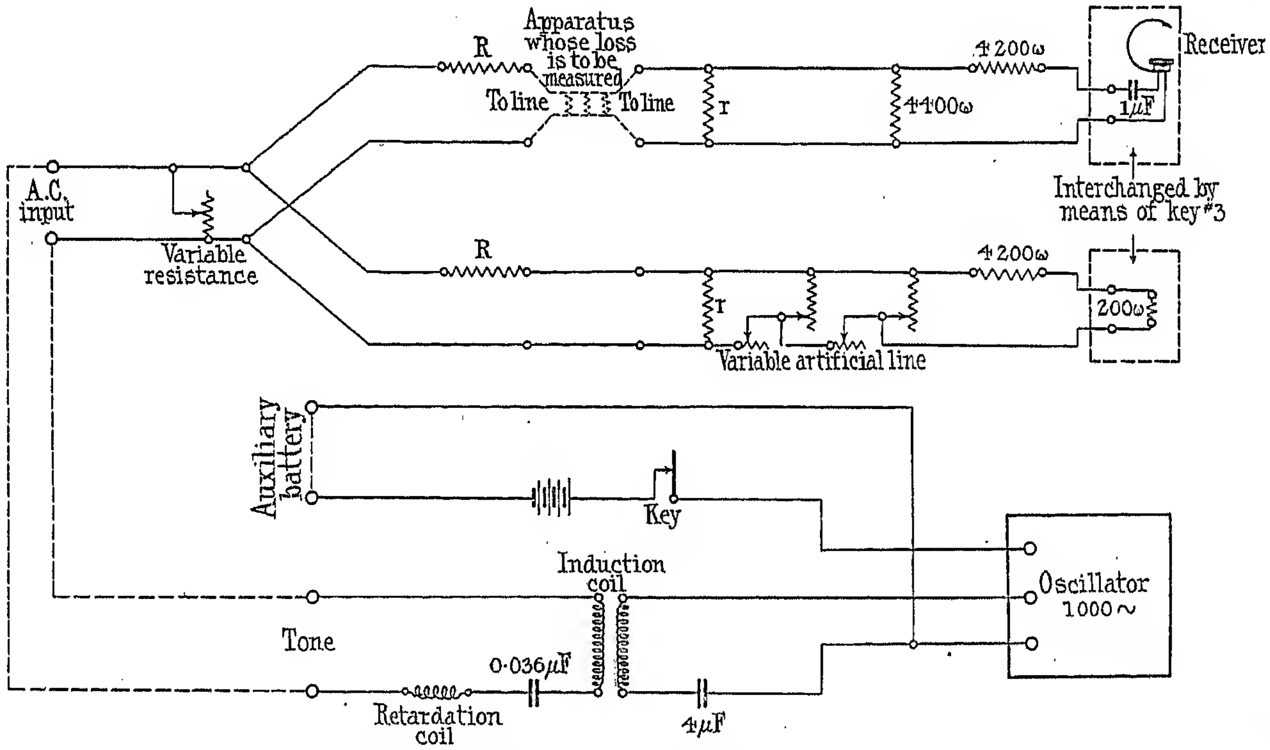

FIG. 12.—Circuit of "1-B" transmission measuring set and "2-B" oscillator.

setting of the variable artificial line, which is calibrated in miles of standard cable. A receiver and a condenser in series are connected to the receiving terminals of the upper branch of the circuit, and a 200-ohm resistance (which simulates at 1 000 cycles the impedance of the receiver and the condenser in series) to the receiving terminals of the lower branch of the circuit. Actually, of course, the receiver combination and the 200-ohm resistance are interchanged between the two branches, as is necessary for making the transmission determination by means of a switch. The artificial lines used in the two branches of the circuit are made up of non-inductive resistances.

The apparatus to be measured is connected between the two parts of the artificial lines in the upper branch. The variable artificial line in the lower branch has been designed in such a manner that, regardless of the setting, the impedance of the circuit to the right of the resistance r in the lower branch is uniform. The resistance R can, by means of a key, be made to have any one of three values corresponding respectively to heavily loaded, medium loaded, or non-loaded lines. Similarly, by suitable changes in the value of r, the artificial line made up of r in conjunction with the resistance to the right can be made to have any one of the three values mentioned. As the transmission loss caused by telephone apparatus depends upon the type of line into which it is inserted, the above-mentioned arrangement makes it practicable to determine the loss due to equipment used with various types of circuits, and thus to measure the losses under the approximate impedance conditions which hold in regular service.

(*c*) *Line attenuation.*—The transmission set described above can be used for measuring attenuation only when both ends of the line or circuit under test are available at the set. This, as has been explained earlier, involves the looping back of lines at a distant point. Apart from the obvious inconvenience of such a method, the disturbance to traffic conditions involved by the use of several lines simultaneously for testing purposes has justified the development of an instrument which in use involves only the line under test. The circuit of this instrument, the 3-A transmission measuring set, is indicated in Fig. 13. It is used for measuring the transmission equivalents of lines, and also to measure the losses in apparatus and exchange equipment, when these are desired, to a higher degree of accuracy than is possible with the 1-B set described above.

The 3-A transmission measuring set is arranged in a portable form and employs a direct-reading meter. It uses visual indication instead of audible indication. It is calibrated directly in miles of standard cable and enables transmission-equivalents from zero to 30 miles of standard cable to be accurately and quickly measured to within 0·1 standard mile. It is also arranged to permit the current supply conditions of subscribers' operator's cord circuits and switching trunks to be measured.

The dimensions of the set are 22 in. × 8 in. and its weight is about 37 lb., excluding the source of testing current. While any source of current having the proper output, suitable wave-form and frequency, can be used, a special oscillator generating a current having a frequency of 1 000 cycles per second has been designed for use with the set and is known as the " 3-A " oscillator. This oscillator delivers more power than is available from the 2-B oscillator used with the 1-B transmission measuring set.

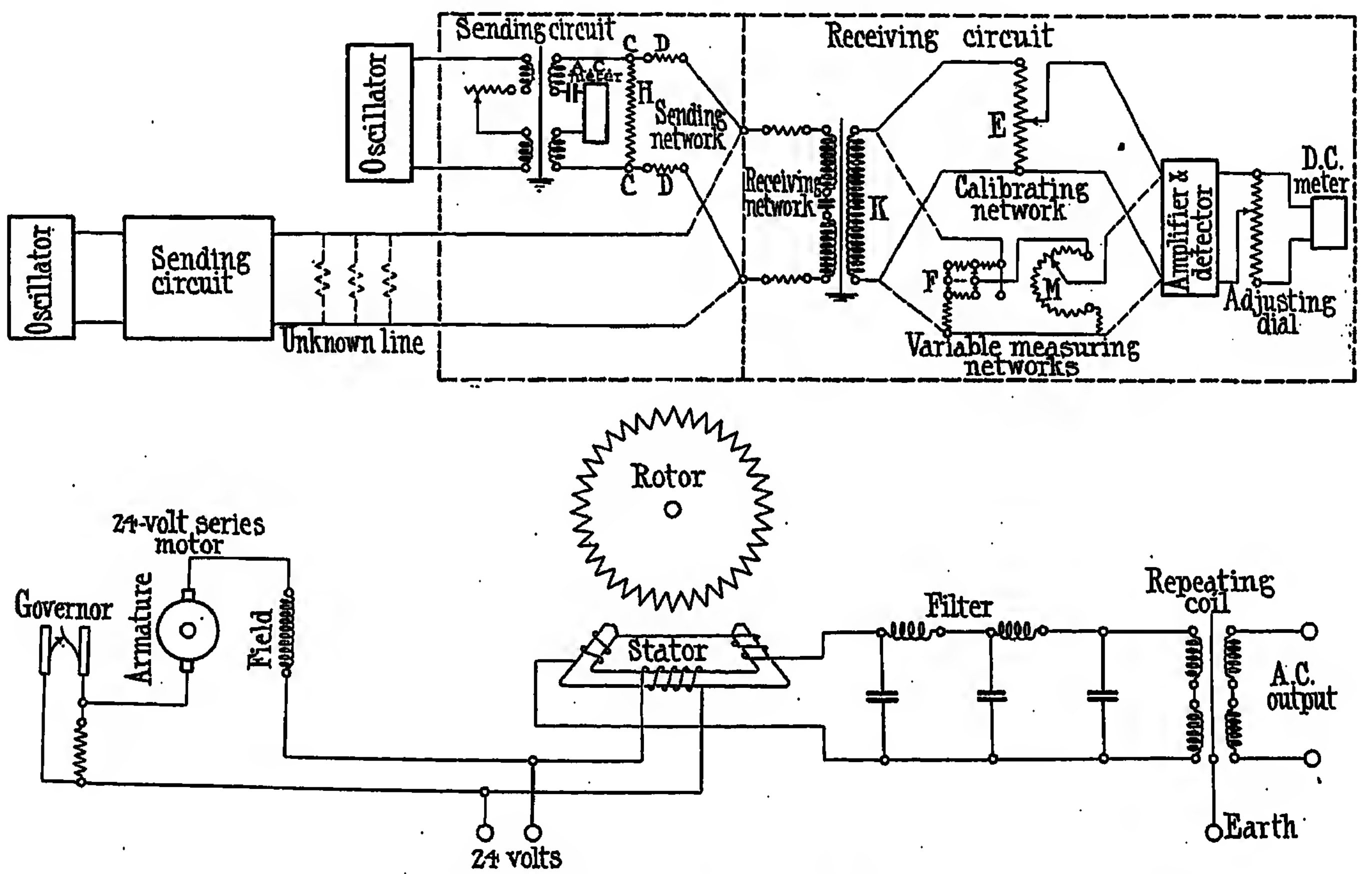

FIG. 13.—Circuit of " 3-A " transmission measuring set and " 3-A " oscillator.

Both the measuring set and its oscillator operate satisfactorily from the regular 24-volt battery as a source of power. The set contains two vacuum tubes but does not require a separate plate battery, the 24-volt battery supplying both filament and plate currents.

The operation of this set when used for measuring the attenuation of a line is briefly as follows :—

Referring to the measuring set located at the receiving end of the line under test, alternating current is passed from the sending circuit of this set into a resistance network, which approximates in impedance to the transmitting end of the line under test. This network is connected to another network (having an impedance approximating to that of the receiving end of the line under test) which forms part of the receiving circuit.

The current from the sending circuit flows through the networks referred to above, and after passing through a transformer and a calibrating network reaches an amplifier-detector, the output of which is connected to a direct-current meter upon which a deflection is produced. By means of an adjusting resistance located across this meter, the deflection is adjusted to a definite value. Such tests with the sending and receiving circuits (both at the receiving end of the line under test) connected together can be called calibration.

The sending and receiving circuits referred to above are then separated, the receiving circuit being connected by means of a switch to the receiving end of the line under test, and the sending circuit, or a similar one, to the sending end of the line. The calibration network, which during calibration caused a definite transmission loss, is now replaced by two variable measuring networks, the substitution being effected by means of switches. One of these networks is variable in small steps to cause losses from zero to 10 miles, while the other is variable in steps of 10 miles. When the line under test is connected between the sending and receiving circuits, the current which flows into the receiving circuit will, of course, be reduced to a value less than that which was obtained during calibration, on account of the attenuation of the line under test. The deflection on the meter will consequently be less than when the circuit was being calibrated. If the transmission loss caused by the variable measuring network is decreased until the deflection on the meter is the same as during calibration, the difference between the loss caused by the fixed calibrating network and that caused by the variable measuring network will be equal to the transmission loss caused by the line under test. The measuring networks are calibrated to read this difference directly.

The complete sending circuit of the set consists of an oscillator, a rheostat for regulating its output, an alternating-current meter for measuring the output, and a network of resistances which form the artificial line.

The receiving circuit consists primarily of a resistance network, a transformer K, a calibrating network E, variable measuring networks F and M, a resistance-adjusting dial, an amplifier and detector, and a direct-current meter.

In the sending circuit the resistance network includes the resistances DD, which are adjustable to have a total impedance of 600, 1 200 and 1 800 ohms respectively, corresponding to low, medium and high impedance. The resistance H is non-inductive and is connected across the terminals of the artificial line DD. It will be noted that the alternating-current milliammeter is connected in the output circuit of the oscillator so that it reads the total current flowing through the resistances DD and H. The resistance H is so low in comparison with DD that only a very small proportion of the total current flows through DD when it is connected to the line or to a receiving circuit. Therefore, with a given current through the milliammeter, it can be assumed that the voltage between the points CC is practically independent of the impedance to which the sending circuit is connected, and that if any two sending circuits have the resistances and currents adjusted to the same values, the voltages across the points CC will be equal.

In the receiving circuit the transformer K is shielded and so designed that its impedance will be approximately 600 ohms when connected to the apparatus to its right. In order that the impedance of the receiving circuit can be adjusted to the values of 600, 1 200 and 1 800 ohms corresponding to the impedance of the receiving end of the line, resistances are connected between the coil and the terminals to which the line under test is connected. The calibrating network E is a potentiometer designed so that the ratio of the voltage impressed by it on the amplifier to that impressed upon it by the transformer K corresponds to a transmission loss of 30 miles of standard cable at a frequency of 800 cycles per second. The variable measuring network M is a potentiometer having a total resistance corresponding to that of the calibrating network E, but designed so that it can be adjusted to cause losses from zero to 10 miles. It is in the form of a circular slide wire and is calibrated in steps of 0·1 mile. The variable network F is a constant-impedance shunt, so that the ratio of the current entering the variable network M, to the current entering the shunt, can be adjusted to values which correspond to transmission losses of 0, 10 and 20 miles of standard cable at 800 cycles per second. The amplifier and detector circuit contains two vacuum tubes, one serving as an amplifier and the other as a combined amplifier and rectifier or detector. The adjusting dial is a circular slide-wire potentiometer, the setting of which determines the current supplied to the direct-current meter. It is so arranged that the impedance, as looked at from the direct-current meter terminals, is constant, thus keeping constant the damping of the meter.

The various jacks and terminals enable the set to be used with different types of jacks, or with ordinary wires, and also permit the use of the set for the measurement of current-supply conditions, etc.

A still higher development in transmission measuring apparatus is the 4-A transmission measuring set. This set has been designed for use at the more important centres in the trunk line plant for making measurements over a greater range of conditions, particularly as regards frequency, than is possible with the sets already described.

The approximate overall dimensions of this set are 33 in. × 18 in. × 14 in. It is intended as a permanent fixture in important terminal stations, and is usually provided with a number of local circuits terminating on jacks for the use of the test clerk, to facilitate the measuring of a large number of circuits with a minimum of delay. Various signals and a telephone set are provided for use in conducting the tests. The circuit arrangements of this set are similar in principle to those in the 3-A set described above.

The range of measurement is, however, greater, as losses from 0 to 60 miles and gains from 0 to 20 miles of standard cable may be measured to 0·1 standard mile. The amplifier-detector provided in this set has three vacuum tubes, this number being necessary on account of the considerable range of the set.

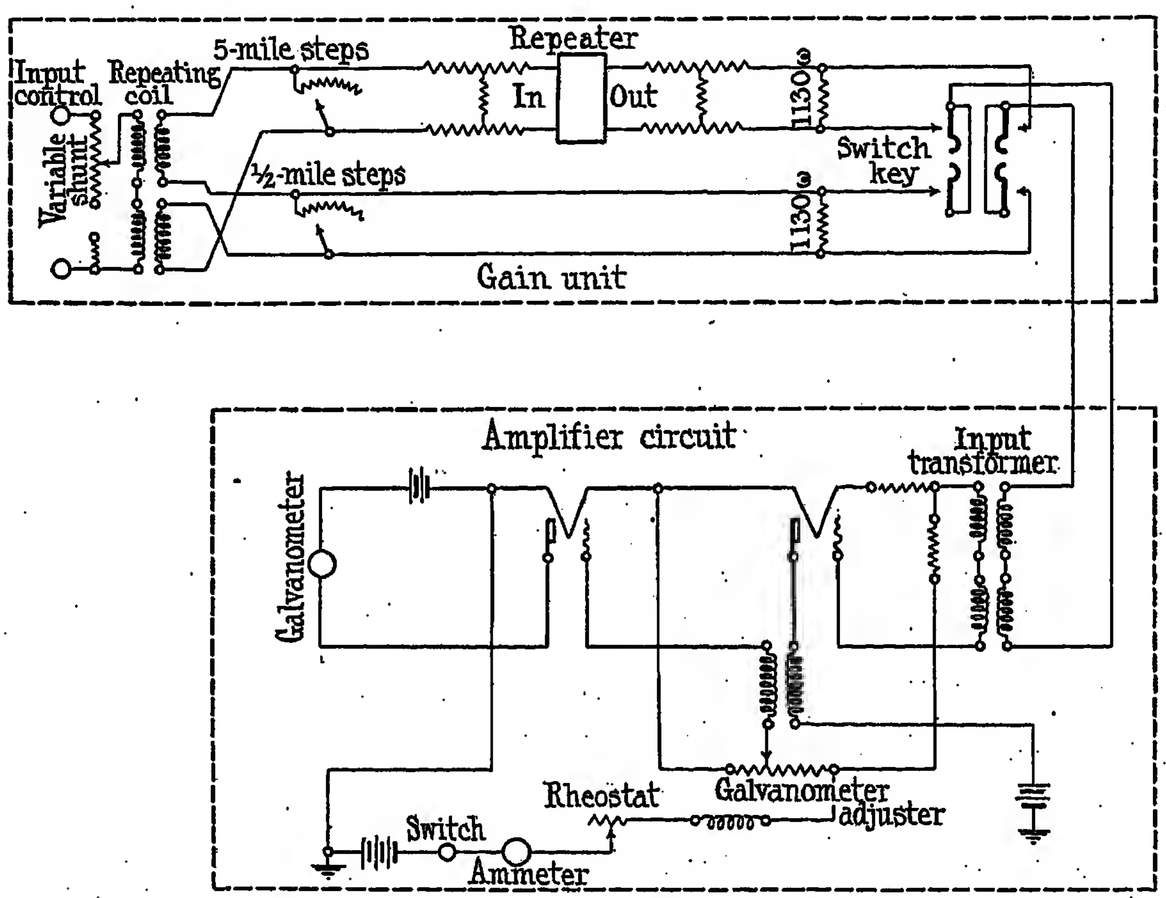

FIG. 14.—Circuit of " 2-A " repeater gain-measuring set.

While for obtaining the relation between attenuation and frequency for any line, a variable-frequency oscillator giving any single frequency between, say, 200 and 4 000 cycles is used, this measuring set is chiefly used in conjunction with a special oscillator (5-A) to make measurements at 1 000 cycles per second.

The 5-A oscillator delivers testing current the frequency of which varies rapidly to and fro over a range from 900 to 1 100 cycles per second, and experience has shown that although the true attenuation/frequency curve of the line is somewhat irregular, owing to slight impedance irregularities in line construction, the attenuation measured when this oscillator is employed is substantially that which would be obtained with a single-frequency measurement at 1 000 cycles per second, if the line construction were ideal, that is, free from all irregularities.

(d) *Repeater gain.*—In order that the gain given by any repeater (of either the 2-wire or 4-wire type) in a repeater station can be checked and calibrated for any setting of the gain control, it is usual to provide at least one repeater gain set of the No. 2 type. This gain set is mounted on two panels which are situated on the same racks as the repeaters, and is located in close proximity to jacks connecting to the various repeaters. One of the panels comprises the gain unit and the other an amplifier unit. The set is capable of measuring gains up to 46 miles of standard cable (800 cycles per second) in steps of 0·5 mile. Fig. 14 shows a simplified diagram of the circuit. Alternating current at 1 000 cycles per second is fed to the input terminals of the gain unit and passes through a repeating coil to two separate circuits, which are connected in series through the secondary windings of the repeating coil so that the same current flows into each. A variable shunt is connected across the input terminals of this coil to enable the input current to be adjusted. The two separate circuits join together again at the switch-key.

Following the upper circuit in the gain unit, the current passes through an artificial line, shunted by a variable resistance controlled by a dial switch and designed to give a series of losses in steps of 5 standard miles. The terminals of this artificial line are connected to the input terminals of the repeater to be tested, the output terminals of which are connected to another artificial line closed with a resistance. The terminals of this resistance are connected to the switch-key.

The lower circuit in the gain unit consists simply of one resistance shunted by another variable resistance controlled by a dial switch and designed to give losses in steps of 0·5 mile. The terminals of this resistance are also connected to the switch-key.

The amplifier circuit, which is shown in the lower

part of Fig. 14, comprises two vacuum tubes, the first of which acts as an amplifier and the second as a detector, in the plate circuit of which is connected a galvanometer. The switch-key is connected to the amplifier valve through an input transformer. The sensitivity of the set is adjusted by varying the grid potential of the rectifier by means of a sliding contact on a resistance connected across the filament of the first tube. The switch-key connects the input of the amplifier to either the upper or lower circuits of the gain unit.

In making the test the repeater is connected in the upper circuit of the gain unit, and the two variable shunts are adjusted until the same reading is obtained upon the galvanometer for either position of the switch-key. It is obvious that under this condition the voltages developed at the end of both the upper and lower circuits of the gain unit are equal, and, since the currents which enter these two circuits are the same, it follows that the gain given by the repeater must be equal to the difference between the losses caused by the shunts in the two circuits, neglecting for the moment the losses occurring in the two artificial lines and the transition losses which may occur at the repeater terminals, due to the impedance values of the artificial lines and the repeater not matching exactly.

Actually account is taken of the latter losses in calibration. A panel-mounted single-frequency oscillator, including two vacuum tubes, is usually provided at repeater stations for use with the above set.

The circuit of a repeater gain-measuring set in a portable form is shown in Fig. 15. This is the 3-A repeater gain-measuring set, which can be used also for the measurement of transmission losses. Its range is from 0 to 90 miles of standard cable (800 cycles per second) in steps of 0·2 mile. The set is contained in an oak case approximately $9\frac{5}{8}$ in. × $6\frac{1}{4}$ in. × 24 in. and weighs about 33 lb.

The repeater of which the gain is to be measured is connected to the set, the input of the repeater being connected to the " In " terminals of the set, and the output being connected to the " Out " terminals. The " Input " and " Output Impedance " dials are set to the required values, seven impedances (300, 700, 890, 1 130, 1 420, 1 800 and 2 280 ohms respectively) being available. These impedances should be set to approximate to the impedances of the lines on which the repeater is designed to work. The " Gain and Loss " key is put in the " Gain " position, and the " Meter-Receiver " key is put in the " Meter " position. The resistances A and B are adjusted until the output currents of each circuit branch are equal. This equality is determined by means of a thermo-couple and galvanometer in a circuit arrangement having an impedance of 1 130 ohms. The operation of the " Test " key closes one circuit branch through the thermo-couple and at the same time connects a resistance of 1 130 ohms across the other circuit branch. When no change in the deflection of the micro-ammeter is caused by the operation of the test key, the readings of dials A and B give the gain of the repeater in miles of standard cable.

The set may be used to measure the transmission loss in a piece of apparatus by connecting the apparatus between the " In " and " Out " terminals, the " Gain and Loss " key being set at " Loss." In general, the energy output from each branch of the circuit will be insufficient to operate the thermo-couple when the set is used in this way. A receiver is therefore employed to balance the set and is connected to the terminals marked " Receiver," the " Meter-Receiver " key being in the " Receiver " position.

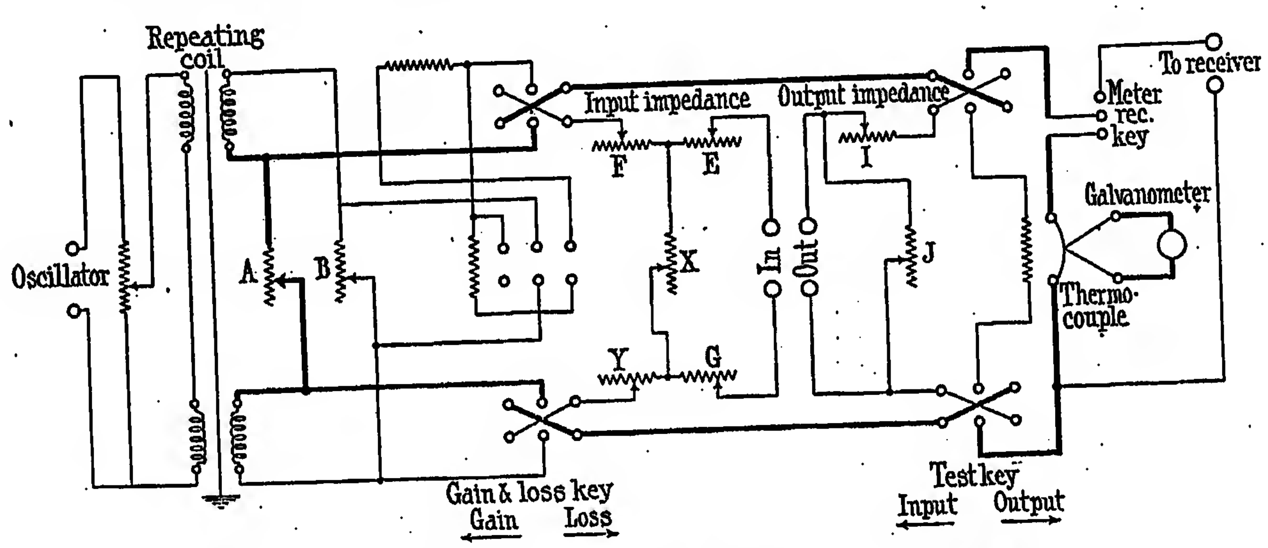

FIG. 15.—Circuit of " 3-A " repeater gain-measuring set.

With both the above sets an oscillator capable of giving power at any single individual frequency between, say, 200 cycles and 3 000 cycles can be employed. An oscillator of this type (the 4-B oscillator) is referred to later.

(*e*) *Line impedance uniformity.*—The gain at which 2-wire repeaters can be satisfactorily operated depends to a large extent upon the degree of balance existing at all essential frequencies between the impedance of the line and the balancing network associated with it.

While the 21-test already described enables the determination of the " singing point " of a line against its balancing network at the particular frequency at which the impedance unbalance is a maximum, it is sometimes necessary to know the " singing point " at a number of frequencies in order that the nature of the cause of the unbalance may be located. This information can

be quickly obtained by means of the 2-A impedance unbalance measuring set.

The impedance unbalance measuring set is a device for the direct measurement of the "singing point" at any desired frequency. Fig. 16 is a diagram of the apparatus, showing the essential parts of the circuit but omitting certain details which are of minor importance in its operation. The heavy lines show the conductors used when making unbalance measurements. The set works on a null system in which a current depending upon the quantity being measured is balanced through a galvanometer against another current from the same source which flows in a reference circuit. This eliminates errors due to fluctuations in the output of the source.

Alternating current from an oscillator is applied through a transformer A to the two resistances B and C in series. The resistance B can be regarded as a 1 200-ohm line supplying the measuring circuit, which begins at its terminals. Current from B passes to the 2-5 winding of the 3-winding transformer D, of which the line and network terminals are connected through the contacts of certain keys to the line and network terminals of the set and thence to the impedances under test. From the bridge terminals the unbalance current passes through an insulating transformer E to the adjustable artificial line F and to the potentiometer G. The voltage-drop in G is applied to the high-impedance input circuit of a 2-stage vacuum-tube amplifier. The alternating voltage in the output circuit of the amplifier is applied to the measuring rectifier and the resistance H in series, giving rise to a unidirectional current flowing in the direction indicated by the arrow. The condenser in parallel with H smooths out the current and increases the efficiency of the rectifier circuit.

The alternating voltage across the resistance C is applied through the transformer J to the resistance I and the reference rectifier in series, giving a unidirectional current in the direction shown by the arrow. The voltage-drops in the resistances H and I are opposed through the galvanometer, which stands at zero when the two currents are equal.

After connecting up, the first step in measuring a "singing point" is to calibrate the apparatus. This is done by using the reference key K which substitutes the resistances L and M for the impedances under test. These resistances are so proportioned as to give a loss of 6·4 miles through the 3-winding transformer (in addition to the copper and iron losses of 0·6 mile) without disturbing its impedance relations with the rest of the apparatus. The measuring dials of the artificial line F are turned to zero—this introduces the maximum loss—and the adjustment dial of the potentiometer G is turned until the pointer of the galvanometer stands on zero.

Restoring the reference key K to its normal position reconnects the impedances under test and reduces the unbalance current. The galvanometer is restored to balance by turning the measuring dials of the artificial line F, which reduces the loss in F and indicates this reduction by the position of the pointers on the dials. The reading of the dials is then the loss through the 3-winding transformer, less the 7 miles (6·4 + 0·6) previously existing, which is the singing point of the two impedances.

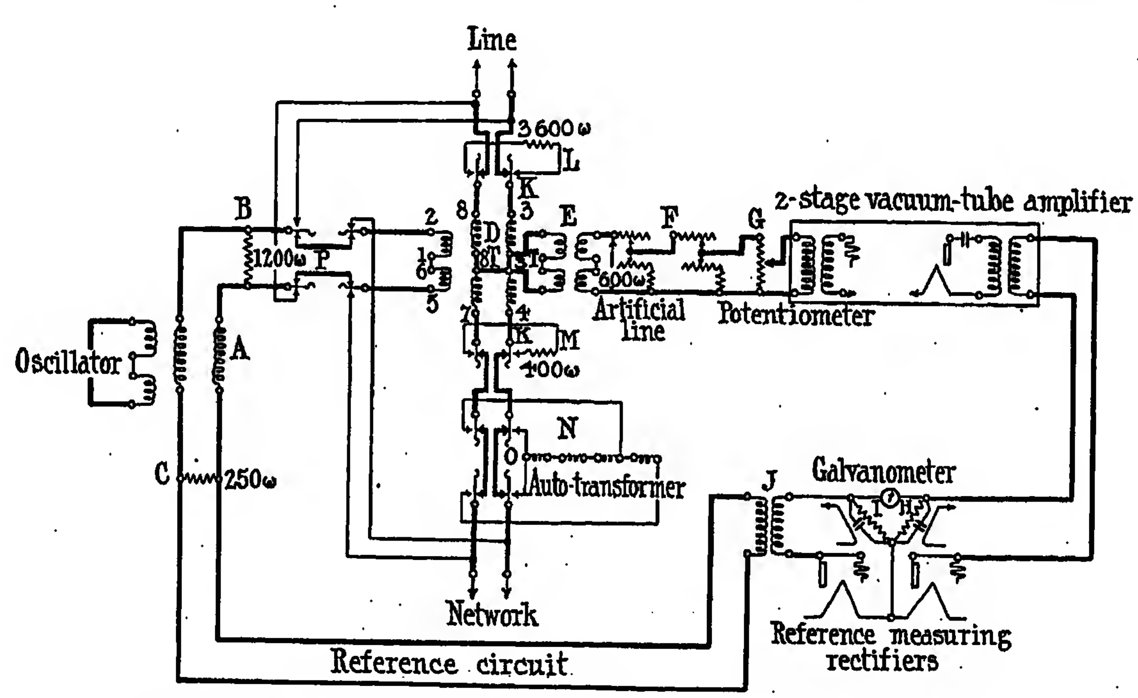

FIG. 16.—Diagram of "2-A" impedance unbalance measuring set.

Having once calibrated the apparatus at some such frequency as 1 000 cycles, the whole frequency range can be covered by successive settings of the oscillator and measuring dials without further calibration.

This set can also be used for the location of line impedance irregularities, although this operation can be more directly and simply determined by the use of the line impedance bridge.

The circuit of the 1-B line impedance bridge illustrated in Fig. 17 is intended primarily for measuring the impedance of telephone lines over a range of frequencies for the purpose of locating line irregularities. It can also be used to measure the impedance of appara-

tus. It consists of a Wheatstone bridge network made up of two ratio arms of fixed resistance, a variable resistance, a fixed inductance and a variable inductance. By means of keys, the inductance may be switched to either arm of the bridge, so as to be either in series

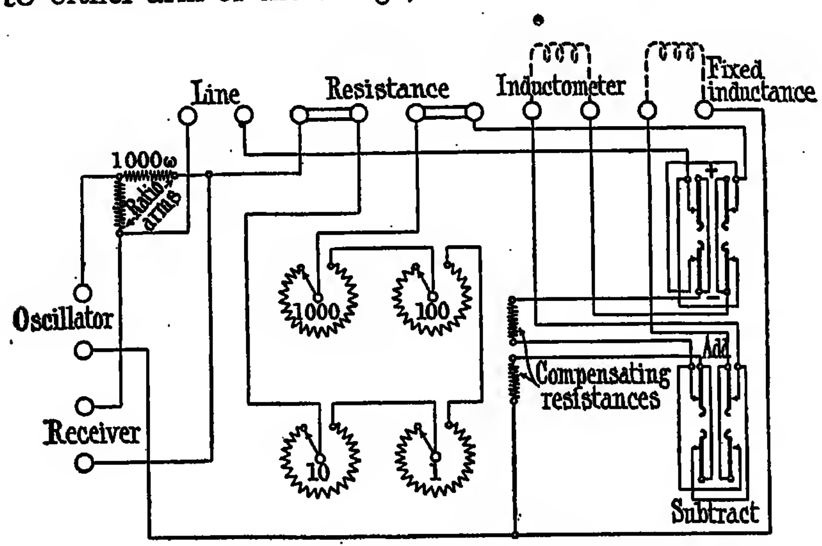

FIG. 17.—Circuit of "1-B" line impedance bridge.

with the line under test or in the opposite arm. Resistances are provided in the circuit to compensate for the effective resistance of the inductometer and the inductance coil, so that the variable resistance can be read directly to obtain the resistance component of the impedance. Detection is effected by means of a head

conjunction with several of the measuring and testing sets described above. It is designed to furnish alternating current of pure wave-form over a range of from 100 to 5 000 cycles per second by steps of 20 cycles per second and with an accuracy of 0·1 per cent.

It comprises an oscillation tube, two amplifying tubes and an adjustable resonant control circuit. The frequency is adjusted by varying the capacity and inductance of this circuit, which is associated with the oscillation tube. A number of features essential in an instrument intended for accurate measurements are secured by circuit arrangements which result in low amplitude of oscillation in the first tube. The frequency of oscillation is made relatively independent of the tube characteristics, so that recalibration is not necessary if tubes are replaced. The frequency, also, is independent of small changes in filament current and plate voltage, and is quite independent of the power being delivered from the output terminals.

The output of the oscillator is controlled by means of a potentiometer connected in the circuit between the two amplifying tubes. The power supply required by this oscillator is 1·0 ampere at 24 volts, and 0·05 ampere at 130 volts. A rheostat and meter are provided for adjusting the filament current.

The oscillator is reasonably portable, being mounted in a box with carrying handles and having overall dimensions approximately 19 in. × 19 in. × 19 in.

It has not been possible within the limits of this

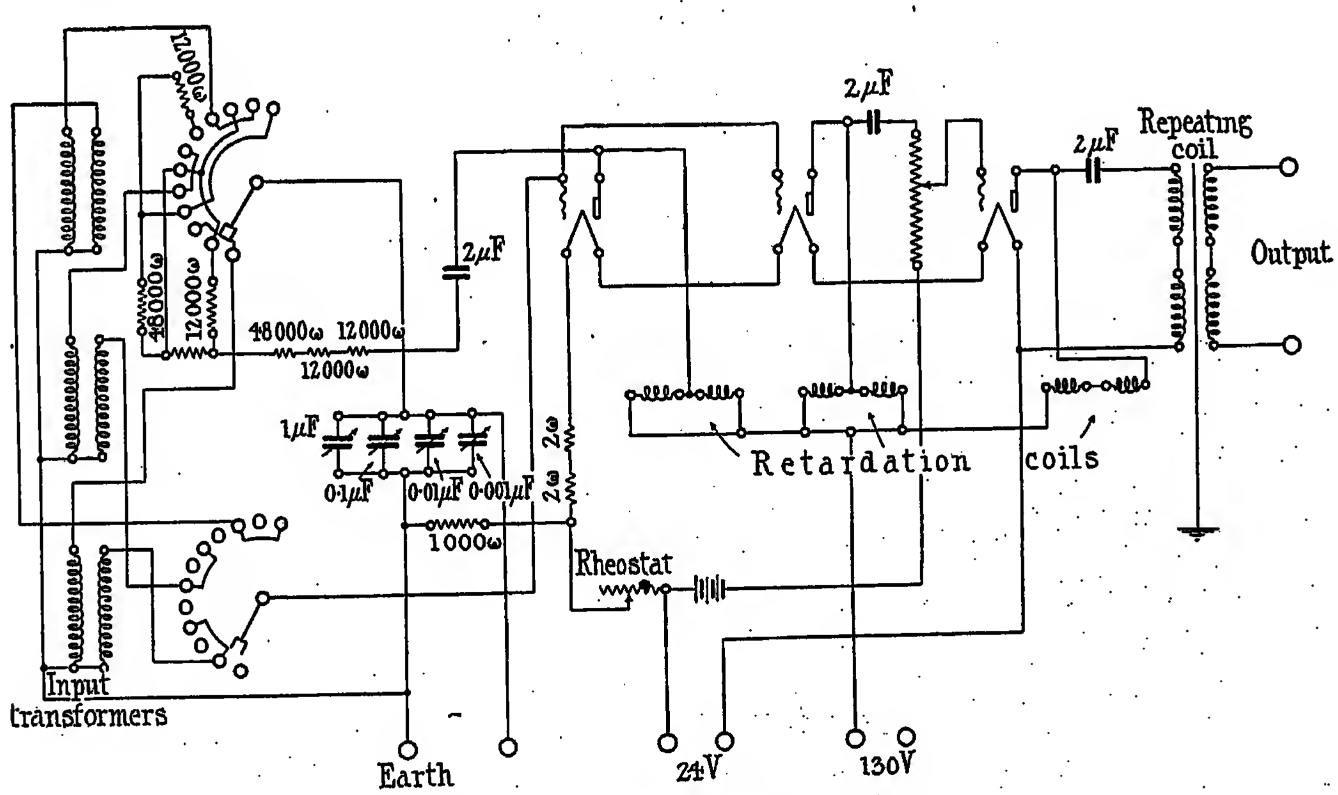

FIG. 18.—Circuit of "4-B" oscillator.

receiver. The set has a range of from 0 to 11 110 ohms and − 0·530 to + 0·530 henry, and an accuracy of about 1 per cent.

With both the 2-A impedance unbalancing measuring set and the 1-B impedance bridge, testing current is usually obtained from the 4-B oscillator.

The circuit of a 4-B oscillator is illustrated in Fig. 18. It is a typical vacuum-tube oscillator which is used in

paper to describe in great detail each testing instrument. The information which we have been able to include will, we hope, be of some assistance to telephone engineers who are not already familiar with the transmission maintenance practices herein advocated. We believe that the time is not far distant when these useful tools will be regarded by the maintenance forces of telephone administrations as being as indispensable as

the Wheatstone bridge is to-day and that they will form part of their regular equipment in the future.

Successful transmission maintenance depends more upon the dissemination of sufficient knowledge throughout the rank and file of the operating staff, than upon expert knowledge possessed by officials at headquarters.

In conclusion, the authors desire to acknowledge their indebtedness to the American Telephone and Telegraph Company and the Western Electric Company for much of the data contained in this paper.

APPENDIX 1.

Location of an Irregularity by Means of Impedance/Frequency Measurement.

Assume that in an otherwise uniform line (Fig. 19) an irregularity occurs at a distance D from a testing point. It is desired to locate the irregularity by means of an impedance test over a range of frequencies. The velocity of wave propagation is known from considerations of the constants of the line. Let the velocity of propagation be V.

The voltage impressed at the testing end causes a current to flow in the line. A portion of this current is reflected because of the irregularity. The distance

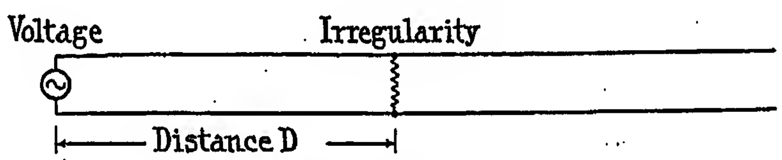

Fig. 19.

traversed by the direct and reflected current is $2D$, and the total time that elapses before the current returns is $2D/V$.

If the current which returns from the irregularity is in phase with the impressed voltage, when it returns to the sending end the apparent current-flow into the line will be greater than would be the case if the line did not contain the irregularity. This means that the ratio between the impressed voltage and the current, i.e. the impedance, is at a minimum value.

As the reflected wave has taken $2D/V$ seconds to make the return trip, if we assume that it has a frequency of f cycles per second, there will be $2Df/V$ complete waves between the sending end and the sending end on the return trip.

If we now vary the frequency of the impressed voltage either up or down, it will be seen that the reflected wave will no longer be in phase with the impressed voltage. This means that the impedance is no longer a minimum, but is increasing. As we vary the frequency the phase will change until a point is reached where the waves are again in phase. This means that there will be one more, or one less, complete wave than in the previous case of the frequency f. Expressed in equation form :—

$$2Df/V = 2Df'/V \pm 1$$

or

$$D = \pm V/2(f - f')$$

Assume an open-wire line in which the speed of propagation is 180 000 miles per second. Suppose the irregularity causes maxima values of the impedance at 300, 600, 900, 1 200 cycles. The interval here, that is $(f - f')$, is 300 cycles. The distance to the irregularity from the end is therefore $180\,000/(2 \times 300) = 300$ miles.

APPENDIX 2.

New Unit for Transmission Measurements.

Throughout this paper the standard-mile equivalent has been used to express transmission losses. This is the unit which has been in use for several years in Great Britain, the United States, and other English-speaking countries. On the continent of Europe it has, generally speaking, been the practice to express transmission losses and efficiencies in attenuation units (βl), that is, in natural logarithms at one or more chosen frequencies.

Recently the transmission engineers of the Bell System in the United States have introduced a new unit for transmission measurements and, since it presents certain distinct advantages, a brief reference may be of interest.

They define the unit in the following terms: The Transmission Unit is one such that two powers are said to differ by one transmission unit if they are in the ratio of $10^{0.1} : 1$.

The following are some of the principal factors that have led to its adoption :—

(1) The new unit does not vary with the frequency.

(2) The new unit is logarithmic in character and expressible in our common system of numbers. The logarithmic scale is used because the losses in the transmission line are a logarithmic function of the length. The logarithmic bases common in applied science are the Napierian base e and the common base 10. The latter is in more general use and tables of common logarithms are more readily available. Furthermore, the base 10 makes it possible to visualize the transmission unit more readily than the base e. Ten units correspond to a power ratio of 10, 20 units to a ratio of 100, 30 units to a ratio of 1 000, and so on. Ten to certain fractional powers very closely represents even ratios also. For example :—

	Approximately	Exactly
$10^{0\cdot 1} =$	1·25	1·259
$10^{0\cdot 2} =$	1·6	1·585
$10^{0\cdot 3} =$	2	1·9
$10^{0\cdot 4} =$	2·5	2·512
$10^{0\cdot 6} =$	4	3·981
$10^{0\cdot 7} =$	5	5·012
$10^{0\cdot 8} =$	6·3	6·31
$10^{0\cdot 9} =$	8	7·94
$10^{1} =$	10	10·0

(3) The new unit is based on a power ratio. The units which were in use are based on ratios of currents or voltages. In considering transmission problems we

are fundamentally concerned with the conversion and transmission of energy. We are usually interested in the ratio of the power delivered to the receiving set under one condition as compared with the power delivered under another or standard condition; or we are interested in the ratio of the power output to the power input of an apparatus or system. For many problems, especially since many long lines are characterized by uniform impedance, we may equally deal with current ratios or voltage ratios, but transmission engineers recognize that it is really the power ratio with which they are fundamentally concerned. The current or voltage attenuation unit corresponding to the one proposed is, of course, $10^{0 \cdot 05}$.

(4) The unit is of convenient size. For a good deal of practical work it is satisfactory to know the transmission equivalent of a long line to within one mile. Single-frequency measuring apparatus now in common use is calibrated to one-tenth of a mile, but seldom, if ever, in field work is there occasion for measurements to a greater degree of precision. It is desirable to have a unit in terms of which the losses and gains of interest can be expressed with the use of not more than one place of decimals.

Discussion before The Institution, 6 March, 1924.

Mr. S. A. Pollock: The paper primarily refers to the provision of apparatus for an organized system of control in maintaining the efficiency of a telephone system. Anyone with experience of telephones will know that it is a very difficult matter indeed to control and maintain a large and complex system in a high state of efficiency. The need has always been felt for convenient and simple apparatus to enable the maintenance staff to supervise and detect any decrease in efficiency. The maintenance of a very large telephone system may be studied from various points of view. The present paper would seem to indicate that the method advocated is to centralize the supervision of maintenance. This method would apparently facilitate a central control in so far as it could enforce a periodical test of the various elements of a telephone system and get the report sent to headquarters for examination. Where the maintenance is centralized in that way, probably no better arrangement of apparatus could be found except, perhaps, in line improvement. I do not think, however, that everyone would agree that the centralization of maintenance is an economic possibility. The apparatus described in the paper would undoubtedly serve the purpose of detecting losses of efficiency; but, as I understand it, when the loss of efficiency is discovered, with this apparatus there remains the location of the trouble and the remedy to be found for it. It is possible, of course, to deal with the question of maintenance in other ways, provided that the test was suitably devised for the critical examination of different parts of the circuit. In the case of a long telephone trunk line, if the organization admitted of each section of that trunk line being critically examined in such a way as to detect any fault, then the tests made would usually enable the fault to be immediately located. The same might be said for a critical examination of, say, a telephone repeater, and also for terminal apparatus such as the subscriber's. The subscriber's line, the connection to the exchange and the circuit might be examined piecemeal, and any fault discovered could generally be remedied by the person who is making the test. The overall test of a telephone line must necessarily be made from a terminal point, for instance from an exchange. The information obtained with this apparatus would, I understand, merely indicate that there is a loss of efficiency. My point is to emphasize the fact that the discovery of a loss of efficiency does not mean its location and solution. If tests are designed to locate a fault, then an efficiency test may be superfluous. On the other hand, sectional tests for the location of faults may not be possible in a great system, and I quite agree that such a method is hardly possible over every line in the country. But do the authors advocate that every line and every circuit should be routine-tested by apparatus of this description? If they do, can they give some idea of the cost of instituting a system or organization of that kind? It will generally be agreed that if it were economically possible every item in a telephone system should be periodically tested, but it may transpire that the cost of doing so would be altogether prohibitive. It is perhaps a question of policy as to whether the subscriber should assist in drawing attention to any fault that exists. He can give valuable information and assistance if anything goes wrong with his transmitter or with his local line, but a subscriber could hardly give much assistance in cases of faults in a long trunk line. The Post Office Department has considered this question of maintaining to the highest point the efficiency of very extensive plant. Probably the underground telephone trunk lines of this country represent the bulk of the extension, and the policy has been adopted of a periodical testing of these important trunk lines. But these periodical tests have been devised not to make the measurement of transmission efficiency, but to detect any defect whatever that arises after the line has been installed and tested for efficiency. The cost of the periodical testing of telephone trunk lines is probably insignificant compared with that of the routine test carried out in the manner suggested by the authors. Our experience shows that the routine tests which are adopted for telephone trunks do, in fact, draw attention to the slightest loss of efficiency, and they also enable the fault to be located at once. In fact, on the more important telephone trunk lines the method of routine testing adopted has had the effect of preventing any loss of efficiency due to faults. This is explained by the fact that the tests are devised to show the minutest defect before it can affect the efficiency of the line. Further, the tests would detect the defects which do not interfere with the use of the line. It would be of interest if the authors were to supplement the paper by information in regard to the localization of faults. The title of the paper is: "Transmission Maintenance of Telephone Systems." The subject might be regarded

as including the location of faults, and the problem of location has probably represented more ingenuity than has the devising of apparatus to discover the mere loss of efficiency. The authors raise very little controversial matter so far as the technical apparatus is concerned, but, having alluded to the economic side of maintenance testing, I think that the paper would be increased in value if the authors could supplement it by particulars of the personnel and cost, and the extent to which they would advocate the use of this apparatus on the system generally. There are, of course, the testing of telephone trunk lines, the testing of junction lines, the testing of subscribers' lines, and the testing of subscribers' apparatus. It is largely a question of cost. There is no difficulty in providing the apparatus for the purpose, as the paper clearly proves; but the question of how much money can be spent economically in routine testing is a very controversial point which I believe has been studied by many officials of the Post Office from time to time. In Appendix 2 the authors put forward a very interesting proposal to make a radical change in the practice of stating transmission losses of efficiencies. It is certainly attractive in its apparent simplicity. I understand that one of the arguments for adopting this new unit is the facility which it will afford for the construction and physical representation of the units. Some further information on this subject would certainly be welcome. In the last paragraph of the paper the authors state: "It is desirable to have a unit in terms of which the losses and gains of interest can be expressed with the use of not more than one place of decimals." In using the word "interest" do they refer to losses and gains of general interest to everyone, or of general interest to telephone engineers, or has the word some other meaning?

Mr. A. J. Stubbs: When, at one period, authority was given for the expenditure on maintenance for certain circuits serving Continental cables to be double the ordinary allowance the result was, not only that the circuits were available for a much greater proportion of time, but that the actual speed of the circuits rose, as far as I can recollect, by about 40 or 50 per cent. The value of this increased care in maintenance was further exhibited by the fact that when, through some change of staff, the arrangement ceased to function, the speed of the circuits altered sympathetically. Most telephone men would welcome the development of some other unit than miles of standard cable by which to express our transmission equivalents. The present unit involves that transmission equivalence is the inverse of transmission efficiency, which is not entirely satisfactory. The fact that to use an "ordinary" repeater coil instead of "the proper type" would lead to a loss of 1·8 instead of 0·7 brings into prominence the importance of ensuring that different items shall be readily recognizable both by design and by stock description. On page 660 we are told that lines loaded just before the war to improve transmission by the then latest known improvement have since been unloaded to secure the best results from the still later development of repeater working. This, as a sidelight, shows that the telephone engineer is quite prepared to make any changes that the rapid development of the art demands. I am not much in favour of the term "frequency spectrum" used on page 660. I would suggest that it be referred to the B.E.S.A. Nomenclature Committee before it becomes firmly established.

Mr. F. Gill: The economic importance of the paper lies in the fact that it gives a line of instruments which deal in the workshop fashion with transmission measurements, so that they can be used by the ordinary skilled man, who can thus grip the maintenance of the transmission part of the system. During the past few years a great amount of apparatus—condensers, repeating coils, shunts, loading coils, repeaters, etc.—has been introduced into the plant, all for the purpose of improving the transmission. But if these do not work, trouble may remain undetected for some time. In an ordinary exchange there are 34 non-inductive shunts and supervisory relays to every "A" operator's position. With 100 such positions in an exchange, there are 3 400 such relays and shunts in use in that exchange. If the exchange has been installed a few years, it is not beyond the bounds of possibility that some of those things may have gone wrong. The paper indicates a ready means of detection which can be used quickly and easily by the regular maintenance men. That is where the importance of this matter lies. The economic value of noise is given as the difference between a 30-mile and a 45-mile standard. If we can measure the noise, and if we can keep it down, we are doing something which is of great economic value. Mr. T. G. Miller, the General Superintendent of the Long Lines Department of the American Telephone and Telegraph Company in the United States, in connection with that plant containing 1 115 000 miles of wire, including overhead wires carried on 27 000 miles of pole line, says: "During the past few years the extensive use of repeaters, complicated cable circuits, carrier telephone and telegraphs, has made better transmission measurements necessary. Without these instruments it would be difficult, if not impossible, to maintain a satisfactory service over many of the circuits in use at present. . . . Eighty-five per cent of all the long lines, including all the more complicated circuits, are now being measured regularly at transmission measuring desks." I take it that one of the things he says is, in effect: "Use these things where it pays, and do not use them where it does not pay." Another use to which they are being put is to check up exchange equipments and toll cables at the time of construction. The authors point out that measurements can be made within something like $\frac{1}{2}$ mile to $\frac{1}{10}$ mile. In the older method, viz. by speech tests, it is quite difficult to make a measurement of that small amount, but it is quite simple, particularly with visual indication, for the maintenance man to measure down to $\frac{1}{10}$ mile, by using these instruments. Mr. Pollock mentioned the centralization of maintenance. From my knowledge of American telephone companies, I do not think that they are likely to centralize anything except major decisions. Their disposition is to push the work of maintenance down the line, and to make everybody do his share. But there is such a thing as centralization of control, such as one gets on board a steamship, where, while the different people do their work, the major decisions are taken at one central place. A means of obtaining

control is by the circuit lay-out; the ordinary telephone line is the resultant of many losses and gains; the circuit lay-out is practically the specification for the line, and determines exactly how the line should work. These circuit lay-outs are made by a committee which sits daily, on which the traffic, engineering and plant branches are represented. The new proposal in Europe is a system of organizations, each one carrying on its own work, with a consultative committee meeting at long intervals and having a permanent office for collecting information. I do not see how the work of making circuit lay-outs, the quick answering of questions as to facilities, and the direction of a long lines service can be done by that type of organization. In my opinion the European International telephone system will sooner or later have to accept some kind of unity of direction.

Mr. A. J. Aldridge: Routine testing is of the utmost importance, bearing in mind the tremendous amount of apparatus that is now in use in many telephone connections. Judging from the figure given on page 666, of the average loss of 15 miles due to noise on the lines, routine testing would appear to be rather more necessary in America than in this country. I should be glad to know what that noise really is. I cannot conceive any lines producing that noise being tolerated at all in this country. Transmission testing sets such as those described in the paper are not peculiar to America, and Mr. Pollock has referred to some that have been designed in England. One set of which I have knowledge is a portable set designed primarily for testing junction lines. A junction line very frequently consists of a large number of short lengths of cable. There may be one or two exchanges in circuit and generally, as the line has no definite line impedance, it cannot be closed through a fixed similar impedance; some test other than that suggested by the authors is therefore necessary. Also, that method of testing by closing the line through its own impedance is not altogether satisfactory, as the constants of the line have to be known. The set to which I refer is arranged in two parts, the first containing an oscillator giving a frequency range of 500, 800, 1 100 and 1 500 cycles, a screened transformer, an artificial trunk line and an ammeter. The other set, which is used at the receiving end of the line, contains an amplifier-rectifier arrangement similar to the one given by the authors, a subscriber's average line, and a subscriber's average instrument. The measurement consists in obtaining the ratio of current sent into the trunk line to that received on the average instrument. A direct test is thus obtained of the complete circuit used as it would be in practice, i.e. terminated at one end by a trunk line and at the other end by the instrument. If desired, the galvanometer can be calibrated to read direct in standard miles. I should be glad if the authors would give a little more information about the noise-measuring set referred to on page 666. The standard noise is apparently produced by a vibrating element, but that does not seem to be the most suitable method. Variations produced by changes in the contacts, and changes in the reed frequency from several causes, would appear to destroy any claim to constancy. We have been developing a set on similar lines, but I think it is an improvement. An alternator produces the standard noise, which is compared with the disturbance on an ordinary cross-talk meter arrangement in the usual way. To facilitate balancing, we have adopted an arrangement which, I think, other investigators have found to be very satisfactory, i.e. a kind of flicker meter. The currents producing the two sounds pass through a commutator on the alternator shaft and are rapidly interchanged in the receiver. By that means it is possible to compare two sounds of quite different character, and different observers are found to obtain results much more in agreement than they would by a simple comparison of the two differing sounds. I am not quite clear how the authors' test is carried out. On page 667 they say that the test is made by comparing the effect on conversation of the disturbance and of the standardized noise. Judging from Fig. 6, I should imagine that direct comparison is made between disturbance and the standard noise, without any speech test at all.

Captain B. S. Cohen: Although the methods of machine transmission testing, that is, methods other than the use of the voice and the ear, are of great value for trunk-line testing, in my opinion they are of even greater value for the transmission maintenance of the terminal lines, circuits and apparatus. A multiplicity of junctions and subscribers' lines, subscribers' apparatus, private branch exchanges, exchange circuits and wiring losses are all connected to the trunk line, and with recent improvements in the design of the trunk lines and in repeatering, the percentages of the overall transmission losses localized in this terminal apparatus are becoming more and more formidable. From the point of view of transmission maintenance the trunk lines which terminate in test-rooms are of course more easy to deal with than the terminal circuit, apparatus and lines. Like so many other advances, the introduction of machine transmission testing apparatus was delayed by the war, although standard cable-balancing sets operated by speech and ear have been in use in exchange testing rooms for some years. Three types of apparatus have been developed in this country, to two of which Mr. Aldridge has already referred. These are a set for general maintenance transmission testing, a disturbance measuring set and one for repeatering and trunk-line maintenance testing. Reference is made on page 657 to a simple and inexpensive means of checking the working and efficiency of subscribers' transmitters and receivers. Details of this, when available, will be of great interest, in view of the fact that by far the greatest variation in transmission efficiency can take place in this apparatus. A rhythmic oscillator has already received attention in this country for this purpose, the rhythm of which will govern the audio-frequency range. In Table 1 figures of abnormal losses and their causes are given. When the first machine transmission testing set was developed in this country two or three years ago, it was first used to straighten up some tangles left by the war at a provincial junction centre, and some faults discovered by its use may be of interest. For example, a cord circuit with a normal loss of 2·5 miles of standard cable (m.s.c.) had an excess loss of 4·3 m.s.c., which as a result of this test was immediately traced down to a faulty repeating coil. In

two other cord circuits, with a normal loss of much the same order, there was an excess loss of 3·4 m.s.c. due to faulty bridging coils. The point which must be emphasized is that no other test would have been capable of finding out these faults with the apparatus in situ. On page 665 the authors give a transmission efficiency chart commencing with intelligibility, for which we use the term " audibility." We consider that audibility is the resultant of three main factors—volume, articulation and interference. We group volume and articulation as being factors of the frequency/amplitude characteristic of the apparatus, which is the same as the authors' frequency response. As regards non-linear distortion, although in general this effect is only noticeable with repeaters and transmitters, it should be made clear that it is capable of occurring with other apparatus such as receivers, and even transformers under special conditions. In common with Mr. Aldridge I should be glad of some further information with regard to the noise-analysing set mentioned on page 666. The figure of 15 m.s.c. referred to as the loss due to maximum normal noise appears to me to be extraordinarily large, and is considerably in excess of the normal maximum loss due to interferences in this country. In general, we are in favour of the new unit mentioned in Appendix 2. There are, however, certain costs involved in its adoption in the way of altering standard cable sets and other apparatus and also in records, and before incurring these we should like to see other countries in agreement.

Mr. G. D. Edwards: I have just returned from a very active personal contact with the installation and placing in service of a long trunk cable system, in which I have seen many of the methods and even of the instruments described in this paper applied with distinctly satisfactory results. In fact, as I look back upon the course of the work, it is difficult to see how it could have been completed satisfactorily without many of them. The cable system which I have mentioned is that between Stockholm and Gothenburg in Sweden and is roughly 330 miles in length. It is loaded, of course, and repeaters and testing facilities are installed at its termini and at six intermediate stations. Its longer circuits, such as those connecting Stockholm and Gothenburg, contain as many as four repeaters operating in tandem. The system was taken into operation completely in September of last year. In the installation of the cable and loading for this system, a number of the instruments and methods described by the authors have been found of exceedingly great value. In this connection I have in mind more particularly the singing-point tests for the detection of irregularities, and the impedance/frequency measurements for their location. Some such instruments as the authors have described are a necessity in the installation of repeater equipment, where the gain/frequency and impedance/frequency characteristics of the amplifying and associated equipment must be thoroughly check-tested before any repeater station can be considered ready for service. A mere attempt to place in operation such a cable system as that between Stockholm and Gothenburg, stretching only over a distance of little more than 300 miles and never involving the operation of more than four repeaters in tandem, will provide anyone with convincing proof of all that the authors have said with regard to unity of control. I believe that the experience with this Swedish cable may be said to have proved the efficacy of unified engineering and operating in connection with long repeatered cable systems, and of the general direction of maintenance activities by a central authority. This does not mean that all maintenance activities must be carried on by that central authority, but it does mean that there should be a single source of general maintenance policies and plans. The Swedish telephone administration was very quick to realize the importance of these factors, and has made the small changes in its organization and operating methods necessary to bring about this essential unity of control. I believe that I can say unreservedly that the results have been most gratifying. Many of the methods and instruments described in the paper are now in regular use on the Stockholm–Gothenburg system in connection with its transmission maintenance. It may be said that their value for this purpose also has been proved, at least so far as this system is concerned. What I have said so far applies only to the application of these principles in a single instance, but the case in question involves what I believe to be the longest loaded repeatered cable system now in operation in Europe. I believe that further and longer experience with such systems will only serve to increase the conviction that these principles are most important and that the methods and instruments described are very valuable tools in connection with the installation and maintenance of the long-lines telephone plan. I have had occasion in America to come into contact with the application of these newer methods of transmission maintenance to exchange area systems, and I am sure that their application to this portion of the telephone plant will prove of correspondingly great value.

Mr. E. S. Ritter: One speaker has already mentioned 15 miles of standard cable lost due to noise. I should perhaps put it in another way. The effect of a certain noise on a very short line will not be the same as the effect of the same noise on a very much longer line. Perhaps the authors will say if this accounts for the very high value taken. They state that with the transmission measuring set an accuracy of 0·1 mile of standard cable is obtained. I do not doubt that this is so in the general case where one has a uniform line to deal with, but I should like to know whether this accuracy is obtainable under the following conditions. At one end of a line there is a loaded underground cable with a medium impedance continued by an open line, and at the distant end of the open line a short section of non-loaded underground cable. The impedance at the two ends of the line will be different. I am rather curious to know whether the results given by testing would be the same from A to B as from B to A. Fig. 17 shows what the authors call a " 1-B " line impedance bridge in which a resistance is used in conjunction with an inductometer. In this country we prefer to use a bridge in which the measuring arm consists of a variable resistance shunted by a condenser. This will measure the line where there is a capacity angle, and when there is an inductance angle the condenser is joined in parallel

with the line. The results are very conveniently obtained in terms of conductance instead of impedance. The noise-measuring set shown in Fig. 7, as I understand it, enables the amount of what may be called the "inducing effect" of the noise present in the line to be compared with the noise received across the line; that is to say, the induced noise effect on the two wires in parallel to earth is compared with the actual noise heard when the telephone is joined across the line. This is a measurement of the state of balance of the line. In connection with heat coils, the authors say that a poor contact may add 1 ohm, or more, to the resistance. I have known a case in which the resistance has amounted to nearly 200 ohms in a bad contact at the heat coils. In another case a dry joint, the resistance of which was 20 ohms measured with direct current on the Wheatstone bridge, gave a loss of the equivalent of about 7 m.s.c. when measured with speech. In connection with the maintenance of underground cables, whereas a comparatively short cable such as is used for direct service between two exchanges is relatively unimportant, and the loss in efficiency would not be of much importance, yet on all cables short or long, or apparatus forming the links in a long-distance circuit, any loss in efficiency is a very serious matter. This country has developed, to a very high degree of precision, methods of testing for insulation and for further localizing any small drop in insulation. For example, it is now possible in, say, a 100-mile underground cable to localize a fault of the order of 300 megohms to within ± 2 miles. This can only be done if the cable is in good condition. Main cables now have an insulation of the order of from 10 000 to 20 000 megohms per mile. Any drop in insulation below this figure is generally due to some defect in the sheath of the cable, which it is possible to localize. Another most common type of fault may be described as the dry or badly soldered joint. This is comparatively difficult to localize, although it causes loud overhearing between a loop and its phantom circuit, but this has now been very successfully done by some new methods. Not only is a dry joint difficult to localize, but it is liable to disappear and come on again at some inconvenient time.

Mr. C. Robinson: Under the heading of "Unity of Control," the authors describe a test which occupies, according to the time stated, at least 25 minutes. It might be possible to deal with two or three circuits at once, but even then it would not be possible to carry out these tests at large stations where there may be 200 lines concerned. I suggest that it would be more practicable to make an overall test first from the control station; after which, if the line is not up to standard form, a detailed test should be made by the different repeater stations in the circuit. The routine tests made at each repeater station should ensure that the repeaters and balances are being maintained in proper order. With reference to the impedance/frequency characteristic of lines, the Post Office are working on the development of an oscillator on the heterodyne principle, the frequency of which can be changed continuously over the audible range. The oscillator also gives constant voltage over the audible range. It is proposed to apply this method to the rapid determination of the impedance/frequency characteristics of lines. An oscillator of this type was demonstrated at the last meeting of this Institution. The repeater gain-measuring set and the transmission measuring set described are similar in principle, if not in detail, to those developed by the Post Office. The form of instrument at present being developed by the Post Office combines the transmission measurement set with the repeater gain-measurement set. On page 677 the bridge used for measuring line impedances is referred to. We have experienced considerable trouble in obtaining accurate results when employing bridges which are dependent upon the use of inductances. The trouble is usually ascribed to the capacity of the windings of the inductances. Mr. Ritter has referred to the form of the bridge used for this purpose in the Post Office. It has one or two other advantages besides those which he mentioned, the chief being that the line balances can be calculated direct from the readings, without any intermediate calculation of the impedances.

Mr. J. S. Elston (*communicated*): The methods adopted to maintain telephone transmission in the various countries no doubt appeal to each administration as best suited to its needs. Mr. Pollock has explained that, in this country, telephone engineers place much confidence in the systematic testing of covered work with a view to the discovery of potential trouble at a very early stage, and in periodical routine testing, combined with the patrol of routes, for open work. In view of the precautions taken to ensure the good maintenance condition of the long-distance loops, it is somewhat difficult to accept the suggestion of the authors that the London–Glasgow telephone trunk circuits—approximately 425 miles of 800-lb. loops—could be degraded to the transmission equivalent of 300-lb. loops without a previous indication of trouble. Nevertheless, no telephone engineer, particularly if immediately concerned with the transmission qualities of telephone plant, would deny the need of testing instruments which will enable a direct comparison to be made, easily and accurately, between theoretical transmission values and the transmission obtained in practice. It is a requirement which has occupied the attention of Post Office research engineers for some considerable time, and earlier contributors to this discussion have indicated the general lines of development. Mr. Gill mentioned circuit plans, and it is assumed that these are, in effect, transmission lay-outs. It is curious that the practical aspect of transmission theory is so seldom referred to and receives such scant attention in technical papers. Given a standard transmission, it is the method of circulating and controlling traffic which determines circuit or transmission lay-out; and transmission lay-out, in turn, determines the plant lay-out. In a going concern the plant will consist of all types of construction, some obsolescent and some up-to-date. The external plant may be open or covered, and, if covered, unloaded or loaded. Single circuits may consist of one or other of the types, or a combination of types of construction. In switching operations the combinations are many and varied, and the individual circuits are generally short lines electrically. The transmission calculations are very difficult, and figures, such as the authors quote as constituting good practice, can be criticized only when

the critic has a full knowledge of the traffic range and the combinations of line circuits and apparatus which will be linked together. Notwithstanding the fact that theory indicates the combinations which should be formed to obtain the best transmission, many problems in economic plant lay-out await solution. It is not always possible to match impedances so as to incur inappreciable losses, and transition losses may then become important in adjusting transmission to traffic circulation. This is particularly so in this country where direct-current signalling is largely used; terminal transformers, at present, cannot be inserted in the circuits to bring them to a common impedance. I think the authors could have made a claim that testing instruments of the character described have considerable possibilities in bridging the gap between transmission theory and the values obtained in practice. A testing instrument which would give reliable transmission tests under practical conditions between two subscribers linked together by various combinations of line circuits and apparatus would enable engineers responsible for external telephone plant lay-out to plan with greater certainty and more confidence.

Mr. A. B. Hart (*communicated*): The authors have stated the case for greater precision in transmission measurements in telephone systems very clearly and completely, but in regard to methods and means there are some points in which further elucidation is desirable. The determination of the transmission efficiency of any telephone apparatus or network involves the measurement of small alternating currents, and it is important in studying a paper of this kind to have a very clear idea of the magnitude of the currents to be dealt with. It may therefore be useful to state that, for example, in an average repeater section 50 miles long in a modern long-distance cable, the magnitude of the currents transmitted is of the order of 1 to 2 mA at the sending end of the section and $\frac{1}{5}$ to $\frac{2}{5}$ mA at the receiving end. The mean frequency of these currents is generally taken as 800 cycles per second. It will be obvious to all engineers acquainted with methods of measuring small alternating currents that the design of commercial instruments to deal with currents of the order of those just quoted with an accuracy anywhere approaching that mentioned by the authors in their description of a transmission measuring set, presents some difficulties. A calibration to 0·1 standard mile is mentioned; in other words the detection and measurement of differences of the order of 1 per cent in a current of 0·2 mA. There is no doubt that such accuracy and precision can be obtained, but it is very important to appreciate the possible sources of error that may arise in translating these readings into terms of transmission efficiency involving the expression of a ratio between sent and received currents. Mr. Ritter has indicated difficulties that may occur in dealing with composite lines. These probably present the most severe conditions, but even in a cable network of nominally uniform characteristic impedance it will be found in practice that circuits differ in capacity to an extent sufficient to cause impedance/frequency irregularities which make it difficult to predetermine the actual line impedance at a given frequency. Consequently, single-frequency measurements cannot be relied upon to represent, with sufficient accuracy, the actual commercial speech-transmission efficiency of any given circuit, and a method of measurement involving a range of frequencies is to be preferred in practice. In describing "Noise Conditions" the authors state that line noise is generally due to inductive interference from external power circuits. So far as the telephone line network of this country is concerned, this statement is not quite accurate. It is true that serious interference has been caused by power circuits, but the principal source of disturbance has been the high-speed telegraph system. Where high-speed telegraph circuits are carried upon the same pole lines as high-grade telephone lines it is necessary that the latter should be maintained at a high degree of balance, particularly when long-distance phantom circuits are operated. The disturbance created by a high-speed telegraph in an unbalanced telephone circuit is of such a nature that the question of measuring and analysing the noise never arises. The noise must be eliminated entirely and the problem resolves itself into locating the cause of unbalance in the telephone circuit. Long-distance aerial circuits with conductors weighing 1 200 and 1 600 lb. per loop-mile are, by the mere fact of their high efficiency, subject to disturbance by slight faults that would hardly affect a short-distance light-gauge circuit. Such faults as badly soldered joints, loose or corroded fuse fittings, cracked insulators, cobweb accumulations, intermittent tree contacts and last, but not least, imperfect regulation in the pole-to-pole spans will set up noise conditions that may prove very troublesome to diagnose and locate. Even the most thorough system of inspection must be supplemented by precision apparatus for fault localization. Most of this apparatus is of course of the direct-current type and is perhaps outside the scope of this paper, but in recent practice the use of alternating-current apparatus for fault localization has increased and it is to be regretted that the authors have not been able to include some description of such apparatus in their otherwise comprehensive paper.

Captain J. G. Hines (*communicated*): There is no doubt that steps should be taken to ensure that results which should follow the introduction of well-designed switching apparatus and scientifically planned lay-out of external plant are obtained. The work of the engineer is a combination of that of the scientist and the economist, as he desires not only to secure better results than have previously been obtained but also to do so in the most economical manner. Telephone apparatus is exceedingly complicated and much ingenuity is expended in devising appliances which will effect many combinations of connections without appreciably degrading the transmission efficiency at any stage. Exhaustive investigations are also made to determine the combinations of switching centres and cable systems which will ensure that each subscriber in a telephone administration shall be able to carry on a satisfactory conversation with any other subscriber with the least expenditure on plant. The calculations used in the determination of the lay-out of an area are based upon the normal transmission efficiencies of the cables and apparatus to be used. If those efficiencies are not obtained or are

not maintained, then much of the careful work that has been done is rendered abortive. It is essential, therefore, that checks shall be made to secure that the calculated efficiency has been achieved, or, if this is not the case, to ascertain the cause and location of the failure. The extent to which the checks should be applied to local lines is, however, a matter that requires very careful consideration, and the authors give no indication of their views upon the matter. There can be no doubt that in the case of long and very costly trunk cables the tests should be practically continuous and, as Mr. Pollock has indicated, this is the standard Post Office practice. Moreover, the tests instituted by the Post Office indicate not only the presence of an incipient fault before it has developed sufficiently to interfere with speech, but also the precise location of the trouble. In the case of local lines, however, there is not the same justification for the employment of staff and apparatus involving considerable expenditure. The lay-out of a telephone area provides for satisfactory speech when a subscriber is talking under the most severe conditions, that is, via the local and trunk exchanges to a subscriber in a remote part of the country. Although the local line and apparatus are designed to meet these conditions, it is only in a very small percentage of cases that the most severe conditions are experienced. Consequently there is nearly always a margin of loss that can be permitted without causing inconvenience to the subscriber. For example, the lay-out in London provides that speech between any two subscribers in the London telephone area shall not be worse than that over 18·3 miles of standard cable on a 300-ohm local line loop basis. Speech is commercially possible, however, over 35 miles of standard cable on the same conditions. A considerable loss may therefore take place without being noticed by a subscriber when speaking on local connections. Of course it is not contended that steps should not be taken to discover and remedy any loss, as the effect would be felt as soon as the subscriber makes a call on a long trunk line. The extent to which transmission testing should be carried out on local lines is, however, largely a question of economics. If the present methods of maintaining the high standard of trunk lines were applied to local lines the result would be reflected in the rates charged to subscribers for the use of the lines. It might be contended that a greater satisfaction with the service would result, but this would not necessarily follow, as subscribers do not require a volume or clearness of articulation beyond that which is necessary to enable them to hear distinctly. Complaints about poor transmission on local lines are comparatively rare. This is no doubt due to the great advances that have been made in recent years in the methods of planning telephone cable systems. It is possible, however, that there may be more complaints in the future, due to the rapid growth of wireless broadcasting. It is noticed that there is a tendency for subscribers to become more critical about the quality of the received speech. Only a few years ago it was a matter for wonder that speech should be possible over wires, and subscribers were satisfied if they could hear at all. Now they are not satisfied if the speech is less clear than that received on a wireless installation, with its remarkable freedom from distortion. This may render it necessary to obtain a higher standard than has been necessary in the past. Although systematic transmission maintenance testing has not hitherto been carried out on subscribers' lines, steps are taken to ensure that all installations are satisfactory before being put into use. The calculated value is supplied by the designing officer to the officer responsible for the final test, and his testing apparatus includes standard cable to enable a check to be made. This apparatus is also used to investigate complaints of poor transmission which may be made subsequently. If nothing can be found locally to account for the trouble, a chain of connections is set up to a central testing point and the loss is then measured. It is not infrequently found that the loss is in the exchange connections, due to one of the causes indicated by the authors in Table 1. Another cause is the use of a multiple jack, the interior surface of which has become dirty through infrequent use. A loss of 4 miles of standard cable has been traced to a fault of this character. It would be a serious item, however, to make regular and frequent transmission tests through all multiple jacks as well as through all cord circuits. I have no doubt that the paper will have the effect of directing attention to the importance of systematic testing, and the ingenious methods described will result in further measures being taken to secure the continuance of maximum efficiency at the least possible expense for testing.

Messrs. P. E. Erikson and **R. A. Mack** (*in reply*): If we understand Mr. Pollock correctly, he contrasts the relative advantages and disadvantages of two general principles of transmission maintenance, the first in which the overall efficiency of the circuit is checked by the periodical inspection and maintenance of each constituent part, and the second in which the overall transmission efficiency is measured directly and in a regular routine manner without separate tests upon the constituent parts. There can be no doubt that neither of these systems is sound in itself. The system with which we have dealt emphasizes the necessity of making direct measurements of transmission efficiency upon the circuits. Apart from whatever other tests may be considered necessary, it is only by the observation of overall transmission efficiency that the satisfactory condition of a circuit can be ensured. Any tests upon individual parts, while they may serve a useful purpose, can never properly establish the correctness of the connection between these various parts. In the event of overall transmission tests indicating a faulty connection it is, of course, frequently necessary to make individual tests upon the constituent parts, and it is definitely recommended in the paper that regular routine tests be made upon certain portions of the plant, e.g. tests upon the cable conductors for insulation and continuity.

Regarding the cost of carrying out regular transmission tests, it is regretted that no data are available which could be applied to the telephone system in this country. On the general question of economy, however, this, as indicated by other speakers, would be taken care of by arranging that the tests are carried out only when and where it is economical to do so. It has

been our endeavour to show that the advantages to be gained by the making of regular routine transmission measurements are much greater than have hitherto been realized by telephone engineers. The last sentence of Appendix 2 was intended to convey the argument that a transmission unit sufficiently small to enable the expression of transmission losses or gains occurring in practice with the use of but one place of decimals was preferable to a larger unit, in terms of which a loss or gain might have to be expressed in two or more places of decimals.

With reference to Mr. Stubbs's objection to the term "frequency spectrum," we would point out that this is a term which has come into prominent use in connection with telephony, telegraphy and radio-telephony. It is realized that it is not a term which, in its present application, has yet been officially recognized by any standardizing committee. However, bearing in mind that the frequencies involved in low-speed telegraphy, telephony, carrier systems and radio-telephony and telegraphy, each cover limited, though contiguous, portions of the whole frequency range, the application of this term seems particularly apt and we know of no other which conveys the general idea so well.

Mr. Aldridge, as well as other members, has questioned the example given on page 666, to illustrate the important part played by noise in determining the transmission efficiency of an average commercial connection. In spite of the opinions expressed by several speakers the facts as stated are correct, but to prevent misunderstanding it should perhaps be pointed out that the average noise assumed in this example includes all noise or disturbance upon the circuit due to causes other than room noise. There is no reason to believe, so far as our experience as telephone users is concerned, that the average line noise for an average connection on the system from which the example is taken is substantially different from that occurring in this country. This striking example was given to bring home to telephone engineers the very important part which noise undoubtedly plays in determining the intelligibility or transmission efficiency occurring in a large commercial system. The disadvantages of a vibrating type of noise standard, referred to by Mr. Aldridge, are quite real. These disadvantages have, up to the present, been met by arranging for a frequent checking of noise-generating elements against a standard element, and in care being taken in service to ensure that the noise element is carefully treated and not left running except when in actual use. A considerable amount of work has been carried out in connection with the development of a more suitable unit. At the moment this work is incomplete, but it is hoped that an improved unit will be available in the near future. For field use it is necessary that the noise-generating unit be small and portable, and this fact appreciably limits the freedom in design. We are not sure whether the noise generator referred to by Mr. Aldridge is of such dimensions as would enable its convenient use in field tests.

The use of the flicker effect for judging balances between sounds having widely different frequency ranges is not new; in fact it was used in investigations by Mr. D. MacKenzie, the results of which were published in the *Physical Review*, October 1922.* Since this time, however, further studies have convinced us that the flicker effect is not satisfactory, and the method has consequently been discarded. There can be no doubt that it greatly facilitates obtaining an apparent balance, but there is considerable doubt as to whether such a balance has much meaning on account of the introduction of overtones, which the interrupting of the sound would cause. It is necessary to use frequencies of at least 25 or 30 per second to increase the facility with which a balance should be made. These overtones may give a considerable change in apparent loudness and thus cause a false balance. In using this method for balancing two sounds, in which the frequency distribution is entirely at random, this effect would be a minimum, but in such cases there is little need for using the flicker method. In balancing out single frequencies, the addition of overtones would probably have the greatest effect and lead to the greatest errors in the results. It is in this condition that the method has its greatest apparent usefulness. We believe that for these reasons this method is not to be recommended. Mr. Aldridge is correct in assuming that in the method described in the paper a direct comparison is made between the disturbance and the standard noise without any speech test at all. The judgment of balance, however, is made upon the basis that the two sounds have equal interfering effect upon conversation.

Captain Cohen asked for further information on the noise-analysing set illustrated on page 666. This set consists essentially of a resonant circuit containing in series a receiver, a fixed inductance and a variable condenser. By suitably choosing the value of the condenser the circuit can be caused to resonate at any frequency between 150 and 2 500 periods per second. When in use the resonant circuit is connected to the circuit under test and the condenser is varied continuously from its maximum to its minimum value. When the condenser reaches such a value that the circuit resonates at the frequency of a harmonic present in the wave that is being analysed, a maximum tone is heard in the receiver; when this occurs, the setting of the condenser is noted and by reference to a calibration chart the corresponding frequency may be determined. In this way all the prominent harmonics present in a complex wave may be picked out and their frequency determined. The resonant circuit can be connected, by means of suitable keys, either between the two test terminals or between the two test terminals in parallel and earth. The first position allows the noise between the two wires of a circuit to be analysed, while the second allows the noise to earth to be analysed. Two terminals marked "110 volts" are connected to the two terminals marked "Test" through resistances of 1 500 ohms. These terminals are used when it is required to analyse a lighting circuit having a voltage not exceeding 110 volts, the resistances reducing the current in the receiver to a permissible value. A variable shunt is connected across the receiver to reduce the noise to a convenient amount. Captain Cohen's reference to the noise example has already been covered in the reply

* D. MacKenzie: "The Relative Sensitivity of the Ear at Different Levels of Loudness," *Physical Review*, 1922, vol. 20, p. 331.

to Mr. Aldridge. With regard to Mr. Ritter's question concerning the accuracy obtainable with the 3–A transmission measuring set, when a composite line is being measured, we think that there is some confusion. As we understand it the question has to do with the efficiency of the line composed of several sections of different construction. He asked whether the efficiency of such a line measured in one direction will be the same, within an accuracy of 0·1 mile, as that measured in the opposite direction. If such a line is measured between equal impedances, the result obtained in both directions will be the same within the precision of the measuring equipment. If, however, the value used for the sending impedance is different from that for the receiving impedance, the two results will differ because of the different transition losses occurring at the terminals in the two cases, since the impedances of the line are also different at the two ends. Either one of these two different results will, however, be obtained within an accuracy of 0·1 mile with this type of set, but these values do not necessarily give a correct idea of the efficiency of the line under normal use. It seems to us that Mr. Ritter has confused the question of the accuracy of the measurement *per se* with the question as to whether the result obtained is a true measure of the line efficiency under other conditions.

Mr. Robinson expressed a preference for an impedance bridge involving capacity elements rather than inductances. Our experience indicates that for the measurement of the small values of reactance which occur in line-impedance measurement it is more practicable to provide a simple bridge circuit involving inductance than a less simple bridge using capacity. As regards trouble due to the self-capacity of inductance coils, it is easily possible nowadays to design inductances in which these effects are sufficiently small to have a negligible effect upon the accuracy of line-impedance measurements.

Mr. Hines raises the question of applying checks to the transmission efficiency of local lines. The reason this question received small mention in the paper was that up to the present it has not been found possible to devise a testing system which meets the requirements for the measurement of local loop losses commercially and in a practical manner. It is perhaps worthy of mention that work upon this question has been proceeding for some time past and there are hopes that a means will be available in the future which will permit the easy observation of instrument and loop losses at a sufficiently low cost to warrant introduction for routine testing purposes.

PROCEEDINGS OF THE INSTITUTION.

716TH ORDINARY MEETING, 10 APRIL, 1924.

(Held in the Institution Lecture Theatre.)

Dr. A. Russell, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting of the 27th March, 1924, were taken as read and were confirmed and signed.

The President announced that the Société Française des Electriciens had founded a Mascart Medal in memory of that eminent French scientist, the Medal to be awarded triennially to scientists or engineers of any nationality distinguished for their work in pure and applied electricity, and that the first (1924) award had been made to Monsieur A. Blondel, an Honorary Member of the Institution.

Messrs. H. Brazil and F. P. Sexton were appointed scrutineers of the ballot for the election and transfer of members and, at the end of the meeting, the result of the ballot was declared as follows :—

A paper by Mr. S. C. Bartholomew, Member, entitled "Power Circuit Interference with Telegraphs and Telephones," was read and discussed.

On the motion of the President a vote of thanks to the author was carried with acclamation, and the meeting terminated at 7.50 p.m.

THERMIONIC VALVES WITH DULL-EMITTING FILAMENTS.

By the RESEARCH STAFF OF THE GENERAL ELECTRIC CO., LTD.

(Work conducted by M. THOMPSON and A. C. BARTLETT.)

(*Paper first received 30th November, 1923, and in final form 5th March, 1924; read before the* WIRELESS SECTION *2nd April,* 1924.)

SUMMARY.

An account is given of the history of the dull-emitting thoriated tungsten filament and of the development of thermionic valves containing these filaments. Intrinsic properties are described and discussed.

(1) INTRODUCTION.

Now that the thermionic valve has become a standardized engineering product it is of great importance in this progressive industry that the operating efficiency of the product should be increased to the greatest possible extent. Broadly speaking, there are two methods by which the efficiency of the valve can be, and is being, improved.

One method consists in so balancing the operating characteristics of the valve against the electrical constants of the circuit of which it forms part, that the maximum output is obtained from the valve with the minimum dissipation of power in the anode of the valve itself.

The second method, with one form of which it is proposed to deal briefly in this paper, consists in reducing the power consumed in heating the cathode to the temperature at which the necessary electrons are liberated from it. The discussion of this method is best introduced by a brief statement of the theory of thermionic emission.

(2) ELECTRON EMISSION (GENERAL).

The mathematical laws connecting the emission of electrons from substances with their temperature, were determined very completely by the pioneer work of Richardson,* who gave two general equations, both of which agreed with experiment equally well.

If i = saturated emission current in amperes per unit area of emitting surface, and
T = absolute temperature of surface,

then $$i = AT^{\frac{1}{2}}e^{-b/T} \quad . \quad . \quad . \quad . \quad (1)$$

or $$i = CT^{2}e^{-d/T} \quad . \quad . \quad . \quad . \quad (2)$$

where A, C, b, d, are constants characteristic of the emitting substance.

More recently, Dushman † has put forward on theoretical grounds an equation involving only one constant, characteristic of the emitting substance:—

$$i = 60 \cdot 2T^{2}e^{-b_0/T} \quad . \quad . \quad . \quad . \quad (3)$$

Whichever of these three equations is considered, it is obvious that at any constant temperature the magnitude of the saturated emission from any substance will almost entirely depend upon the value of the exponential factor b (or d). This constant, b, is related to the quantity ϕ, the work necessary for an electron to escape through the surface of the emitting substance, by the simple relation

$$b = \phi/k$$

where k = the gas constant for a single electron.

This relation between b and ϕ is confirmed by Richardson's proof that the contact difference of potential between two substances is equal to the difference in the values of ϕ for the substances.

Now directing our attention to the relation between i and ϕ, and neglecting the comparatively small effect of changes in the constant A (or C), we see that log $(1/i)$ is approximately proportional to ϕ/T.

In other words, at the same temperature substances having a low value of ϕ (i.e. electro-positive) will emit more electrons than will substances having a high value of ϕ; or, expressing the same statement in another way, the temperature at which we can get a definite amount of electron emission will be lower the smaller the value of ϕ or the more electro-positive the substance.

In order, therefore, to obtain most economically the necessary electrons for our valve, why should we not take the most electro-positive substance known and simply arrange to maintain it at the requisite temperature? The problem is not, however, quite as simple as that, on account of other factors, mainly those depending upon the physical and chemical properties of the substance.

Sodium, for example, will give 14 mA of electron current per cm^2 of surface at about 400° C., but it is easier in practice to heat a thin tungsten filament to 2 000° C. than it is to maintain a small amount of sodium at 400° C. Again, the vapour pressure of sodium at 400° C. is so considerable that we should no longer have a hard valve; and lastly, highly electro-positive substances are generally chemically reactive and cannot be maintained unchanged in the presence of any appreciable quantity of the residual gases, which are difficult to remove completely from an evacuated vessel.

Such considerations have so far prevented the use of any material but tungsten for the cathodes of large transmitting valves where mechanical strength is important and the removal of the last traces of residual gas almost impossible, owing to the high temperature attained by the anode. But in the smaller valves used for wireless reception and for the amplification

* O. W. RICHARDSON: "Emission of Electricity from Hot Bodies."
† *Physical Review*, 1922, vol. 20, p. 109.

of telephone currents, two forms of electro-positive cathode have been introduced. The first is the cathode covered with oxides of the alkaline earth metals. The great emission from these oxides at moderate temperatures was observed by Wehnelt * in the early days of thermionics. The Wehnelt or "oxide-coated" cathode has been developed very skilfully by the Western Electric Co. A very complete and authoritative account of their work is given by H. D. Arnold in the *Physical Review* (vol. 26, p. 76), and it is therefore unnecessary to offer any further account of it here.

The second form of electro-positive cathode is the thorium-coated tungsten cathode, with which alone this paper is concerned. It is usually known as the "dull-emitting" filament because it gives the requisite emission at a temperature much lower than that of the plain tungsten filament. This temperature is higher than that at which oxide-coated filaments are run, and consequently the term "dull emitter" might with even greater justice be applied to the latter. However, it is not generally so applied. It is unnecessary to discuss here the appropriateness of the nomenclature, so long as it is realized that by a "dull emitter" is here meant, not any valve with a cathode at a relatively low temperature, but only that form which employs the thorium-coated tungsten filament.

(3) History of the Thorium-coated Tungsten Filament.

The admixture of a small proportion of thorium oxide with tungsten has for very many years been common practice amongst electric lamp manufacturers when preparing their tungsten filaments, which as a result of this admixture are then less brittle than similar filaments not containing this or some other "impurity." For example, British Patent 18 467 of 1911 (W. D. Coolidge) claims the use of thoria and other refractory oxides mixed with tungsten powder before sintering, etc.

The first reference to any electrical peculiarity being shown by these thoriated tungsten filaments is contained in, and forms the subject matter of, two patents taken out in 1914 by Langmuir in America.† The first of these patents describes a method of heat treatment for such filaments, resulting in an extraordinary increase in the electron emission from the filament, the treatment consisting in heating the filament to a temperature of about 2 900° K. for a period of 1 or 2 minutes, followed by a few minutes at about 2 250° K. The electron emission from the filament was then measured at 1 380° K. and found to be equal to that obtained from a similar pure tungsten filament at about 2 000° K.

The changes brought about by this heat treatment were considered by Langmuir to be: (*a*) the evaporation of all gaseous and solid impurities from the filament surface at 2 900° K., followed by (*b*) the diffusion from the interior of the filament of thorium material which gradually formed a film covering the surface of the filament. The enhanced electron emission was then characteristic of this surface film of thorium material.

The emission from this activated or dull-emitting filament was, however, found to be quickly destroyed in the presence of traces of residual gas, and Langmuir's second patent describes a valve containing the dull-emitting filament and also a small amount of hydrocarbon or alkali-metal vapour, introduced in order to fix all those residual electro-negative gases which were likely to combine with the thorium on the surface of the filament.

Although no valves utilizing these dull-emitting filaments were being commercially manufactured at the end of 1919, the phenomenon could not escape the attention either of valve users or of valve manufacturers. It was a frequent occurrence during the war for thoriated filaments, especially in the hardest valves, to show unusually high electron emission, which sometimes survived several hundred hours of operation.* Also, in the actual manufacture of valves, during the electronic bombardment of the anode while the valve was connected to the pumping system, occasionally the electron emission from the filament would suddenly increase, as shown by the overheating, and even melting, of the anode. This phenomenon was generally associated with the presence of a more volatile metal such as copper, contained as an impurity in the nickel electrodes, and it was doubtless really due to a temporary development of the greatly enhanced thorium emission as a result of the action of copper vapour upon the thorium oxide in the filament.

One of the first problems undertaken by the Research Laboratories of the General Electric Co. was that of investigating the electrical behaviour of thoriated tungsten filaments, with the object of stabilizing their enhanced electron emission so that use could be made of them in valves.

Work was begun on the problem at the end of 1919 and a promising degree of success with receiving valves was fairly quickly achieved. Langmuir's results in regard to the effect of residual gases on the enhanced emissions were completely confirmed, and a method was evolved for producing regularly and with certainty a degree of vacuum considerably higher than that obtained in the average hard valve of that time. Further, it was found that, in addition to an extremely high degree of vacuum, it was also essential that all surfaces which collect electrons during operation of the valve should be free from adsorbed layers of gas. It was a comparatively easy matter by the classic method of electron bombardment to free the anode of the valve from all traces of gas, but much more difficult to do so with the grid.

The obvious method of heating the grid by passage of sufficient current through it was ruled out because experience had shown that a spiral grid with no damping wire was a cause of microphonic noises in the receiving set.

It proved possible, however, to cover the surface of the grid with a gas-free deposit or varnish,† after which deposition electron current could be passed from filament to grid for long periods (the grid potential being 50 volts or more) without liberating harmful gas from the surface of the grid, despite the fact that the grid metal certainly contained occluded gases.

† British Patent No. 169 546 (Thompson and General Electric Co., Ltd.).

By June 1920 it was possible to draw up a schedule for the production of dull-emitter valves, and about this time, in order to test the process, the first fair-sized batch (about 50) was made at the works of the Marconi-Osram Companies by partially-skilled girl labour working in accordance with this schedule. Uniformly good valves were the result, and as a matter of interest the target diagram is reproduced in Fig. 1, which depicts the filament voltage and current required by these first 50 valves for the emission of 5 mA of electron current. Meanwhile, life tests under operating conditions of earlier valves showed steady electron emission for a period of 800–1 000 hours, so that by September it was possible to market the valve. Actually, the first large order was placed in March 1921 after considerable trial of sample valves.

The first type of dull emitter manufactured was then known as the "L.T.1" and, except for small modifica-

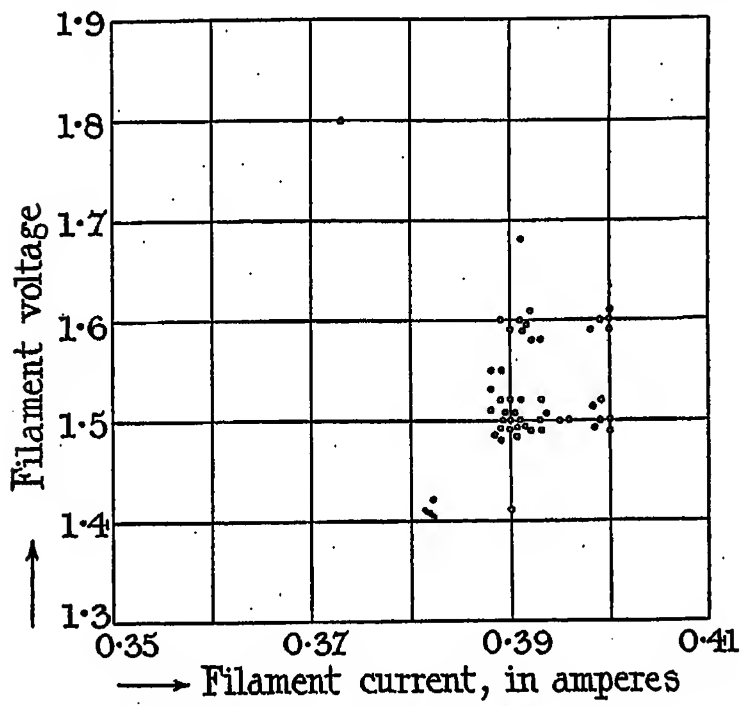

FIG. 1.—Target diagram for first 50 dull emitters produced in 1920: filament voltage and current required to give 5 mA of electron emission.

tions, has been in continuous production ever since, although it is now usually known as the "D.E.R." valve. The filament of this valve required 0·38 to 0·40 ampere of heating current at 1·5 to 1·8 volts, the total emission under these conditions being 5 mA. Compared with an ordinary tungsten filament of the same dimensions this showed a saving of about 75 per cent in the power consumed in filament-heating.

If the anodes of these L.T.1 valves were freed from gas by the usual method of electron-bombardment, a lower limit would be set to the filament diameter and, consequently, to the filament current, since filament wastage sufficient to cause the failure of the finest filaments always occurs during the process. If some other method of anode-heating could be adopted which would avoid this difficulty, there would be no lower limit other than that set by the mechanical strength necessary for the drawing down of the wire, for handling during the assembly of the valve parts, and also for the small amount of tension necessary to keep the filament straight inside the grid of the finished valve. It was known that induction heating by radio-frequency currents could be used for this purpose, and this was tried with success for the Royal Air Force, in collaboration with whose experimental department the trial was made. A valve oscillator was used for the generation of the high-frequency current. By this method, receiving valves were produced in 1920 in which the filaments required only 0·07 ampere of heating current at 1·8 volts, and also other valves having a lower anode impedance, in which the filaments consumed 0·1 ampere at 3 volts. Both these types (known as the "L.T.2" and "L.T.3") were made in small numbers in the Marconi-Osram works, but were not thoroughly satisfactory, chiefly on account of the great difficulty in applying the correct amount of tension to the filament. The margin of tension between that which would break the filament and that necessary to keep the filament off the grid was exceedingly small.

For valves in which filament tension is essential, about the right diameter of filament was found in the dull-emitter V.24 valve (D.E.V.), in which the diameter was gradually increased in successive trials until entirely satisfactory results both in the factory and in subsequent operation were obtained with a filament consuming 0·2 ampere at 2·7 to 3 volts.

The possibility of using as a dull emitter the thinnest filament of lamp manufacture has recently been demonstrated by the General Electric Co. of America, who have returned to the subject of the thoriated filament. They have met the difficulty of filament tension by using no tension at all, and arrange the dimension of filament length and grid diameter so that the filament on being heated does not expand sufficiently to cause it to sag on to the grid. This American valve takes 0·06 ampere at 3 volts and is truly within the capacity of dry cells. A similar type of valve is also made by several manufacturers in this country.

(4) PROPERTIES OF THE DULL-EMITTING THORIATED FILAMENT.

(*a*) *Contact-potential effects.*—When carrying out the first experiments on thorium emission in a complete triode, a valve of a standard type was used. Thorium emission having been stabilized, there appeared to be a considerable reduction in the grid current at zero grid voltage, and on plotting the usual anode and grid current characteristic curves it was clear that both curves were shifted bodily to the right, when compared with a similar valve containing an ordinary tungsten filament. The amount of shift was equivalent to about 1·5 volts on the grid. By plotting the characteristic curves before and after the formation of the thorium surface layer it was possible to demonstrate this particular effect with the same filament in the same valve (Fig. 2).

In addition to the bodily shift of the curves, the anode-current/anode-voltage characteristic was also less steep with the dull-emitting filament, while in diodes the saturation part of the curve was less flat than it is for tungsten emission. Both these effects are illustrated in Fig. 3. This lack of sharp saturation was ascribed by Langmuir to a kind of grid effect at

the heterogeneous filament surface which is not completely covered with thorium, the tungsten part of the surface acting in the same way as a negatively charged grid.

The effects described in the preceding paragraph necessitated the re-design of the electrodes, inasmuch as a slightly narrower grid of rather closer pitch was required to obtain approximately the same characteristic at the same operating voltages on grid and anode.

(b) *Stability of thorium emission.*—This question is of course of fundamental importance and, needless to say, always receives first consideration when new types of dull-emitter valves are being designed.

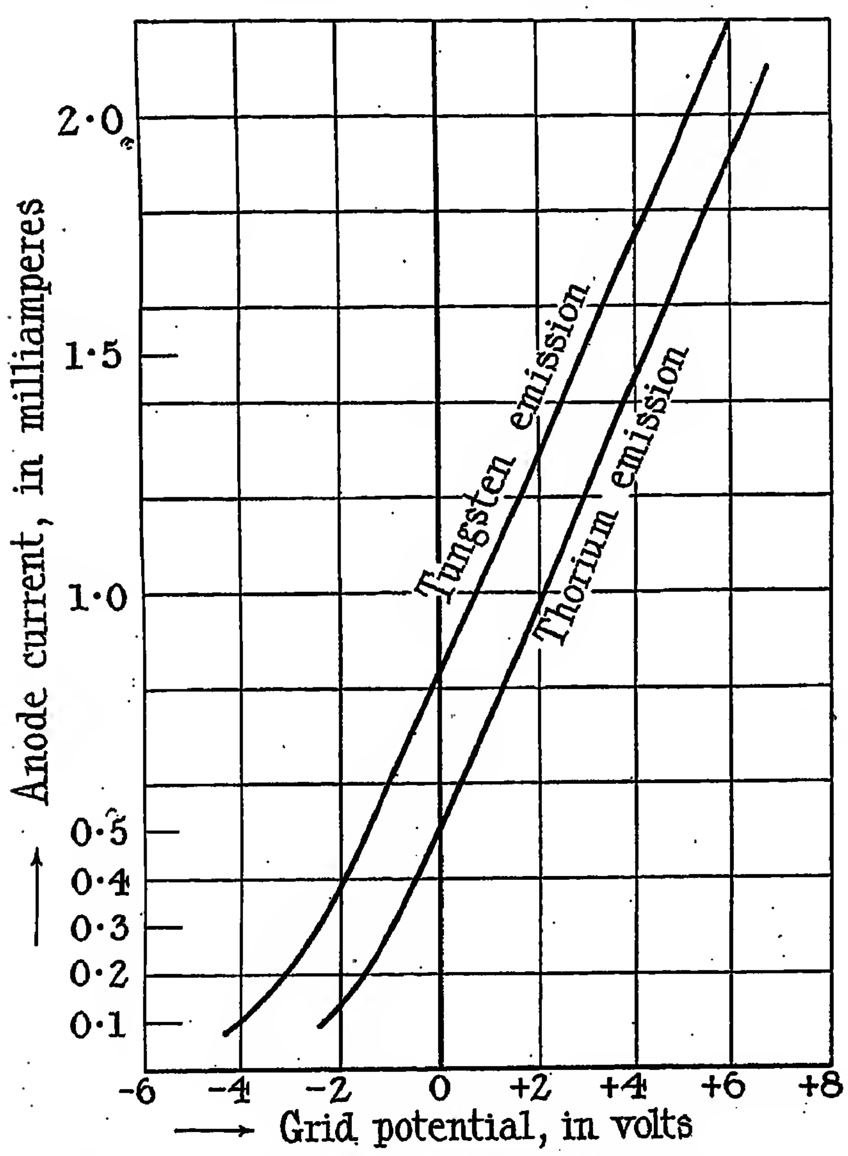

FIG. 2.—Anode-current/grid-voltage characteristics for one valve, with the same total emission (9·6 mA) from the same filament with (1) tungsten emission, and (2) thorium emission.

The three chief factors upon which depends the constancy of the electron emission from a dull-emitting filament were found to be: (i) Filament temperature, (ii) anode voltage, and (iii) the degree of vacuum. It is proposed to discuss these three factors in this order.

(i) Langmuir's early patents accurately described the effect of changes in filament temperature upon the electron emission from the filament. After the production of enhanced electron emission by heat treatment at 2 900° K. for about a minute, followed by 2 250° K. for several minutes, the emission was found to be steady over very long periods, during which the filament remained at a temperature of 1 700° to 1 800° K. If, however, the filament temperature were raised above 2 250° K., say to 2 500° K., the emission rapidly decreased until only the characteristic emission of pure tungsten remained.

By bringing the filament back to 2 250° K., however, the enhanced emission was again restored. The explanation of these changes, as being due to evaporation of thorium from the filament surface at the higher temperatures and diffusion from the interior of more thorium at the lower temperature, was easy to understand. It is not so easy, however, to visualize what happens during the original treatment at 2 900° K. which was found necessary in order to produce the emission, unless the actual formation of elementary thorium from its oxide occurs at this temperature.

Several thoriated filaments were therefore incandesced at 2 900°–3 000° K. for various lengths of time, after

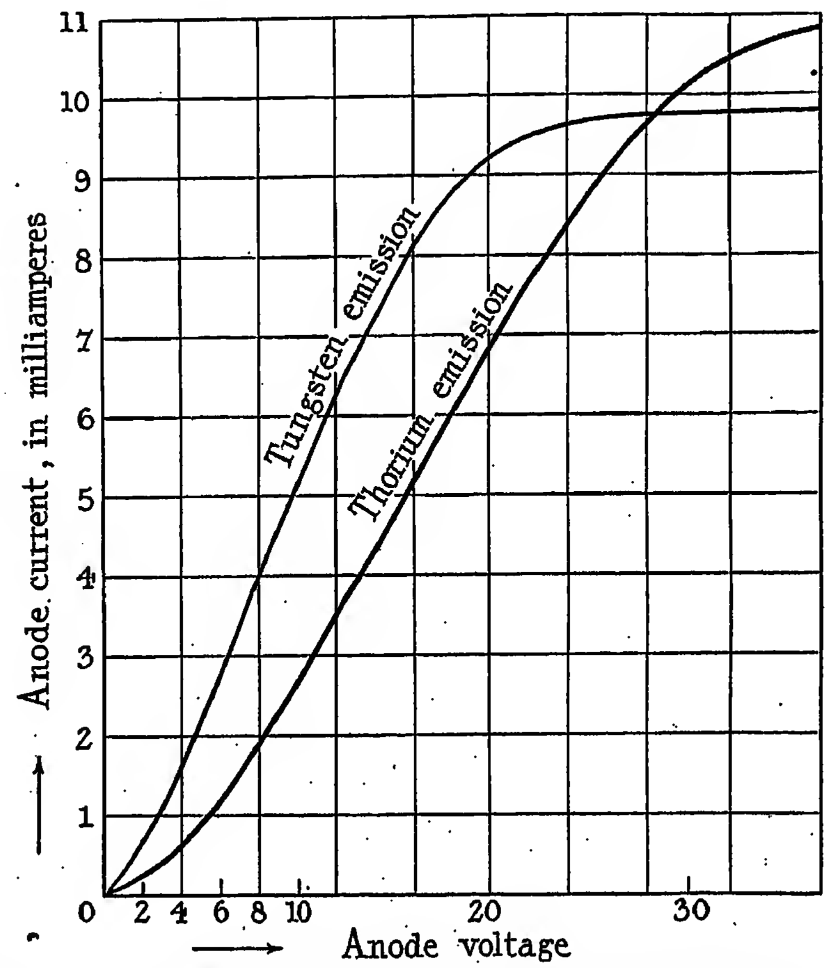

FIG. 3.—Anode-current/anode-voltage characteristics for two similar diodes: (1) tungsten filament and (2) dull-emitting filament.

which chemical tests were applied which could distinguish between thorium and its oxide. As a result it was found that after an hour's treatment at this temperature no oxide remained in a filament 0·06 mm in diameter, but that there was still present an amount of thorium of the same order of magnitude as that which would be equivalent to the original oxide.

Very numerous life tests carried out on valves have shown that, with filament temperatures not exceeding about 1 900° K., practically constant electron emission is obtained during periods which are very seldom less than 1 000 hours and are generally in excess of that

figure. In general, the life of the emission is longer the lower the temperature of the filament.

At the operating temperatures of 1 700°–1 900° K. our early results showed that some diffusion of thorium to the surface must be occurring, although much more slowly than at 2 250° K., for if for any reason, such as the presence of excessive residual gas, the electron emission decreased during the life test, it would increase almost to its former value if the filament was kept at the same temperature but with zero anode potential, so that no space current was flowing.

Langmuir * has recently attempted to separate the two factors (diffusion to the surface and evaporation from the surface) which govern the amount of thorium in equilibrium at the surface at any particular temperature. Amongst other results, he finds that thorium gas molecules which are always adsorbed on the surface of the bulb, the resulting positive ions then travelling to the filament, where they slowly but surely contaminated the thorium surface.

It was considered that in a larger bulb fewer electrons would actually hit the glass, and that those which did hit would do so with less kinetic energy, since they would be, figuratively speaking, travelling uphill. The energy of impact would consequently be less likely to be sufficient to cause ionization of adsorbed gas molecules.

In the light of these results a safe anode voltage was always stipulated for the various types of valves manufactured; for example, 30 volts in the V.24 bulb and 50 volts in the L.T.1 bulb of 25 mm diameter.

(iii) From the point of view of manufacture the deter-

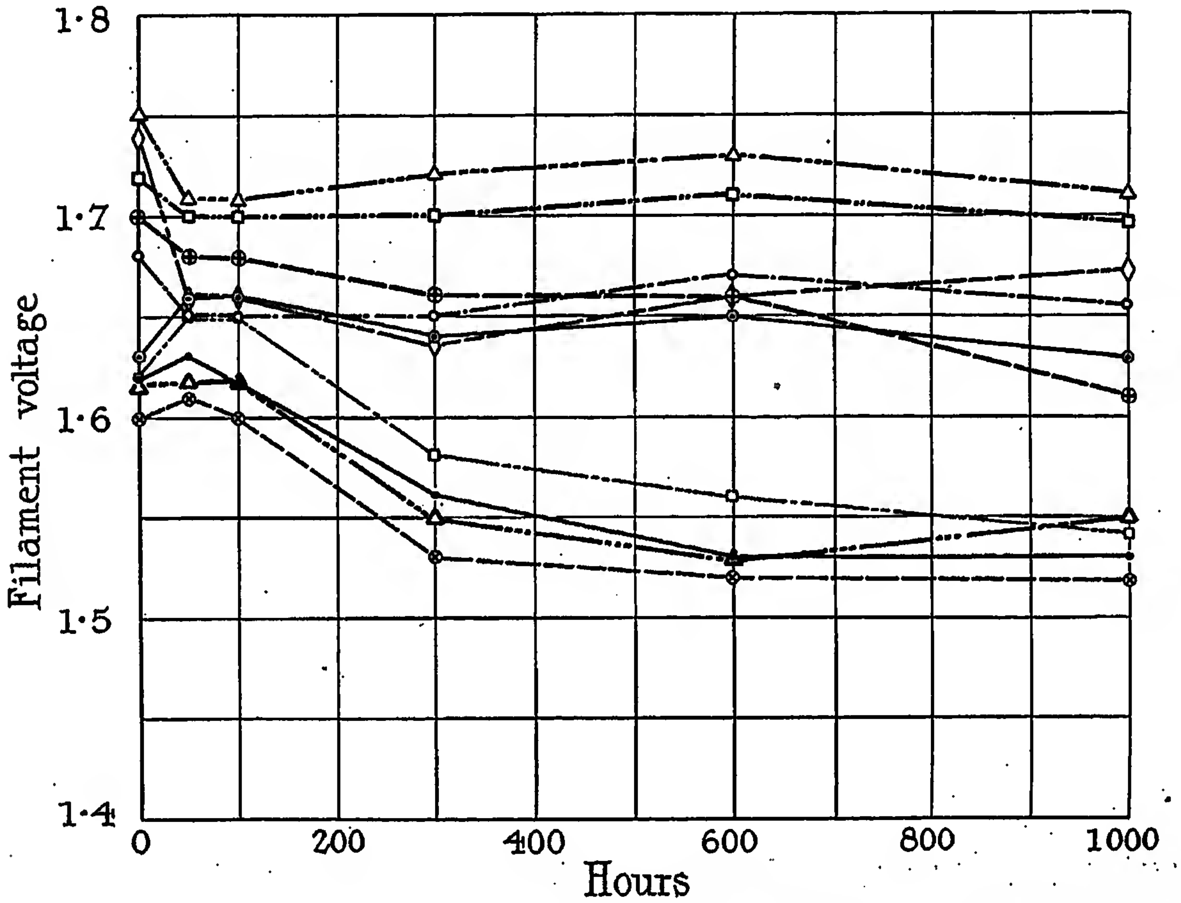

FIG. 4.—Life test of D.E.R. valves: filament voltage required to give a constant emission of 5 mA.

atoms evaporate from underlying thorium atoms at a rate very high compared with that of thorium from underlying tungsten atoms.

(ii) In general, and with other factors constant, the life of thorium emission in a valve was found to decrease with increasing anode voltage. Also the maximum anode voltage which would allow of a satisfactory life was a function of the size and shape of the enclosing bulb, the permissible voltage increasing with increasing bulb diameter. For a life of 1 000 hours, or more, the V.24 tubular bulb (of 15 mm diameter) was found to give this maximum at about 40 volts, while a tubular bulb of 25 mm diameter allowed about 80 volts, and so on.

This dependence upon bulb diameter seemed to indicate that stray electrons which followed circuitous paths to the anode were causing ionization of some of the

* *Physical Review*, 1923, vol. 22, p. 357.

mination of the degree of vacuum necessary for a satisfactory life of thorium emission is probably of more importance than any other consideration, for, in addition to the cost of an elaborate evacuation process, there is also the increased cost due to the proportion of valves which may be rejected on account of a degree of vacuum lying outside the specified limit.

In the early days of the development of dull emitters it was apparent from the results of life tests that, although thorium emission might be shown by the filament, in any particular valve this emission was not stable under operating conditions for more than 100 or 200 hours unless the degree of vacuum were very high, and, generally speaking, the higher the pressure of residual gases the shorter was the satisfactory life.

In order to obtain stable emission during a life approximating to 1 000 hours, the pressure of residual

gas had to be not more than about 0·00001 mm (of mercury).

This pressure was therefore aimed at as the maximum permissible, for it was of course realized that the future of the dull emitter would depend not only upon the great economy in filament-heating but also upon the satisfactory life which the valve gave under operating conditions.

However, except for occasional epidemics of "low vacuum," which were generally traced to their source, the proportion of valves rejected on this score was at first encouragingly small, and became progressively smaller as workers became accustomed to the manufacturing schedule.

It was realized that this upper limit of 0·00001 mm pressure of residual gases was somewhat arbitrary, inasmuch as account was taken only of quantity and not of quality of the gases. Experiments were therefore contrived with the object of finding out what was the effect of various pure gases upon thorium emission, the results of which experiments were to show that water vapour, carbon monoxide, and nitrogen all depressed the electron emission from a thoriated filament, even below that which is characteristic of tungsten itself, but that in the presence of hydrogen, even at a pressure as high as 0·01 mm, thorium emission was perfectly stable throughout a normal life.

If anything, therefore, we were erring on the safe side in setting a maximum limit of 0·00001 mm pressure; but as it was not possible to ensure that only hydrogen —and no other gas (particularly water vapour)—was present in the valve, this maximum limit was not altered.

(iv) *Life test.**—A small percentage of the Marconi-Osram works production is collected periodically (actually two or three times a week), and this small percentage is subjected to various tests by the laboratories, including life test.

With regard to the life tests on dull emitters, we may take the D.E.R. valve as an example. In our routine tests the valves are run with a steady a.c. filament voltage of 1·8 and anode voltage of 50, the grid being connected to one filament lead so that the grid potential virtually oscillates between zero and 1·8 volts positive. Except for the alternating voltage on the filament, these conditions are then very similar to actual operating conditions. The test is run on each particular collection of valves for 1 000 hours, measurements of emission, etc., being made at the end of 50, 100, 300, 600, and 1 000 hours. The emission measurement consists in reading the filament voltage necessary for obtaining a flow of 5 mA of electron current to the grid and anode, which are connected in parallel while the potential of 50 volts is applied to them. The filament voltage required is then plotted against the time during which the life test has run.

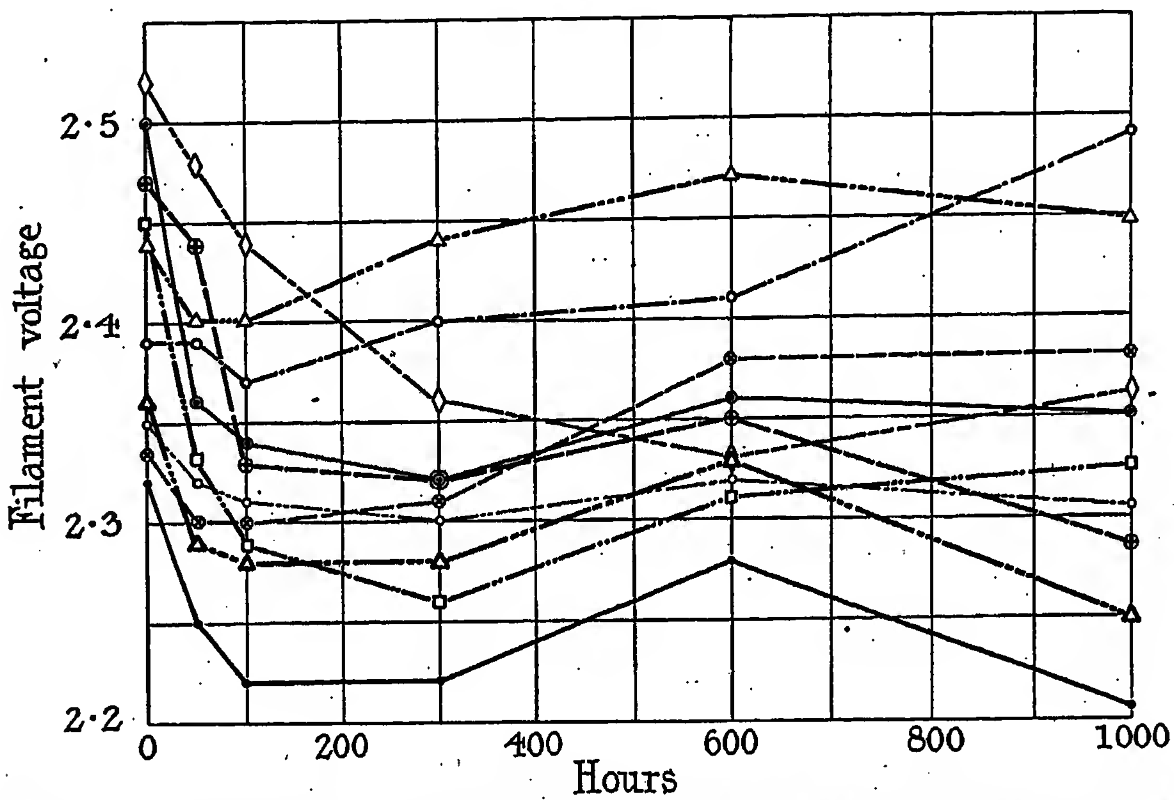

FIG. 5.—Life test of D.E.V. valves: filament voltage required to give a constant emission of 5 mA.

Typical curves obtained in this way for the D.E.R. valve are shown in Fig. 4, where the voltage scale is purposely made very open.

Similar curves for the D.E.V. valve, of which the filament takes 0·2 ampere at 3 volts, are shown in Fig. 5, and other curves for the power-amplifier valve (L.S.5) in Fig. 6.

(v) *Valve noises.*—Under this heading are included the two effects generally known as (*a*) crackling, and (*b*) microphonic noise. Both phenomena only become important in receiving circuits in which more than two stages of audio-frequency amplification are employed.

By the first term is meant the continuous series of sharp reports frequently heard in the telephones when valves with hot tungsten filaments are employed, and by the second term the more or less musical note

* The methods adopted in the life-testing of valves will be described in a later paper.

similarly heard when a blow or tap is delivered to a valve occupying a position before the last two.

The cause or cure of crackling has not proved easy to discover, although the phenomenon is generally looked upon as being due to impurities in the filament and although, also, the magnitude of the effect can be reduced to some extent by heat treatment of the filament.

Dull-emitting filaments are, however, almost entirely free from this first defect, but are offenders in respect of the second.

Very numerous experiments in connection with the microphonic noise characteristic of dull-emitter valves have driven us to the conclusion that the effect is entirely due to the filament retaining a high degree of in the offending valve by means of a low-power microscope, so that the effect of various types of electrode construction could be easily studied.

The first valve studied in this way was a 3-year-old one of the original L.T.3 type having a 70 mA filament current, and with this as the first valve the set was easily arranged to howl. When this occurred, no vibration of the grid, anode, or filament support could be observed with the microscope, but the filament bowed out to four or five times its original diameter. The same bowing out of the filament was also observed, but to a much smaller extent, in a D.E.R. valve.

A valve was next constructed having a small iron weight hanging from the filament spring so that by means of a solenoid the amount of tension on the

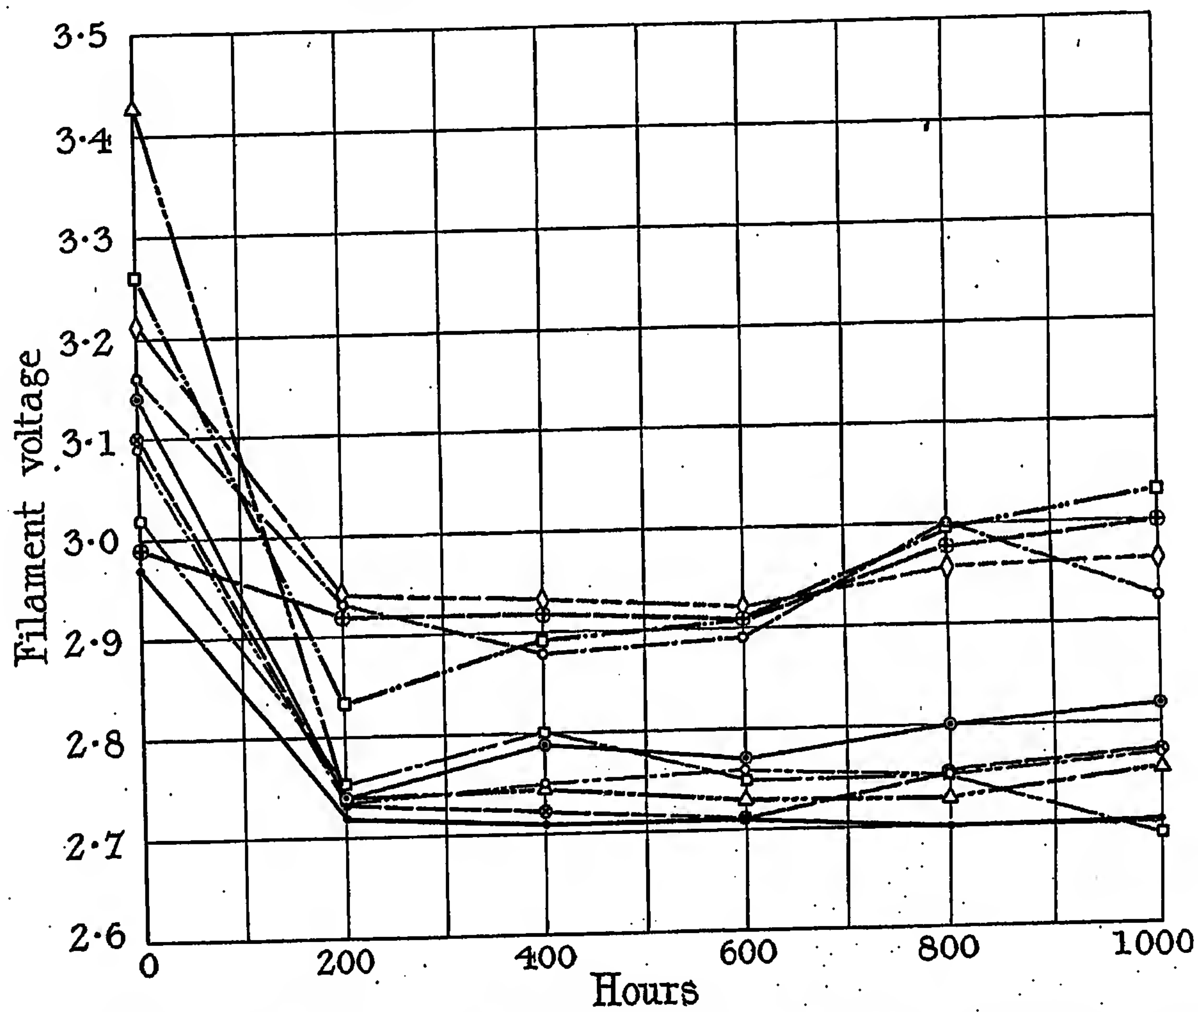

FIG. 6.—Life test of L.S.5 valves: filament voltage required to give a constant emission of 5 mA.

elasticity at its normal operating temperature. At present the only practicable method of eliminating these noises seems to be to mount the valve on a special type of holder designed to prevent any except very low-frequency vibrations from reaching the valve.

In carrying out the above-mentioned experiments use was made of the well-known howling effect which is obtained when a loud-speaker is used in conjunction with many stages (four or five) of audio-frequency amplification. Under these conditions, particularly when using dull-emitter valves, any signal or extraneous noise will start a persistent howl at a frequency near to the natural frequency of the diaphragm of the loud-speaker.

The persistence of the effect offered the readiest means for actually observing the electrode movement filament could be varied. It was found that by increasing the tension the pitch of the howl was raised slightly and the quality of the note was altered, but the general volume of noise was unchanged.

Various other valves were tried in this way with one or other, or all, of the three electrodes mounted on springs of very low natural frequency, and also with various bulb sizes, but no reduction of microphonic noise could be obtained.

There is no doubt, therefore, that these noises are due simply to the transverse vibrations of the filament, although we have a certain amount of evidence that the rate of damping of these vibrations is influenced slightly by the kind of supports used.

In order to eliminate the noises entirely, the only practicable way seems to be to prevent any vibrations

from reaching the filament from outside. A design of valve holder which achieves this object depends upon the fact that a spiral spring can be made which has a very low natural periodicity for transverse, longitudinal, and torsional vibrations. The valve holder is supported on such a spring and connections are made to terminal points on the base by means of phosphor-bronze springs.

There is no necessity, of course, to use this type of holder when only two stages of audio-frequency amplification are used.

Conclusion.

In concluding this account of the properties of the dull-emitting thoriated filament it may be interesting briefly to compare the efficiency or economy of this type of dull emitter with that of the oxide-coated filaments.

In order to do this, previously published curves * connecting electron emission with power consumed in cathode-heating may conveniently be referred to. H. D. Arnold in his paper states that the customary operating power for the oxide-coated filament is from 8 to 9 watts per cm^2 of cathode surface, and that the range of efficiencies lies between 10 mA of electron emission per watt (of heating power) and 100 mA per watt.

On the other hand, with the thoriated filament this efficiency ranges from 10 mA per watt at 1 630° K. to 200 mA per watt at 1 910° K., and 400 mA per watt at 2 005° K.*

These figures, however, neglect the loss of power in the leads, and the apparent difference between the two filaments is in practice reduced as a result of the increased loss due to the heat conducted away by the filament leads in the case of the thoriated filaments, which operate at a temperature about 500 to 600 degrees higher than the oxide-coated ones. Actual valves of the two types, produced commercially, show practically no difference between the efficiencies of the two filaments, and the results of any rivalry between the two will probably be determined by other factors.

Discussion before the Wireless Section, 2 April, 1924.

Professor C. L. Fortescue: This paper deals with the only marked new development in the small valves that has taken place during the last seven or eight years, and it is interesting to note that it involves a number of very subtle physical problems. Frequent mention is made of Richardson's work function, and the possibility of reducing this to one-tenth or one-hundredth of its present value by some indirect treatment of the surface of the filament immediately suggests itself. If this were possible the life of the valves might be enormously increased. Two important practical considerations with respect to the dull-emitting filaments are the effects of running at too high a temperature and of working the valves at too high a voltage. With regard to the former, the authors have demonstrated the re-forming of a filament after overheating, and a natural inquiry is whether it is always possible to carry out this process of re-forming after a filament has been damaged by overrunning. So far as the high voltage is concerned this appears to be necessary when working with loud-speakers, and it would be interesting to know what are the limits actually found with the various types of dull-emitter valves and what are the hopes of raising this limit in the near future. The possibility of using these filaments for transmitting valves also suggests itself, and the authors' views on the likelihood of this development would be interesting.

Mr. R. C. Clinker: I am much interested in Fig. 3 in which the difference in the shape of the characteristic curve is shown for both tungsten and thorium emissions. On page 37 of Van der Bijl's book on the "Thermionic Vacuum Tube" an additional explanation is given of the non-saturation effect. It is pointed out that the filament is not a perfect cylinder but is full of protrusions and hollows, the effect of which is to cause large electrostatic fields at the surface. High plate potentials are required to overcome these fields and to pull all the emitted electrons across. Is it not possible that a difference in surface conditions between the pure tungsten and the thorium-coated filament will account for some of the difference shown in Fig. 3? In the section dealing with the life test, the statement is made that the valves are run with a steady a.c. filament voltage of 1·8 and an anode voltage of 50, the grid being connected to one filament lead so that the grid potential virtually oscillates between zero and 1·8 volts positive. I think that the last figure should read 2·5 volts. With regard to microphonic noises and the fact that the dull-emitting filament has a corresponding higher resilience than the high-temperature filament, we have found that if the voltage is raised from 3 to, say, 5, the damping is markedly greater. This can be clearly seen by twanging a stretched wire (as employed by the Royal Aircraft Establishment at Farnborough) tuned to agree with the natural frequency of the filament. The latter is seen to vibrate over a smaller amplitude when operating at the higher temperature. On the other hand this does not appear to reduce noticeably the total microphonic noise in the telephone.

Mr. S. R. Mullard: The result of this work can, I think, be traced back to that period during the war when those who were experimenting with valves were trying to solve the troubles arising from crackling noises occurring in receiving valves. This trouble was ultimately traced to impurities in the filament, and from that stage the information gathered was helpful to valve manufacturers in the production of dull-emitting filaments. Certain transmitting valves in which impure tungsten was used certainly showed this dull-emitting property. I think that Prof. Fortescue had a 250-watt or a 500-watt transmitting valve which gave very good results as a dull emitter. The experience which we have obtained runs almost parallel with the research carried out by the authors, and I think that the future

with dull-emitting filaments lies in an arrangement for damping microphonic noises as shown in the new holder, or in the use of "oxide-coated" filaments, the latter having the advantage of being non-microphonic when used in the standard holder.

Mr. J. F. Herd: I believe that we at the Radio Research Board Station, Aldershot, were actually among the first to be supplied with dull emitters when these were available, as an experimental product, from the company which the authors represent. We were interested in their use in connection with a continuous recorder for atmospherics, working with 7 to 9 filaments burning 24 hours a day and 7 days a week. The advent of the dull emitter gave great promise of a reduction of accumulator maintenance. The valves then supplied were known, I think, as "S.R.1." These were set up and used continuously for 24 hours a day for rather more than 6 months, representing a burning life of 5 000 hours, without any diminution of emission. Only one filament burned out of its own accord. Then, unfortunately, the whole of the 9 filaments were accidentally burned out, and the subsequent batch of production valves which were used to replace them were those referred to in the paper as "L.T.2." With these the stability of emission was much inferior to that of the experimental samples and of those now being supplied. We have at present set up later dull emitters which are giving great satisfaction. In common, I think, with other valve users, I regret to learn from the authors that microphonic noises are more or less inherent to this type of filament. When a 7- or 8-stage amplifier is used, these noises become serious, and in our case might readily give rise to spurious "atmospherics" on a record. We have practically solved that difficulty by means of shock absorbers which protect the amplifier from floor vibrations. One regrettable feature of the dull emitters, as compared with the oxide-coated filaments mentioned by Mr. Mullard, is their comparative fragility. Many users will agree that they are liable to be broken by an accidental knock. They seem to me to be more fragile than an ordinary tungsten filament and certainly much more so than an oxide-coated one.

Mr. E. Y. Robinson: I should first like to refer to the authors' remarks on the contact-potential effects as illustrated in Fig. 2. The shift of the anode characteristic to the right is what one would expect from a consideration of the effect of contact potentials. From the space-charge equations which have been given by various people two formulæ have been evolved, neither of which, in my opinion, represents the true conditions existing in the valve. If we take the current in the valve as I_a, the anode potential as E_a, the grid potential as E_g, the voltage factor as μ and the contact potential as E_c, we have the following formula :—

$$I_a = K(E_a + \mu E_g + E_c)^n$$

The other type of formula is as follows :—

$$I_a = K(E_a + \mu E_g + \mu E_c)^n$$

This second formula is the more correct, and in explaining the reason for this I should like to give my views as to what actually does happen in the valve. In the case of a valve which has a plain tungsten filament and nickel electrodes, then, taking the work function for tungsten to be 4·6 and for nickel to be about 3·6, the application of 100 volts to the plate will give in effect 101 volts on the plate, and 10 volts applied to the grid will give in fact 11 volts on the grid; if a molybdenum grid were employed, 10·2 volts instead of 11 volts would be obtained. Considering, now, the case of a valve having nickel electrodes, if we have 101 volts effective on the anode and 11 volts effective on the grid, and if in place of a tungsten filament we put in a thoriated filament, instead of the 101 volts on the anode we have 99·6, and instead of 11 volts on the grid we have 9·6, so that in effect we shift the anode current and voltage characteristic to this extent. Incidentally we also shift the grid-current characteristic, so that we lose practically nothing. (Actually we lose 1·4 volts on the anode.) That explains the shift of the curve. Now I come to the formula which I think should be employed. It is as follows :—

$$I_a = K\{(E_a + {}_aE_c) + \mu(E_g + {}_gE_c)\}^n$$

where ${}_aE_c$ is the contact potential between filament and anode, and ${}_gE_c$ is the contact potential between filament and grid. Although the adoption of this formula has no practical use since the refinement introduced is far outweighed by such effects as emission velocities, etc., which are not capable of calculation, this type of formula enables us to visualize the operation of contact potentials. There is a certain effect that I have found with oxide-coated filaments which I should like to record. When using an oxide-coated valve as a reacted detector, the circuit being very critically reacted and adjusted so that there was no backlash when it started oscillating, a feature when using certain valves was that the circuit would oscillate for about 5 seconds, then remain silent for a further 5 seconds, then oscillate again for 5 seconds, and so on. Various possible causes, including the presence of gas in the valve, were ruled out by experiment, and I was led to accept the following explanation. In an oxide-coated filament valve the slope of the characteristic curve is very much more dependent on the total emission from the filament than in the case of the ordinary tungsten filament valve. Consequently a small increase of emission will increase the slope of the anode characteristic and thus cause a critically reacted circuit to oscillate. What apparently happens in the case given above is that the work function of the oxide coat—or more possibly of one spot in the oxide coat—changes periodically and thus periodically changes the slope of the anode characteristic. This effect has been observed in several valves both purchased and made by myself, so that it seems to be a common failing. The moral is that oxide-coated valves which are very closely designed as regards emission may prove to be unsuitable for use in critically reacted sets. As pointed out above, the grid-current curve is shifted over to the right of the zero grid voltage. Consequently, when the valve is being employed as a detector using cumulative grid rectification, the grid leak should be connected to the positive terminal of the filament battery in order to bring the grid potential to its optimum value.

Mr. H. W. Edmundson: One point arises with

regard to the dull-emitting filaments as compared with the pure tungsten filaments, and that is the increase in the length of filament which is possible with the former. If one takes two filaments to work on the same voltage, the dull-emitting filament consuming $\frac{1}{4}$ ampere and the pure tungsten $\frac{1}{2}$ ampere, the dull-emitting filament is nearly twice as long as the pure tungsten filament. This enables a lower anode resistance to be used. Valves with dull-emitting filaments are stronger than valves with pure tungsten filaments, even when the dull-emitter filament is smaller in diameter.

Mr. C. F. Phillips: It is to be regretted that in the latter part of the paper the authors confine themselves particularly to their most recent development, the D.E.3 valve. The conclusions set out at the end of the paper relate to dull-emitting filaments in general, whereas a large part of the paper deals only with that specific type of valve. There is a new type of filament known, I believe, as the "XL," or thoriated tungsten, filament with possibly some special addition such as the authors have mentioned. This filament is applied to-day to valves of many different kinds. For instance, a somewhat similar filament to that used in the D.E.3 is applied to a valve which consumes 0·8 ampere at a pressure of 4·5 volts; such a valve has a very large emission, approximately 90 mA. For experiment, two valves were taken consuming respectively 60 and 800 mA in the filament (XL type in each case); as might be expected, the first valve was extremely microphonic, whereas the second was not in the least noisy. It therefore occurs to me that in the desire to make a real dry-battery valve there has been a tendency to go down to the extreme limit, i.e. 60 mA, when perhaps, had the manufacturers endeavoured to make an XL filament valve consuming 100 or 120 mA, we might have got a more advantageous valve for use commercially with dry batteries, as such a valve would be deprived to some extent of its microphonic properties because the filament consumption would lie between the 60 and 800 mA that I have mentioned. I have noticed what seems to me to be an unfortunate fact in connection with valves having oxide-coated filaments. To-day we are most of us interested in that portion of the valve curve which lies to the left of the zero grid line. In a valve with a thoriated filament we can make that portion of the curve extremely long by applying a comparatively high anode potential and maintaining the grid at a suitable negative potential. If we try to do the same thing with an oxide-coated filament the same conditions do not apply, because as we increase the anode voltage above the limits fixed on the box the valve starts to "blue," so that the very valuable portion of the curve to the left of the zero grid line cannot be prolonged.

Mr. P. G. A. H. Voigt: I have had two very poor D.E.R. valves which I ran all night without high tension, and the emission was only normal for 2 minutes. I should like to know whether there are any hopes of restoring the emission of these valves. As Mr. Phillips has said, the negative side of the grid voltage is the one that most interests the wireless user, and I have been applying high tensions (up to 300 or 400 volts) on the anode to increase this side. The authors say that the use of a very high potential depends on the diameter of the bulb. I should like to know whether it is safe to use the L.S.5 valve at 500 volts when it is marked for only 120 volts.

Mr. W. H. Edridge: Previous speakers have emphasized the utility of the left-hand side of the valve plate-current/grid-potential characteristic. Since there can be no doubt that it is the portion of the curve which lies outside the corresponding grid-current curve which should be utilized, I would ask the authors to give further particulars concerning the position of such grid-current/potential curves for the various types of valves which have been examined by them in the course of research and which are alluded to in the paper. The question of admissible plate potential also hinges upon the same question. I should be glad, therefore, if the authors would state whether the limits given for admissible grid potential for various sizes of dull-emitter valves may not be considerably increased if the plate current is maintained at a given figure, for example half the saturation value, by means of negative grid bias. My reason for raising this point is that it would appear possible that the tendency of the valve to lose efficiency when higher plate potentials than those specified by the authors are employed, may possibly be a function of the plate current rather than of the plate potential producing it; that is to say, the detrimental effect of high plate potential may be eliminated by an equivalent negative grid bias. With reference to the fact that these dull-emitter valves appear to be considerably more sensitive to variations of filament current in so far as oscillation is concerned, should this prove to be an objectionable characteristic it would appear to be easy to compensate for it by suitably placing a filament rheostat in the circuit.

Mr. L. S. Harley: I should like to know whether the maximum safe anode voltage, which is stated to be a function of the size of the bulb, does not depend also on the emission from the filament and possibly on the state of cleanliness of the interior surface of the valve bulb. It occurs to me that the limiting voltage may not be quite so definite as is stated in the paper.

Mr. W. F. Marriage (*communicated*): The paper deals primarily, of course, with valves of the thoriated-filament type. The authors refer to the work which has been carried out by the Western Electric Company in the development of valves using oxide-coated filaments. The paper to which the authors refer for information on this latter type of valve (*Physical Review*, vol. 26, p. 76) does not, however, deal with a number of features of considerable importance in valve work, and it will probably be of interest to members to touch briefly upon some of these points. I propose therefore to confine my remarks under four headings: (1) Microphonic noises, (2) Uniformity of production, (3) Stability of emission, and (4) Life.

(1) *Microphonic noises*.—As demonstrated by the authors at the conclusion of the paper, the thoriated tungsten filament is particularly microphonic. The oxide-coated filament, on the other hand, is much less liable to trouble of this kind so that no special precautions are needed in practice as regards light and flexible wiring. This lack of microphonic effect is controlled by

the fact that the oxide-coated filament is made with a special alloy core which is not so highly elastic as thoriated tungsten. Furthermore, the oxide-coated filament is of sturdy dimensions, the dimensions in the case of the "Wecovalve" being 0·0022 in. diameter and in the case of the repeater tube 0·002 in. by 0·012 in. This introduces a greater impedance to movement and makes the oxide-coated filament much less susceptible to vibration. Can the authors supply corresponding figures for similar valves with thoriated tungsten filaments?

(2) *Uniformity of production.*—The emission from thoriated tungsten over the operating range is several times as much per cm^2 as from the oxide-coated filament over its operating range. This greater density of emission from thoriated tungsten has the effect of requiring for thoriated tungsten filament valves a smaller plate and grid structure than is required in the case of an oxide-coated filament valve having the same characteristics. This smaller structure has the disadvantage that slight departures from specifications in assembly cause greater departures from normal tube characteristics. Thoriated tungsten tubes would therefore be expected to be less uniform in characteristics for equal skill in assembly. Uniformity of characteristics are, of course, of very great importance to ensure that when valves are replaced the same performance will result.

(3) *Stability of emission.*—On pages 692 and 693 the authors treat this subject in a very comprehensive manner. Their remarks on anode voltage and degree of vacuum apply, in general, to the oxide-coated as well as to the thoriated tungsten filament. With regard to filament temperatures, however, the thoriated tungsten filament is under the serious disadvantage that, when overrun, its normal emission is changed to that of a pure tungsten filament. The effect of momentarily overrunning an oxide-coated filament is to produce increased emission and to take a few hours off its average effective life, but, unlike thoriated tungsten, the oxide-coated filament returns to its normal stable emission when the filament is reduced to its normal operating temperature. Consequently no inconvenience is occasioned by the necessity of reactivating the filament. With the oxide-coated filament such temporary overrunning does not result in a changed anode impedance when the normal filament current is resumed. It would seem probable that in the case of thoriated filaments the process of rejuvenation would have to be carried out with very great care, and probably by expert hands to ensure that the anode impedance did not differ from its original value. Change of anode impedance will, of course, affect the performance of the valve in the circuit in which it is used, and might result in appreciable distortion due to this changed impedance no longer matching the impedance of the transformer or the circuit to which it is connected.

(4) *Life.*—Reliable data are available on the average life of oxide-coated tubes as used in telephone repeaters, and very extensive tests involving many thousands of this type of valve indicate that the average effective life exceeds 20 000 hours. This life figure covers failure from all causes. It would be interesting if the authors were to give corresponding figures for telephone repeater valves having thoriated tungsten filaments. The life of an oxide-coated filament culminates in a process lasting for a considerable period of time—several hundred hours in many cases. This process begins with the formation of a "bright spot" in the filament which very gradually increases in brightness until the metallic core is fused. The valve is usually in good operating condition throughout this period. The advantage of this behaviour lies in the fact that ample warning is given of the approaching failure and the valve may be replaced while not in actual service. I should like to remark on two points which arose during the discussion. Prof. Fortescue asked whether it was not possible to manufacture a power valve utilizing dull-emitter filaments. In this connection it may be stated that the Western Electric Company manufacture standard valves ranging from 0·05 watt up to 250 watts. These figures represent the safe energy which can be dissipated by the plate. Another speaker made reference to the fact that when the anode voltage for an oxide-coated filament valve was raised above that specified by the manufacturers, blue haze became apparent in the valve. This phenomenon would appear to apply to all types of valve. I should like to say that it does not seem a fair test to overload a valve to obtain increased output: the solution appears to be to obtain a valve which has been designed to cope with the power required.

Messrs. M. Thompson and **A. C. Bartlett** (*in reply*): Prof. Fortescue is probably too optimistic in thinking it possible to reduce the work function to one-tenth or even one-hundredth of its present value. The most electro-positive substance known is probably metallic cæsium, for which Langmuir has obtained the preliminary value of 1·4 equivalent volts for the work function, which compares with 4·5 for tungsten and about 3·0 for thorium.

In the event of a dull emitter being overrun the process of re-forming will generally restore the emission except where the available supply of thorium is consumed, as, for example, at the end of its long life, or where overheating of the other electrodes and of the glass has caused the liberation of electro-negative gases such as water vapour. For those valve users who require a dull emitter to withstand an anode voltage of 300 to 500, the L.S.5 type will be found suitable. The filament of this valve requires about 0·8 ampere at 4·5 to 5 volts, the total emission being 60 to 100 mA. This valve will also allow an anode dissipation of 15 watts.

In reply to Mr. Clinker, the saturation part of the characteristic curve is very nearly flat for the ordinary tungsten filament, while there seems to be no reason why a dull-emitting filament should have either larger or more numerous hollows in its surface than ordinary tungsten. The figure of 1·8 for the virtual oscillating grid voltage during the life test is of course the R.M.S. value.

In reply to Mr. Herd, our experience is that with filaments of the same dimensions the dull emitter is stronger throughout its life than an ordinary tungsten filament. This advantage is the result of the fact that, at the operating temperature of dull emitters,

crystal growth, which sometimes gives rise to the well-known "off-setting" in hot tungsten, does not take place.

Mr. Phillips is, we believe, under a misapprehension in thinking that the D.E.3 valve received more than its fair share of attention in the paper. If one type of valve is dealt with more than another it is probably the 1·8-volt L.T.1 (or D.E.R.) type. The suggestion that a filament consuming 100 to 120 mA would be better for the D.E.3 valve should perhaps be referred to the dry-battery experts. Three filaments each consuming 60 mA are already a heavy load for the present-day dry batteries, and four such filaments are almost more than they can deal with.

Mr. Edridge suggests that the stability of thorium emission might be almost independent of anode voltage provided the anode current were kept constant by a suitable grid-voltage bias. We can only state that this is contrary to our experience and that, in addition to the mere heating effect of anode power dissipation, there is an additional effect due to the electrical field. The actual value of the safe anode voltage does, of course, vary in valves of the same type, probably as a result of variations in the state of the bulb surface. It is mentioned in the paper that the grid characteristic undergoes a shift similar to that of the anode characteristic. It is therefore possible for the grid voltage of a dull emitter to have a higher positive value than in the case of the hot tungsten filament.

Mr. Marriage gives dimensions of oxide-coated filaments. Corresponding dimensions for thoriated filaments are as follows:—

D.E.3 valve	0·0007 in. diameter.
D.E.R. valve	0·0023 in. diameter.
Repeater valve	0·0035 in. diameter.

We find that under works conditions the proportion of rejected dull-emitter valves manufactured in accordance with close specifications is very small.

It should not be understood that a small amount of overrunning is injurious to thoriated filaments. All types, for example, will easily withstand for lengthy periods a filament voltage 30 per cent above the value at which the valve operates efficiently, and this should be a sufficient margin for the most careless user. One source of trouble may well consist in this, that when the over-voltage is considerably greater than that mentioned above, the filament refuses to melt, as would be the case if the oxide-coated filament were similarly overloaded, so that the user does not acquire sufficient respect for the properties of the filament.

With regard to the life of repeater valves, it is only a little more than a year since the Marconi-Osram works began to manufacture a dull-emitter type of valve. Our life tests have therefore lasted only about 8 000 hours, but, judging from the shape of the curves, we see no reason why the performance of the oxide-coated type should not be at least equalled. We might also mention that with other types of thoriated dull emitters, lives exceeding 20 000 hours have been recorded in actual operation.

In conclusion, reference should be made to two recent developments—both due to the General Electric Company of America—in the technique of dull-emitter manufacture. Visible evidence of one of these developments is afforded by the silvery appearance of the bulb in most modern dull emitters. The silvery film consists of magnesium, which assists in producing a perfect vacuum in much the same way as phosphorus assists in producing the vacuum in lamps.

The second development is outlined in E.P.184 446, which describes the introduction of carbon into a thoriated tungsten filament, as a result of which thorium emission becomes less sensitive to the action of electro-negative gases present in the valve atmosphere. The oxidation of the thorium atoms lying on the surface of the filament is counterbalanced by the reducing action of adjacent carbon.

SOME RADIO DIRECTION-FINDING OBSERVATIONS ON SHIP AND SHORE TRANSMITTING STATIONS.*

By R. L. SMITH-ROSE, Ph.D., M.Sc., Associate Member.

[From the National Physical Laboratory; communicated by permission of the Radio Research Board.]

(*Paper first received* 19*th January, and in final form* 10*th April,* 1924.)

SUMMARY.

An account is given of some experiments conducted with two direction-finding receiving stations taking observations on ship transmitters located at various positions in the North Sea between England and the Continent. Damped waves of length 450 m were employed, as given by the ordinary spark transmitting sets with which the ships were fitted. The results obtained are analysed in detail and the various errors encountered are described. The effect of the various local errors to which a direction-finder is subject is not, however, studied in any detail, the object being rather to examine conditions prevailing across the sea, as compared with those across land. By careful attention to certain details various sources of error present in the earlier experiments were eliminated, with a resultant improvement in the overall accuracy. The general conclusion drawn from the experiments is that when the path of transmission is entirely over sea and in a direction making an appreciable angle with the coast line so as to be free from coastal refraction effects, the accuracy of radio direction-finding is sufficient for many navigation purposes up to ranges approaching 100 miles. Observations taken on various land stations with spark transmitters on wave-lengths of 450 and 600 m show that for greater distances over sea the variable "night" errors encountered are of a much higher order. When the propagation of the waves is entirely over land the corresponding variations are encountered at shorter distances.

1. INTRODUCTION.

Since the early part of 1922, an organization of 10 direction-finding stations under the auspices of the Radio Research Board has been engaged in the accumulation of data on the variations of the apparent bearings of fixed transmitting stations. These stations have worked on the comparatively long waves from 2 km upwards, utilizing the transmissions from the European medium-power and high-power stations. Towards the end of 1922 it was decided to extend the investigation to shorter waves down to 450 m. For this purpose only two stations were employed, one installed at the Slough station of the Radio Research Board, and a second station at Orford which was rented from the Admiralty for the experiments.

With the commencement of operation of the Orford station it was proposed to take the opportunity of studying direction-finding conditions when the propagation was entirely over sea for varying distances. The co-operation of the authorities of the Great Eastern Railway Company made this possible by permitting the transmission of special signals by the Company's ships passing between England and the Continent. Experiments were commenced in October 1922 and continued at various periods until their conclusion in November 1923. The present paper is a descriptive summary of the results and experience obtained during this part of the main investigation and is considered particularly from this point of view of the application of direction-finding at shore stations to the navigation of ships at sea.

2. THE DIRECTION-FINDING STATIONS AND PERSONNEL.

At the Orford station a standard type of Bellini-Tosi direction-finder was used as supplied and erected for the Admiralty by Marconi's Wireless Telegraph Co. The aerial loops were of an approximately diamond shape, supported on a central mast 92 ft. high and four corner masts 32 ft. high, the horizontal span of the loops being 120 ft. On the wave-length of 450 m employed in these experiments the loops were used in the untuned condition, being connected directly to the field coils of the radiogoniometer, with the mid-point of these coils earthed. The goniometer was of the tightly-coupled type and its search coil was connected to the primary coil of an intermediate circuit and tuned with a variable air condenser. The secondary coil of this circuit was tuned with a second condenser, leads from which were taken directly to the amplifier. In the initial experiments a single stage of high-frequency amplification with tuned anode and grid circuits was employed, followed by a detector valve and two or three stages of note magnification. At a later date this was replaced by a standard type of 7-valve high-frequency amplifying detector followed by two stages of note magnification. With these arrangements wireless bearings were usually obtainable on ship and shore transmitting stations with an angle of swing at the minimum down to 1°, i.e. the angle at the minimum over which no change in signal strength can be observed. Although the sensitivity of the 9-valve receiver was such that loud signals were frequently obtained on the intermediate circuit with the aerial loops disconnected, no diminution of this angle of swing was ever obtainable by a reduction in the sensitivity.

At Slough the set was also of the Marconi-Bellini-Tosi type similar to that of Orford but of a more temporary nature, particularly in the matter of mast construction. The set was of the portable land-station type as formerly used by the British Army, with triangular aerials sup-

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

ported on a 70-ft. central mast, and a horizontal span of 200 ft. The receiving arrangements were otherwise identical with those at Orford, with the exception that the whole hut containing the apparatus and the operator was screened with a lining of wire netting of 1-inch mesh. Measurements within such a screen have shown that the strength of an incoming electromagnetic wave is reduced to about 5 per cent of its value outside the screen.* This resulted in the practical elimination of all direct pick-up of signal on the intermediate and amplifier circuits, with the 9-valve receiver working at its highest sensitivity, and a ship's type of spark transmitter operating at a distance of about 11 miles.

The two direction-finding stations were run under the personal supervision of the author, who took an active share in all the observations made. The bulk of the observations were, however, made by the author's assistants, each of whom is highly skilled in this direction, as a result of a large amount of direction-finding observation work carried out during the past two or three years.

3. Duration and Procedure of Experiments.

The first tests made on special transmissions from the boats of the Great Eastern Railway Co. were carried out during the two weeks commencing the 9th October, 1922. On a somewhat extended scale the experiments were resumed on the 12th February, 1923, and continued intermittently until the 15th November, 1923, at which date the experiments were concluded, after a total period of nearly 14 weeks' nightly observations had been worked.

The general procedure adopted during this work was briefly as follows: As each of the various ships approached one of the light vessels or light buoys on its route to or from the Continent, the wireless operator, being warned by the navigation officer, made a preliminary call to Orford. After receiving the reply from Orford, the ship's operator sent a special code signal for a period of about 1½ minutes to enable the observers at Orford and Slough to make simultaneous determination of the wireless bearings of the ship. Direct and reciprocal readings on the goniometer scale were always taken and the mean of these (with the appropriate 180° correction) was taken as the observed bearing. At the time of sending of the special signal the ship's navigation officer recorded the ship's position, as estimated by distance and compass bearing from the light vessel. The above procedure was repeated for each ship on passing each light vessel or buoy, the code signal used in the transmission being sufficient for identification purposes in the recorded readings. At the conclusion of each week of the experiments the log sheets from the ships and from the direction-finding stations were sent in independently to the National Physical Laboratory. With the unavoidable exception of the author, the direction-finding observers were purposely kept uninformed as to the positions of the ships, the operators of which also knew nothing of the conditions or results at the direction-finding stations. These precautions, together with the prohibition of any communication between the operators on ship and shore, permitted the reception of absolutely unbiased results.

In the majority of the experiments the period of working was from 2245 to 0400 G.M.T., use being made of that portion of the passage of the two outward-bound and the two inward-bound boats which fell within this period. In practically every one of these cases darkness prevailed throughout the whole test. During the summer, however, when the schedule times of the boats were altered to British summer time, the periods worked were 0100 to 0700 G.M.T., to observe the effect of sunrise and subsequent daylight.

In addition to the above special signals sent from the ships, transmissions were made at intervals during each observation period by the Great Eastern Railway Co.'s station at Parkeston Quay, the National Physical Laboratory's station at Teddington, and (for the use of the Slough direction-finding observer only) by the Orford station. This arrangement was made to enable a comparison to be effected between the direction-finding observations taken on the ship stations and those taken during the same periods on land stations over distances of the same order.

In entering the readings on the observation sheets for both ship and shore stations, the observer recorded his opinion as to the reliability of the observation as judged from the nature of the signal minima. As previously noted, bearings on signals of adequate strength could be observed with an angle of swing of 1° to 2°, and under favourable conditions this angle was not greater than 8° in observing at Slough on signals transmitted by a ship on the far side of the North Sea over a distance of nearly 200 miles. In many cases, however, this angle was necessarily much larger, due to the adverse conditions experienced, the most prominent of these being interference, flat minima and wandering minima.

The two latter were very frequent in some portions of the test and were characterized first by a signal audible all through the minimum, but the strength of which gave no detectable change over an angle sometimes amounting to 90°; and secondly by a drift of the minimum at a varying rate round the goniometer scale. Although no really hard-and-fast rule can be given to observers to determine the reliability of observations, it is in general not considered that accurate bearings can be obtained when the angle of swing is greater than about 20°.

When observing on the ship transmitters at Orford the signal minima were always steady, apart from the drift due to the actual motion of the ship, when transmitting at short ranges. Although the minima in some cases had become appreciably flattened, and the observations were accordingly marked "unreliable," the results given in Table 1 show that the corresponding error in bearing was usually quite small.

4. Discussion of the Results obtained.

During the whole period of these experiments the total number of observations taken on the ships' transmissions was 996, and an additional 3 444 observations were made on the transmissions from the land stations. A summary of all the results is given in Tables 1 to 8, and these are discussed in detail in the present section.

* R. H. Barfield: "Some Experiments on the Screening of Radio Receiving Apparatus," *Journal I.E.E.*, 1924, vol. 62, p. 257.

From the various ships' positions recorded on the respective log sheets, the true bearings of the ships at both Orford and Slough were obtained from charts, each case being worked out individually. The true bearings so obtained were compared with the observed wireless bearings, and the difference between these is termed the "error" in the following tables. It will be noted that in some cases the results are divided into the two classes "Reliable" and "Unreliable" in accordance with the notes made by the observers of the wireless bearings. This classification does not necessarily indicate that the bearings are inaccurate. In 46 cases no bearing was obtainable on the ships at Slough, on account of the absence of any detectable minimum of signal strength for the whole rotation of the goniometer search coil.

(a) *Ships' transmissions.*—Table 1 gives a summary of all the observations made (at Orford and Slough) in the form of numbers and percentages of bearings with varying errors. Considering first the observations at Orford, it will be seen that there is little difference in the percentage of the errors of the bearings marked "reliable" and "unreliable." Over 87 per cent of the bearings in each class are correct within 3°, while the maximum errors are 7·6° and 9·3° respectively for the two classes. Referring to the observations made simultaneously at Slough, however, it will be seen that while the percentage (83·8) of those in the reliable class which are correct within 3° is a little less than the corresponding figure for Orford, the majority (57 per cent) of the unreliable readings at Slough are more than 3° in error. The largest errors recorded at Slough are also much greater than those at Orford.

From these considerations it may be concluded at once that while, for the observations at Orford, the observer's opinion as to the reliability of the reading was no criterion of its probable accuracy, at Slough the observer was able, to a limited extent, to detect and condemn those readings which were more seriously in error.

A detailed consideration of the results as observed on the ships while passing the various light vessels and buoys shows that the errors are practically of the same magnitude for each position, although the actual extreme values are much greater at Slough than at Orford. The systematic error involved in taking bearings on ships in the various positions is not greater than 1° in the majority of cases and is thus comparable with the limit of accuracy of the direction-finders. In the case of the Shipwash and Sunk light vessels, however, the error amounts to 2°. It was thought at first that this might be a permanent local error of the direction-finding installation, due possibly to coastal refraction. Considerations of the directions of the above light vessels relative to Orford on the chart reproduced in Fig. 1, shows that the waves transmitted from these positions would cross the coast at only a small angle to the normal, and the possibility of any appreciable refraction is therefore remote. Furthermore, it will be seen that signals arriving from positions at the Outer Gabbard and Longsand in closely related directions to those from the Shipwash and Sunk, respectively, are subject to a

very reduced systematic error. Since the ships' positions were estimated from the light vessels, the accuracy of the true bearing depends upon the accuracy of their charted positions. It is understood from the Trinity House authorities that the possibility of these charted positions being incorrect is somewhat remote. Such inaccuracies are not unprecedented, however, for three cases were brought to notice recently as a result of radio-acoustic experiments carried out in the English Channel.* One of these light vessels, the West Hinder, was found to be $1\frac{1}{2}$ nautical miles out of its charted position. Such increase in distance, however, suggests that some at least of the errors arise from some uncertainty of the knowledge of the ships' positions from which the true bearings are obtained. In the last column of Table 2 are given the values of the error in the position which correspond to a 2° error in bearing at Orford, and from these it is seen that for the positions closer than the Galloper it is necessary that the ship's position recorded be correct within 1 mile, and that at the Shipwash light vessel an accuracy of $\frac{1}{3}$ mile is required. Now whereas under favourable conditions the estimated

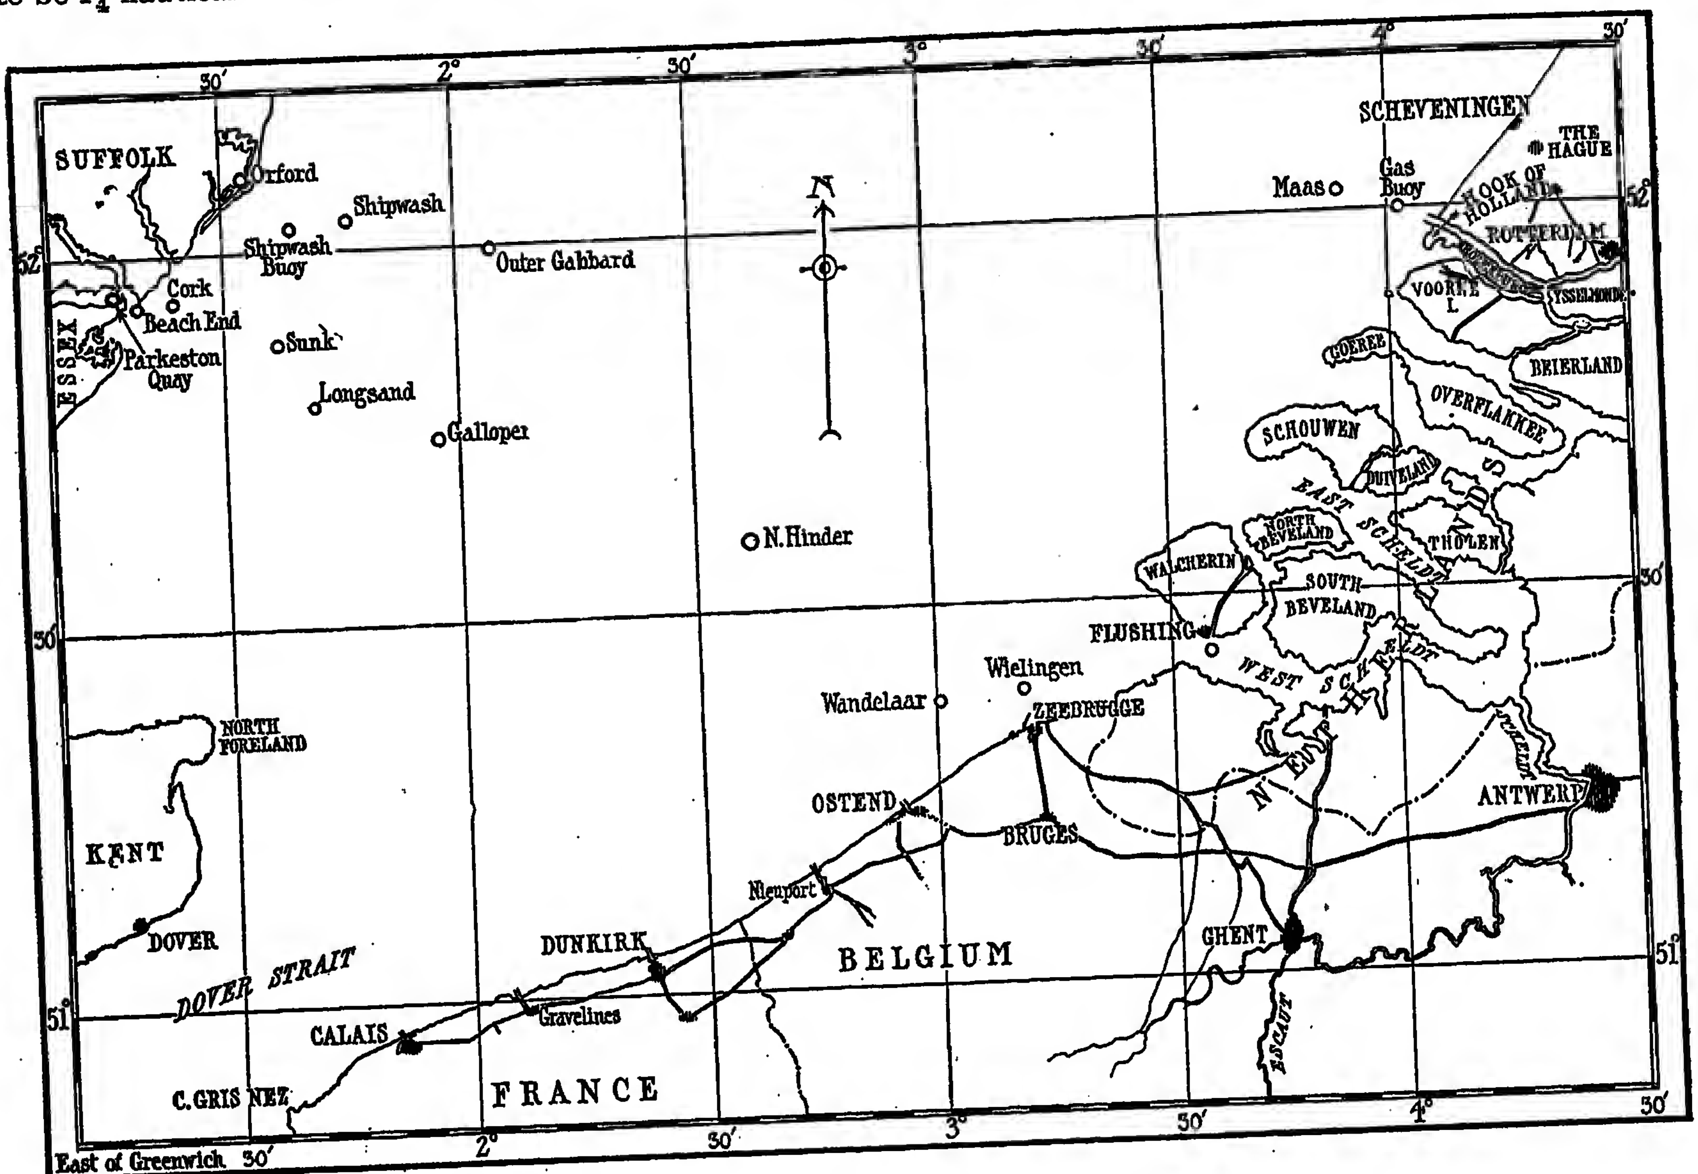

FIG. 1.

an error in the case of either Shipwash or Sunk would produce a change in bearing at Orford of several degrees.

Table 2 gives an abstract of the results in the form of the numbers and percentages of the observed bearings whose errors are not greater than 2°. These figures show generally that as the distance from the ship to Orford increases, the proportion of the results correct within 2° increases from about 45 per cent to 90 per cent.

The relation is not a strict one in view of the high percentage accuracy obtained at the Cork position, and it is also to be remembered that compensation for the systematic errors discussed above would greatly increase the percentages corresponding to the Shipwash and Sunk positions. The general increase in accuracy with position is well within such a limit of accuracy, various circumstances arose in these experiments which might considerably increase the difference between actual and recorded positions. Among these circumstances were the prevalence of bad weather, mist, etc., which made a visual estimate of distance uncertain, and some unavoidable delay between the determination of the position and the transmission of the special wireless signal; while on some occasions interference prompted the observer at Orford to request a repeat signal, from a fresh position of the ship which was not always corrected. It should also be noted that all observations were made while the ships were travelling at a speed in the neighbourhood of 20 knots, and that at a short range such as from the Shipwash the motion of the ship during the transmission of the $1\frac{1}{2}$-minute signal corresponds

to a change in bearing at Orford of about 3°. This drift in the observed bearing was very noticeable, but the mean of the direct and reciprocal readings gives the only average value which can be used. This point is one which must frequently arise in the commercial use of direction-finding at short distances, and is partially avoidable by decreasing the duration of the transmission and observing the bearings as quickly as possible, in the manner adopted in the special tests to be described later.

The general result of this analysis of the observations taken at the Orford station is therefore that under ordinary working conditions at sea, wireless bearings can be obtained on ships at distances up to about 100 miles across open sea to an accuracy such that over 80 per cent are correct within 2°, and that the frequency of occurrence of an error of more than 5° is such as to be negligible for practical working. What may be termed "incipient night effect" was evidenced at the longer ranges by flatness of minima, but no error of any magnitude due to this cause has been experienced.

The words "across the sea" must be understood to exclude the case in which the transmission is in a direction making a small angle with the coast line, resulting in coastal refraction effects. In a similar manner the effect of waves crossing cliffs, or being subject to any other disturbance at the direction-finding receiver, are excluded from the above statement of observed results.

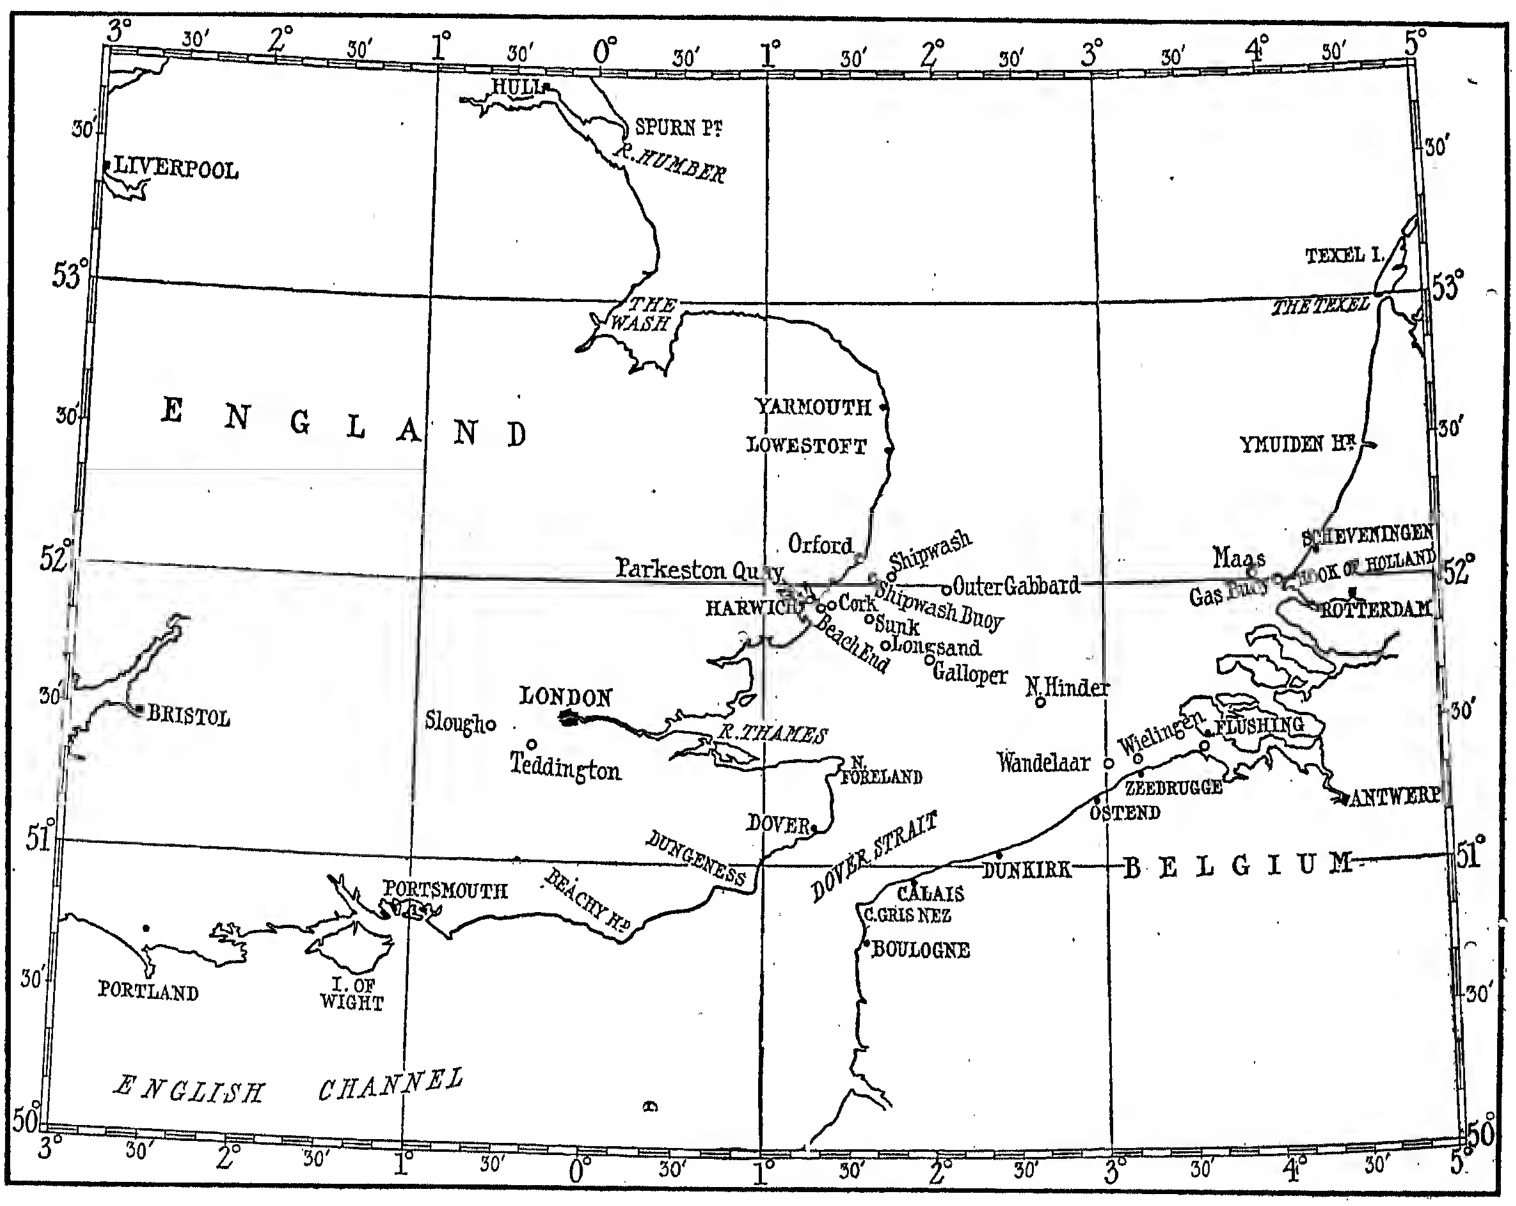

FIG. 2.

At the Slough station the night effects were very much more prominent in the way of extreme flatness of minima and large errors in observed bearings ranging up to nearly 34°. As demonstrating the accuracy which is obtainable in the absence of these night conditions, Table 3 gives a summary of all the observations taken on the ships at various times after sunrise. Nearly 77 per cent of the reliable readings were correct within 2°, these being taken at distances ranging from 89 up to 191 miles (see Fig. 2). At the Maas light vessel at a distance of 191 miles from Slough, 8 of the 9 readings obtained were within 2°, the remaining reading being − 2·2° in error.

(*b*) *Transmissions from land stations.*—In Table 4 is given a summary of the results obtained during these experiments in making direction-finding observations on the three land stations employed for the purpose. The spark transmitting set at each station was employed and the wave-length of 450 m was used throughout.

Total	69	100·0	3	100·0

As previously mentioned, the majority of the work was done at night, but the day readings tabulated are those taken in the portions of the observation periods which were more than one hour after sunrise. The results given are typical of those which may be observed at any direction-finding station when working at comparable distances and when the path of transmission is partly or wholly over land.

Where the distance is comparatively short, as in the cases of Parkeston Quay to Orford and Teddington to Slough, no difference by day or night is found in the accuracy of the observed bearings or in the sharpness of the minimum signal readings. In the absence of any interference the angle of swing at the minimum is from 1° to 2°, and the mid-position can usually be determined to about 0·2°. Under such conditions quite definite variations in the observed readings are experienced which, however, have a maximum amplitude of about 3°, corresponding to a maximum difference from the mean of about 1·7°, and Table 4 also shows that in less than 2 per cent of cases is the difference greater than 1°. In the two cases quoted there is a permanent deviation of the mean observed bearing from the true value, of over 3°. In the case of Parkeston Quay to

Orford this is possibly due to coastal refraction, since the path of transmission is in this case nearly parallel to the coast line for a considerable distance (see Fig. 1). It will be observed that the permanent error from Teddington is also about 3°, and other observations show that when receiving at Orford in the sector of approximately 220° to 240°, a correction of + 3° must be made to the observed wireless bearings.

In the case of Teddington to Slough, the cause of the error is obscure and is still under investigation. Replacement of the Bellini-Tosi installation by a portable frame-coil direction-finding set has shown that the error is not due to the apparatus, and an exploration of the neighbourhood has shown that the error varies rapidly with change in position; this indicates that the cause is a very local one.

Reverting to the results given in Table 4, it will be noted that for the greater ranges of transmission (83 to 98 miles) the observations obtained by night differ greatly in several respects from those obtained by day. In the first case, whereas practically all the readings obtained in the daytime were marked reliable, only a few being missed due to interference, a large proportion of the night readings obtained were classed as unreliable, due principally to the flatness of the minima. Secondly, the variations in observed bearings at night were very much more noticeable than in the day, the extreme magnitude of these being 65° by night as against 4·5° by day. Thirdly, in a large proportion of cases bearing observations were impossible at night, due either to the extreme flatness of the minimum signal or to the rapidity with which the apparent bearing was wandering about. For example, of the transmissions from Teddington observed at Orford, in 69·5 per cent of cases no definite indication of the bearing could be obtained during the period of the special signal (1½ minutes) whereas perfectly good bearings were being obtained on the same transmissions at Slough. At the latter station bearing observations on Orford were impossible in 34·2 per cent of cases, due to the prevailing night-effect conditions. These phenomena were experienced nearly every night and the extreme cases were quite frequently encountered in which no variation in signal strength was experienced for a complete rotation of the goniometer search coil, this signal at night often being much stronger than that observable in the daytime in the maximum position.

When it was realized that the accuracy of the results obtained in transmission from the ships was of a high order, several weeks' observations were carried out at Orford on the coast transmitting stations which, with the exception of North Foreland, are on an open sea path from the direction-finding station. The majority of these observations were made on the 600-m wave, and a summary of the results is only given in Table 5 for comparison purposes.

Although North Foreland is the nearest of the stations the path of the waves to Orford scarcely comes within the scope of the term "open sea," since it involves considerable tracts of sandbanks at the mouth of the Thames. For practical purposes the transmission is therefore over land for a portion of the distance and as a result it is seen that while a maximum error of 10·4°

occurs, over 87 per cent of the observed bearings are within the 2° limit. The nearest of the remaining four stations is over 80 miles from Orford, so that although the transmission is entirely over sea the errors in bearings observed are increasingly larger and the proportion of those less than 2° in error becomes appreciably less. As the distance becomes greater there is an increase in the frequency of the usual night effects as shown by the variations in the observed bearings and the proportion of observations missed owing to the absence of any signal minimum.

In the case of Scheveningen, at a distance of 117 miles, less than half the observed bearings are within the 5° limit of error.

The observations made on the two wave-lengths of Dunkirk, viz. 450 and 600 m, do not show any striking difference. These results obtained on fixed coast stations therefore support the conclusion that 80 to 100 miles is the maximum reliable distance for wireless direction-finding when working entirely over sea.

5. Results of Final Tests.

With the benefit of the experience gained during the experiments above described, two special tests at the Orford station were arranged in October and November 1923, in which every effort was made to reduce to the minimum all the errors which had previously been encountered or suspected. At the invitation of the Great Eastern Railway Co., the author was privileged to be on board the two ships participating in the test to supervise the transmission of the special signals and observe the conditions under which ships' positions were determined. Two tests were carried out on return journeys to the Hook of Holland and Antwerp respectively. During each of these tests, after the first communication had been established with Orford all preliminary wireless procedure was dispensed with, and as the ship passed abreast of each of the selected marks en route the special signal was transmitted for a total period of 1 minute only. By adopting this procedure it was possible to reduce to the minimum all delay and consequent error due to the motion of the ship.

On the journey to and from the Hook of Holland, the selected buoys and light vessels from which transmissions were made were passed, with one exception, within 200 yards and several of them within 100 feet. Conditions were as far as possible arranged so that the ship passed abreast of the mark at about half-way through the special signal, but accurate time records were kept to enable corrections to be made for the drift of the ship during the transmissions, the speed of the ship in this test being 18 knots in the open sea.

* Wireless bearings corrected by + 3° to compensate for direction-finding station error.
† Charted bearing corrected by + 2° to compensate for constant error experienced at these positions. ‡ L.V. = Light vessel.

The first observation was taken during the preliminary communication, while the ship was alongside Parkeston Quay, and, as in the case of observations on the land station at the Quay, a correction of + 3° is necessary to make the observed bearing agree with the true value. A similar correction was also made for the observations taken on the ship at two buoys between the Quay and the mouth of the river.

In Table 6 a correction of — 2° has also been applied to the bearings taken when the ship was passing the throughout and, although fine weather was experienced, the sky was overcast on the outward journey. An average speed of a little over 17 knots was maintained by the ship. The route in this case did not lie so close to the lighted marks, the distance of which varied up to 3 miles. This distance was, however, obtained by the "four-point bearing" method, using the ship's magnetic compass, the distance run being recorded on the ship's log. The results obtained are given in Table 7 and, as before, corrections have been applied

* Wireless bearings corrected by + 3° to compensate for direction-finding station error.
† Charted bearing corrected by + 2° to compensate for constant error experienced at these positions.
‡ L. V. = Light vessel.

Shipwash Buoy and light vessel, to compensate for the systematic error brought to notice at these positions.

The results given in Table 6 show that, assuming that the corrections made as above are justifiable, the maximum error of the wireless bearings throughout the test is 1·1°, all the remainder being correct to within 1°. It is also notable that, although in the case of the longest ranges employed the readings were marked "unreliable" on account of the flatness of the signal minima and consequent large angles of swing which were necessary to determine the bearings, the resulting errors are all less than 1°.

The test made on the journey to Antwerp was under very similar conditions. A strong wind prevailed at the direction-finding station for the sector 220°–240°, and also to the charted bearing taken on the Sunk light vessel. It would appear from the table that this correction, applied for the latter case, is scarcely sufficient, since the resulting errors are two of the five which exceed 1°. The only errors greater than 2° were obtained at the N. Hinder light ship, but as this was passed at a distance of 3 miles the estimate of the ship's position may not have been sufficiently accurate. The reading on the outward journey is notable since the direction-finding bearing was particularly sharp, the minimum being located with a swing of only 1·5° from its mid-position. In this test also, five readings were experienced as flat minima and were marked unreliable,

but the resulting errors are again small, three of the five being less than 1°.

A summary of the combined results obtained in these two tests is given in Table 8, which shows the high percentage accuracy of the wireless bearings obtained. It is to be observed that throughout these tests the usual phenomena of "wandering bearings" and "no detectable minimum" were experienced at Orford on of the order of 83 to 98 miles, the evidence supplied in Table 4 is sufficient to show that such direction-finding is practically useless for any navigational purpose at nights, when most serious errors are of very frequent occurrence. In some cases the observing operator is able to judge whether the bearing is a good one or not, but this judgment does not appear to be sufficiently reliable to be used as a working rule. The experience

TABLE 8.

Summary of Results obtained at Orford in the Two Special Tests with Ships' Transmissions, October and November, 1923.

Error in bearing	Reliable observations		Unreliable observations		All observations	
	Number	Per cent	Number	Per cent	Number	Per cent
Up to 1°	24	85·7	8	80·0	32	84·2
Up to 2°	27	95·4	9	90·0	36	94·7
Up to 3°	27	95·4	10	100·0	37	97·4
Up to 4°	28	100·0	—	—	38	100·0

the transmissions from Teddington, so that the wireless direction-finding conditions on these nights cannot be described as being in any way unusual.

6. CONCLUSIONS.

The accuracy to which wireless direction-finding can be carried out has both a practical and scientific interest. On the practical side those concerned with the application of direction-finding to marine navigation are anxious to know the most serious errors that are likely to be met with under various conditions and to know also what precautions are necessary to avoid these errors or reduce them to the minimum. On the other hand there are those who, while not being directly interested in the practical side of direction-finding, look to the results of its investigation for the shedding of light upon the more general problem of the propagation of electromagnetic waves over the earth's surface. It is thought that the results of the experiments here described will afford some tangible information of interest to both parties.

The general deductions to be drawn from this investigation may here be given as a conclusion to the present paper. With radio direction-finding apparatus of the type now obtainable for commercial use at a land station, the limiting accuracy of observed bearings which is obtainable by highly skilled operators under the most favourable conditions is of the order of 1°. To attain such an accuracy careful attention must be given to various details of the apparatus, and the installation must be calibrated somewhat elaborately for any local deviations. When operating over long periods of time the above accuracy is only maintained throughout both day and night for short ranges of the order of 10–16 miles. At greater distances up to about 200 miles the limit of error increases to about 2° and this can be maintained for daylight working only. When the transmission is entirely over land for distances of the author and other experimenters has shown that these variations and night effects are encountered at ranges down to about 30 miles over land.

When, however, the transmission is entirely over sea, so as to be well clear of any land effects, the accuracy of observed bearings is maintained within the limit of 2° for night as well as for day working at distances approaching 60 miles; and even up to 100 miles over 90 per cent of bearings are correct within 2°, the limiting error under ordinary working conditions being about 4°. Such an accuracy is probably good enough for most navigational purposes. The effect of an error of even this magnitude can be very much reduced by taking several observations at intervals of, say, 5 or 10 minutes. The above distances probably indicate the extreme ranges for accurate working for, as previously noted in the paper, many of the observed readings showed distinct signs of the approach of night errors as commonly experienced in transmission over land. Also, the results given in Table 5 for transmission from a land station entirely over sea show the errors which may be incurred at distances in excess of 80 miles.

For the successful application of direction-finding to the navigation of ships it is first necessary to obtain a good site for the direction-finding station, as free as possible from errors due to local disturbances. This latter source of error is not treated in the present paper, but it is well known that such objects as trees, overhead wires, cliffs and mountains, etc., produce serious disturbances in the neighbourhood of a direction-finding station. With satisfactory conditions prevailing at the receiver, reliability of observed bearings is secured at distances of 60 to 100 miles when the path of transmission is over sea and in a direction well away from land and coast lines.

Should the path of transmission include more than about 16 miles of land, variable errors are likely to be encountered at night in addition to the ordinary coastal

error at all times. From the results given above it will be evident that the taking of check bearings on a fixed station transmitting over land affords no indication whatever as to the reliability of bearings observed on a ship at sea at the same periods. What is usually required by the navigator of a ship at sea, however, is not a line bearing but a position fix; but, assuming the same error in wireless bearings to be obtainable by two or more direction-finding stations, the accuracy to which such a position fix can be given by simultaneous observations is a matter of mere geometry. The extension of the present investigation to cover the operation of two or more direction-finding stations *on the coast* was not considered sufficiently useful to justify the expense involved.

The result of the investigation which is of more scientific interest is that the minimum range of transmission for the occurrence of the well-known phenomena of night effects on closed loop direction-finders is about three times as great over sea as that over land. The exact ratio is possibly dependent upon the relative conductivities of the sea and land, and the resulting attenuation accompanying the propagation of the electromagnetic waves. While some of the existing theories may account for these effects in a qualitative manner, experimental evidence is lacking in other directions, and a purely theoretical discussion is considered to be outside the scope of the present paper.

This investigation was carried out for the Radio Research Board under the direction of the Committee on Directional Wireless, the members of this Committee being as follows:—Mr. F. E. Smith, C.B.E., F.R.S. (*Chairman*); Mr. F. W. Davey; Mr. C. E. Horton, B.A.; Capt. C. T. Hughes, M.C., R.E.; Dr. J. Robinson, M.B.E.; Dr. C. G. Simpson, F.R.S.; Dr. R. L. Smith-Rose; and Mr. O. F. Brown, M.A., B.Sc. (*Secretary*).

The author wishes to express his personal indebtedness to all members of the staff of the Great Eastern Railway Co. concerned in these experiments, for their interest and kindly co-operation in the work which was carried out entirely in addition to their normal duties. Grateful acknowledgment is also given of the valuable services rendered in various parts of the investigation by the following assistants:—Petty Officer R. Taylor, and Telegraphists G. A. Williams and D. Connolly, at Orford; Messrs. R. H. Barfield, M.Sc., S. R. Chapman, B.Sc., and M. G. Bennett, B.Sc., at Slough; and Messrs. E. L. Hatcher and A. C. Haxton, at Teddington.

DISCUSSION ON

"DIRECTIONS FOR THE STUDY OF VARNISH-PAPER AND VARNISH-FABRIC BOARDS AND TUBES."*

Dr. H. M. Barlow (*communicated*): I am surprised to observe that the British Electrical and Allied Industries Research Association have repeated an error which is really inherent to the method employed for measuring the internal resistance of these dielectrics. Some time ago Mr. H. L. Curtis of the Bureau of Standards put forward (*Bulletin of the Bureau of Standards*, 1914, vol. 11, p. 359) various tests for determining the properties of solid dielectrics, the internal resistance being measured by placing the sample between two mercury electrodes. The present Report of the Association has adopted practically the same procedure. In my paper on "An Investigation of the Friction between Sliding Surfaces" which immediately precedes this Report (see page 133), I believe I have established beyond doubt that the contact resistance between mercury and these so-called semi-conductors is always large compared with the true internal body resistance of the material. Once the electricity has been transferred from the electrode to the semi-conductor, it passes relatively easily through its mass, and it is the interface which mainly provides the insulating property. In view of the fact that my original thesis was in the hands of the Electrical Research Association in May 1923, it appears that the fallacy involved in the method advocated has not yet been realized, and that the actual conditions are not properly understood. The matter seems to me to be very important, both scientifically and commercially. I venture to suggest that there are few, if any, switchboard makers who realize that the insulation between the positive and negative busbars is almost entirely provided by the contacts between the fixing bolts and the slate or marble employed. To sum up, perhaps I may repeat what I said in my recent paper: "such materials as slate, red fibre, paxolin and celluloid can only be classed as dielectrics in virtue of their high contact resistance, and . . . the true body conductivity of these semi-conductors cannot be measured with mercury electrodes."

Mr. E. B. Wedmore (*in reply*): Dr. Barlow, in the report to which he refers, demonstrates that with certain materials, for instance slate and lithographic stone, the surface-resistance phenomena are so large as to screen such internal resistance as the material

* Report of the British Electrical and Allied Industries Research Association (see page 160).

may have, when any attempt is made to investigate this resistance by the usual methods. This is a valuable contribution to knowledge on the subject and opens a very wide question, but it must not be hastily assumed that this same result will be found to be characteristic of poor insulators in general, or that the methods advocated by the Bureau of Standards and by the Electrical Research Association serve no useful purpose. At the present time these methods are the best known for the examination of the resistivity of large and important classes of insulating materials. It is as yet too soon to define in what classes of material the surface phenomena are so important as to require the use of some other method. The validity of the methods advocated has been proved over and over again with large numbers of materials, some of good and some of inferior insulating properties, and the Electrical Research Association have made it their business to advocate the general use of the best known method. Dr. Barlow has indicated that he found similar phenomena in dealing with varnish-paper board, red fibre and celluloid, but hitherto he has furnished no data on the subject. Until further data are available we do not know to what extent the surface properties influence the results in dealing with these materials. The work of the Electrical Research Association has shown that on the market there are examples of these materials very defective in insulating properties, and we have, in fact, had examples of varnish-paper board which were practically conductors at ordinary temperatures. Nevertheless, it has been shown experimentally that by the methods advocated we can detect differences in quality between different samples of the various materials in question and it has yet to be shown that the Association are in error in this matter. This can be done only by showing that a material which is not suitable for its purpose may be approved for use in the industry under the methods advocated. This is not a scientific, but a practical point. Revolutions in practice may arise out of scientific discoveries, but much spade work is required to bring them about. Further research will no doubt result in the development of a method of testing the surface properties and isolating them, but no one is yet in a position to offer a test for this purpose suitable for general use. Developments on these lines may introduce some revolutionary changes, but if one takes the extreme case of slate, I cannot see that any change in practice is in prospect. The switchboard manufacturer knows from long experience that the electric strength of slate is adequate, but that the insulation resistance is low and an uncertain quantity. In the relatively few cases where high insulation resistance is required he obtains it by bushing the holes. Dr. Barlow's observations do not point to any change of practice in this connection, and if any change were indicated it is likely that the research would have to be repeated employing materials as used in the industry, i.e. not wetted prior to test. Every research undertaken by the Electrical Research Association on insulating materials has produced new evidence of the urgent necessity of making a scientific attack on the whole subject of dielectrics, as the observed phenomena of resistivity and electric strength are full of anomalies. The importance of the subject is shown by the fact that the insulation repair bill of the electrical industry is of the order of one million pounds per annum. To deal with this problem at all adequately will require much larger funds than have hitherto been available, but there is no doubt that the provision of such funds would be a very good investment by the electrical industry.

SOME FACTORS AFFECTING THE WORKING COSTS OF SMALL ELECTRIC GENERATING SETS.*

By E. G. KENNARD, Associate Member.

(*Paper first received 28th December, 1923, and in final form 24th March, 1924.*)

SUMMARY.

The paper is intended to show how the working costs per unit of electricity are influenced by various factors, viz. type of engine, nature and magnitude of load, price and calorific value of fuels.

Internal-combustion engines only have been considered, as these are practically the only types in use for small modern plants.

TABLE OF CONTENTS.

(1) INTRODUCTION.

Although many papers and technical articles dealing with the economical generation of electricity on a large scale have been published, the question of costs for small lighting and power plants has not received the amount of attention it deserves, considering the many thousands of these sets there are in use. The author has consequently endeavoured to give comparisons of costs for generating current, using various types of small internal-combustion engines under various working conditions.

Special attention has been given to the several causes which influence the thermal efficiency of internal-combustion engines, and, although this subject is proper to the field of mechanical engineering, the data given should be of use to electrical engineers in designing new plants, and also in the improvement of working costs for existing ones.

(2) SUMMARY OF TESTS ON SMALL INTERNAL-COMBUSTION ENGINES.

In Table 1 a summary is given of published tests on small internal-combustion engines adapted to work with various fuels. These have been selected from various sources, and should therefore be representative of modern practice.

The brake thermal efficiency is calculated from the total number of therms in the fuel consumed per hour at full load by the engine, and from the brake horsepower at full load, from which, calculating from Joule's mechanical equivalent of heat, the value 0·0254 therm per b.h.p.-hour is obtained.

(3) COMPARISON OF THERMAL EFFICIENCIES OF VARIOUS TYPES OF ENGINE.

In Fig. 1 the brake thermal efficiencies for the various types of engine have been plotted from the values given in Table 1. It will be observed that efficiencies vary considerably for various types and rated outputs, the lowest value being 14 per cent for a high-speed petrol engine, and the highest value 32 per cent

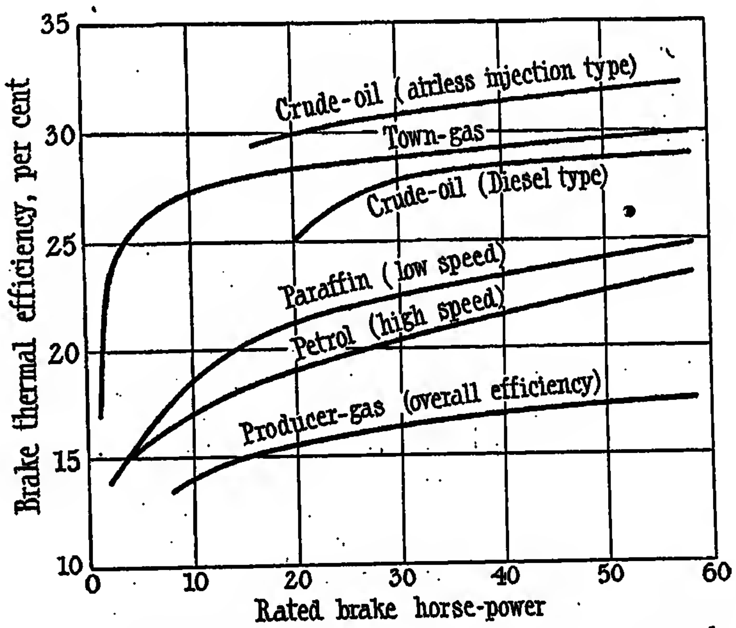

FIG. 1.—Full-load brake thermal efficiency of internal-combustion engines.

for the latest pattern of crude-oil engine (airless injection type). These differ from the Diesel pattern in the respect that pure air only is compressed up to ignition temperature, and the oil charge is not introduced until the exact moment for the explosion. It will be noticed that these engines are not obtainable in ratings of less than 15 b.h.p. The town-gas engine comes next in order of efficiency, a good curve being obtained which drops rapidly below 5 b.h.p. The Diesel type of crude-oil engine takes the next place, and is seen to compare favourably with the town-gas engine. Here again these are not manufactured in small sizes much below 20 b.h.p. The next curve in order of efficiency is for

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

the ordinary oil engine which burns paraffin or kerosene as fuel. These engines are made in two general patterns :—

(*a*) Using an external vaporizer.
(*b*) Vaporization obtained by spraying into a heated chamber extension of the cylinder.

Fig. 1 shows the efficiency curves for class (*b*), which are of higher efficiency than class (*a*), these being of the same order as for petrol engines. The next curve gives the efficiency for high-speed petrol engines. It may be noted that at low rated horse-powers this curve gives approximately the same values as are obtained for the paraffin engine, but the increase in efficiency is not so marked when larger outputs are reached. The last curve is for engines driven by producer gas. In general, the actual thermal efficiencies are only slightly lower than those of the gas engine, but the values shown in the figure include the producer losses.

Some causes of variation in thermal efficiency.—The main factors affecting engine efficiency are :—

Calorific value of explosive mixture.
Degree of compression employed.
Temperature of explosive charge.
Temperature of cooling water.
Mechanical efficiency of engine.
Degree of combustion.
Dimensions of engine cylinder.

Some properties of the various fuels used for the engines considered have been obtained, and are given in Table 2.

It is evident that in no sense is the thermal efficiency of an engine proportional to the calorific value of the fuel used.

Item 5.—The values for the gaseous fuels were obtained from a table given in Clerk's book, "The Gas, Petrol and Oil Engine" (vol. 1), and the values for the hydrocarbon fuels were calculated.

Item 6.—It will be noted that although there is such a wide variation in the calorific value per cubic foot of gaseous vapours, there is relatively little difference between various explosive mixtures of gas and air, and

it will be seen that a fuel having a high calorific value requires a large amount of air, and vice versa, so that too much importance need not be attached to calorific values of fuel in connection with thermal efficiency. It is found in practice that the proportion of fuel and air in the mixture required to obtain maximum power does not coincide with the correct mixture for maximum thermal efficiency. The figures given below for gas engines are due to Prof. Hopkinson. His tests on a 32 h.p. engine using town gas show :—

	Weak mixture	Strong mixture
Calorific value (B.Th.U. per cub. ft.)	48	63
Indicated h.p.	39·3	45
Indicated thermal efficiency ..	37 %	33 %

With weaker mixtures than that shown above it was found difficult to fire the charge regularly.

tent igniting at the lower temperatures. It is necessary to allow a large margin of safety, partly because pre-ignition is also caused by particles of hot carbon inside the cylinder.

Correct temperature for the cooling water.—If the cylinder is kept too cool the exploded gases lose heat too rapidly, causing a reduction in the mean effective pressure. If kept too hot the volumetric efficiency is affected, resulting in a reduced charge of mixture, but the pumping losses are also lower. The effect of cooling-water temperature on the pumping loss has been measured by Prof. Hopkinson on a 40 h.p. gas engine at 180 r.p.m., and he found that with normal lubrication the mechanical loss was reduced from 6 h.p. to 4¾ h.p. by increasing the temperature of the jacket water from 70° F. to 180° F. This point has also been investigated by Mr. Morse in the form of tests on a 14 h.p. 4-cylinder Daimler motor.* The higher relative heat consumption

TABLE 2.

Properties of Fuels.

	Town gas	Coke producer gas	Crude oil	Petrol vapour	Paraffin vapour
Calorific value (net), B.Th.U. per lb. ..	—	—	18 000	18 500	19 500
Present price per lb.	—	0·214d.	0·485d.	3·0d.	1·64d.
Price per therm	7·0d.*	2·14d.	2·7d.	16·3d.	8·5d.
Calorific value, B.Th.U. per cub. ft. of gas .	500	130	—	4 650	6 450
Cub. ft. of air per cub. ft. of gas to effect combustion	5·0	1·1	—	49	63
Resultant calorific value of mixture (theoretical), B.Th.U.	83	62	—	93	102
Compression ratios commonly employed ..	5½/1	6½/1	14/1	4½/1	4/1
Approximate explosion temperature of mixture	850° F.	910° F.	910° F.	900° F.	900° F.

* Price in London at power rate.

Prof. Watson also arrives at the same conclusion for petrol engines † :—

	Weak mixture	Strong mixture
Ratio of air to petrol	17/1	12/1
Calorific value	83	116
Indicated h.p.	16·2	19·9
Indicated thermal efficiency ..	27·5 %	22·2 %

It will be noticed that the calorific value of the mixture is much higher for the petrol engine. This explains why less power is obtained when a petrol engine is worked from town gas.

Item 7.—Compression values usually employed. Generally speaking, thermal efficiencies are increased with higher compression. The limit for working compression values depend partly on the temperature at which pre-ignition is liable to take place.

Item 8.—This shows the probable ignition temperatures for the various fuels, those with a large hydrogen con-

† *Proceedings of the Institution of Automobile Engineers*, 1908–9, vol. 3, p. 387.

at no load in his tests shown below is due to greater mechanical losses.

	Full load	Half load	Light load
Speed, r.p.m.	720	720	720
Brake horse-power ..	14·5	7·4	0·6
Friction, horse-power ..	0·74	0·74	0·74
Pumping loss, horse-power	0·36	0·58	1·45
Indicated horse-power ..	15·6	8·72	2·79

This increase in pumping loss at light load, was shown to be due partly to throttling and partly to the lower temperature of cooling water, the contraction of the cylinder causing higher friction loss.

These tests confirm the general opinion amongst gas engine experts that it is more efficient to keep the cylinders at about 150° F. for small engines.

* *Proceedings of the Institution of Automobile Engineers*, 1908–9, vol. 3, p. 274.

We may sum up the various causes which affect engine efficiency as follows :—

(*a*) It is found that within certain limits the thermal efficiency decreases with an increase in the calorific value of the mixture (probably due to imperfect combustion), and indicated power increases with the calorific value of the mixture.

(*b*) Up to a certain point higher compression gives higher efficiency, but the gain due to higher compression is sometimes nullified by increased heat loss due to the greater ratio of surface to volume in the compression chamber. The best degree of compression depends also on the fuel employed.

(*c*) An increase in temperature reduces the weight of the entering charge, affecting the thermal efficiency. In some types of engines (such as paraffin or petrol) initial heat is, however, required to vaporize the fuel.

(*d*) An increase in cylinder dimensions gives a higher thermal efficiency; a high-speed engine with two or more cylinders is, therefore, less efficient than an engine of similar power having one cylinder (see Callendar's formula given below).

(*e*) Raising the cooling-water temperature tends to increase the efficiency, as shown by the test previously referred to.

(*f*) Mechanical efficiencies also vary considerably in various types of engines.

Thus the variation in thermal efficiency for the engines shown in Fig. 1 is accounted for. In addition, with petrol or paraffin engines a very careful adjustment of mixture is required to effect complete combustion, otherwise unburnt gases find their way into the exhaust. Tests on 12 motor-car engines, carried out by the Royal Automobile Club in 1907, showed 2 per cent and upwards of carbon monoxide (an explosive gas) present in the exhaust gases.

(4) Full-load Running Costs of Generating Sets.

It will be noticed from Table 1 that there are very few test-figures of engines below 5 h.p. In order to fix some values for thermal efficiency of low-power engines the portion of the curve for town-gas engines below 5 h.p. has been calculated from Prof. Callendar's formula :

$$\text{Thermal efficiency} = 0\cdot75\,E\,(1 - 1/D)$$

where E = "air standard" efficiency at desired compression,
D = cylinder diameter, in inches.

Makers of generating sets have found it advisable to allow a certain margin of excess engine power over dynamo output; for example, one finds a 4 kW dynamo coupled to an 8 h.p. engine. Assuming the dynamo to be of 82 per cent efficiency this gives a loss of 950 watts at full load. Allowing 5 per cent for belt or transmission loss this gives a further loss of 250 watts, making a total power of 5 200 watts, or an equivalent of 7 h.p., thus leaving a margin of 1 h.p. On this basis the running costs in pence per unit have been worked out, for different types of engines and sets, at the prices of fuel shown in Table 2, and the results are plotted in Fig. 2. It will be observed that producer-gas sets and crude-oil engines are not obtainable in the smaller output, nor are paraffin engines of the non-vaporizer type below 2 h.p. Five per cent has been added to the fuel costs to allow for lubricating oil and water, except for producer-gas sets where 10 per cent has been added, as a considerable amount of water is used for the scrubbers and is run to waste. No allowance has been made for wages for running the plant. Small plants do not require very much attention during normal running periods, and are often attended to by the owners. The costs of maintenance repairs is included later under capital charges. It will be seen that town-gas sets are much more economical for outputs up to 4 kW than are either petrol or paraffin sets, the running costs for petrol and town-gas sets being in the ratio of 3 : 1, with town gas at 7d. per therm.

The difference between producer-gas and crude oil for larger sets is not very marked, but the

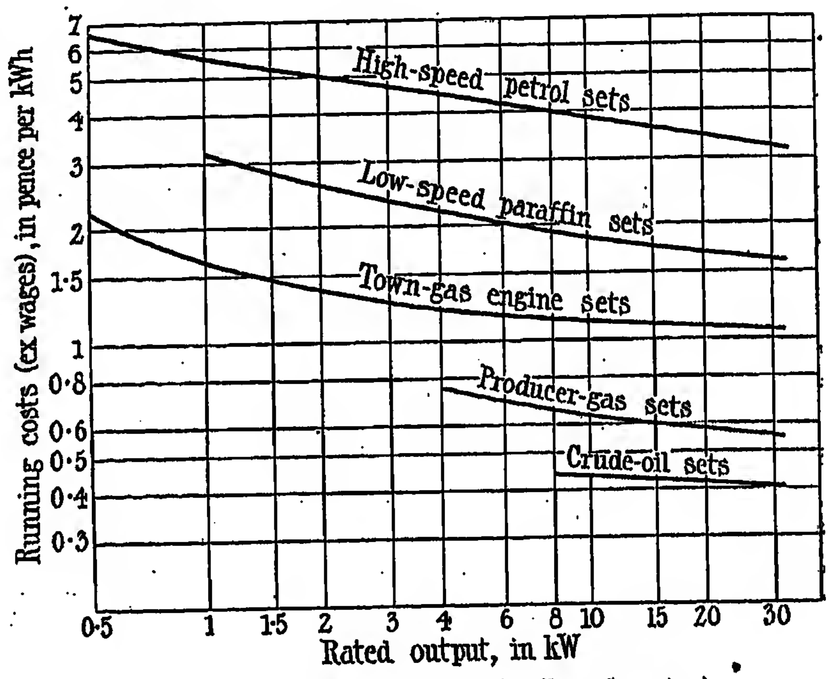

Fig. 2.—Running costs (fuel, oil and water).

ratio of costs as between petrol and crude-oil sets is approximately 10 : 1; the petrol set labours under two great disadvantages, namely, low thermal efficiency and high price of fuel.

When it is realized that all these internal-combustion engines are, broadly speaking, of the same type, the difference in the running costs is remarkable.

(5) Effect of Load Factor on Working Costs.

The above figures are not, however, a reliable guide to the choice of a generating set unless they are taken in conjunction with considerations of load factor and capital outlay. Some representative costs for engines, dynamos and necessary switchgear have been obtained for the various types of sets. It may be stated that wide variations in price are found on comparing several makers' lists; the prices selected, however, represent plant of the best quality. Owing to lack of space the author has not included the various items, but, as a convenient basis for subsequent working, the total charges for each type of set have been reduced to pence per unit at 10 per cent load factor. Ten per

cent per annum on the total outlay has been allotted to cover capital and maintenance charges, and the load factor is based on the rated output of the set working continuously throughout the year.

For plants working on lighting load only, the load factor ranges from 7 per cent to 12·5 per cent according to the requirements of the consumer. Taking 10 per cent as an average figure, the following standing charges in pence per unit generated are obtained :—

Rated output = ½ kW		2 kW	8 kW	32 kW
	per unit	per unit	per unit	per unit
Petrol plant ..	3·15d.	1·35d.	0·75d.	0·50d.
Paraffin plant ..	—	1·65d.	1·0d.	0·66d.
Town-gas plant	3·5d.	1·57d.	0·93d.	0·63d.
Producer plant .	—	—	1·78d.	0·85d.
Crude-oil plant .	—	—	1·3d.	0·8d.

These figures indicate the importance of taking capital charges into account, especially in the case of small sets working at low load factor.

Only in exceptional circumstances are lighting plants required to furnish current to light all the lamps continuously connected to the circuit, and in the majority of cases the load varies considerably. If a storage battery be used, the load may be equalized during lighting hours by charging the battery in parallel with the lamps. The effect on the total working cost of using a storage battery has been investigated, but there are many variable factors to be considered and it is not possible to include the material in the present paper. The results point to the conclusion that if current is required only during the normal period of lighting each evening, the addition of a storage battery to the plant will not enable working costs to be reduced very much, as the increased capital charges for the battery and the considerable losses which occur in charging tend to offset the gain due to working the engine at its most efficient load. If, therefore, sets are used for lighting without storage batteries, before the working costs can be estimated it is necessary to know not only the load factor but also the average load on the set. If the normal lighting period throughout the year be taken to extend from dusk until 11 p.m. each evening, the total number of lighting hours per year will be approximately 1 620. Calculating on a basis of 10 per cent load factor for lighting sets the average load is

$$\frac{\text{kW} \times 8\,670 \text{ hours}}{10 \times 1\,620} = \text{approx. } 0{\cdot}5 \text{ or half load}$$

To get an accurate idea of the normal running cost for a lighting plant, it is necessary to know how the fuel consumption varies with the load.

Fuel consumption of engines at various loads.—Some figures from various published tests are shown in Table 1. If the fuel consumption at different loads be plotted, it is interesting to note that in most cases the points will lie in practically a straight line between one-quarter load and full load, but at no load there is a tendency for the curve to bend upwards. The no-load consumption is considerable, and if it is expressed as a percentage of the full-load heat consumption it ranges from 33 per cent for a 1 h.p. engine down to 22 per cent for a 60 h.p. engine. Taking proportional values for these no-load figures at intermediate engine sizes, and given the full-load brake thermal efficiency of an engine, an approximate value can be determined for the heat consumption at intermediate loads by plotting no-load and full-load values and joining the two points by a straight line.

In the case of electric generating sets the engine is never actually working on no load, as it has to provide for the constant losses of a fully-excited dynamo, and also the belt or transmission losses. This may cause the no-load consumption to be considerable, especially in the smaller sizes where the dynamo efficiency is comparatively low. Having made allowance for these extra losses some figures are given below for the number of therms consumed per hour by the engine at the loads indicated, using town gas as fuel.

kW output	No load	Half load	Full load
½	0·055	0·095	0·135
1	0·090	0·150	0·210
2	0·14	0·250	0·370
4	0·24	0·450	0·670
8	0·40	0·850	1·26
16	0·70	1·60	2·40
32	1·3	3·0	4·50

A study of these figures enables the following comparisons to be made :—

(1) The heat consumed at no load varies from 40 per cent of the full-load value in the ½ kW size, to 29 per cent in the 32 kW size.

(2) The heat consumption of any set at no load is approximately equal to the half-load consumption of a smaller set of one-half the rated output.

(3) The same amount of gas required to operate a set at full load will give approximately half the amount of electrical energy if a set of twice the rated output is used.

To get economical results, therefore, it is important not to have a larger set than is necessary and also to avoid running on very light loads for long periods.

Fig. 3 shows the (total capital running) costs at 10 per cent load factor for various types of sets. These values are based on the running costs for each type operating at one-half the rated load, and therefore represent with fair accuracy the average price of current per unit. The addition of a storage battery would not influence these costs to any great extent, because the extra capital costs and battery losses would be balanced by the improved economy due to the higher average load on the generating set.

Some interesting conclusions may be drawn from these results. In a country district where town gas is not available, a small lighting set of ½ kW capacity

supplies current at a total cost of 1s. per unit. Lower costs are obtained for petrol, with a 1 kW set at 10d. per unit, or 7d. per unit using a low-speed paraffin engine. Using engines driven by town gas, ½ kW to 1 kW output costs from 6d. to 4½d. per unit, a figure which compares favourably with the charges made by electric supply authorities.

The costs for sets worked by producer gas, at the

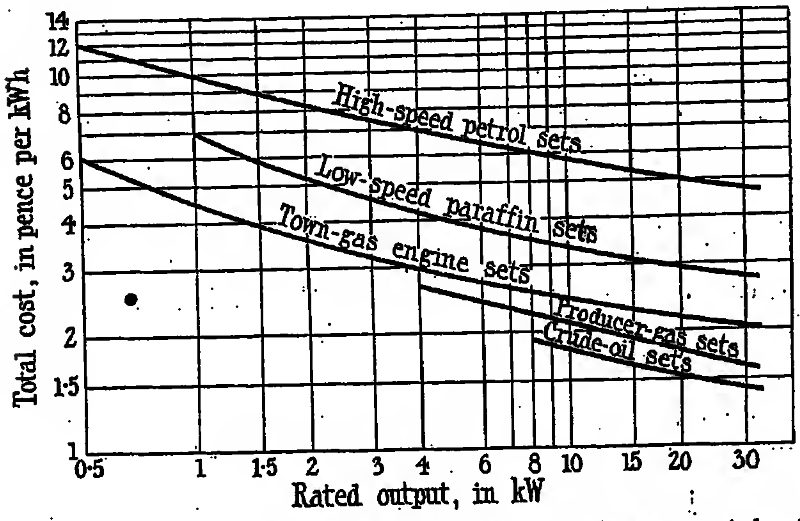

FIG. 3.—Total costs per kWh, based on 10 per cent load factor and an average load of one-half the rated output.

present price of coke and anthracite, show that very little is saved by using it instead of town gas, although in some cases it is profitable where wood sawdust or chips can be employed. Where the load is sufficiently great to require a plant of 8 kW and above, crude-oil sets can be used with advantage, the total costs per

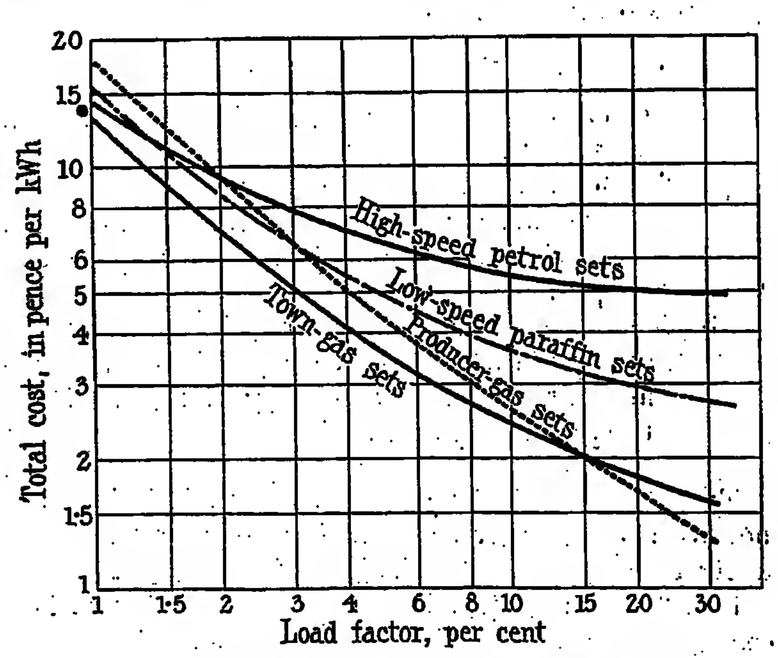

FIG. 4.—Total costs per kWh, using sets of 4 kW rated capacity at different load factors.

unit being less than 1·8d. All small generating sets used for lighting only have the same disadvantage of low load factor, resulting in a somewhat high capital charge per unit.

To show the influence of load factors on total working costs some curves have been plotted in Fig. 4 for sets of 4 kW rated output running on full load. It will be noticed that producer-gas sets are only more economical than town-gas sets (at 7d. per therm) above a load factor of 15 per cent, also that below 2 per cent load factor they are less economical than petrol sets. Lighting loads in this country for sets constantly in use would rarely have a load factor of less than 5 per cent, and below that value would indicate work of an intermittent character, such as is performed by portable sets, and here the petrol set is seen to its best advantage.

(6) THE INFLUENCE OF A DOMESTIC HEATING AND COOKING LOAD.

If the plant be utilized for cooking and domestic apparatus an improvement in load factor is possible, and in this connection reference may be made to some experiments of the Glasgow Corporation described *

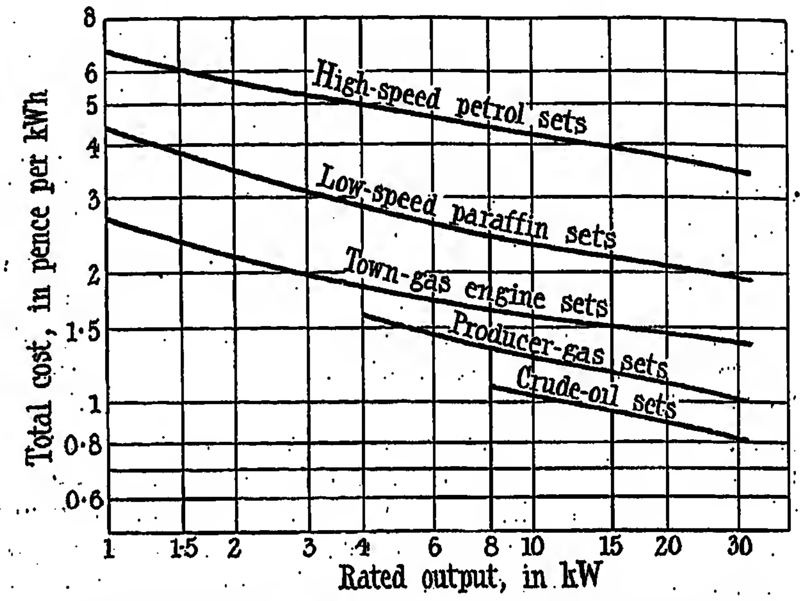

FIG. 5.—Total costs per kWh for plants used for lighting, heating and cooking, at a load factor of 20 per cent.

by Councillor Denny. Two small houses were fitted up as "all electric" houses, no coal, gas or form of heating other than electricity being used. The apparatus installed in each house consisted of:—

One 3 kW oven.
One ½ kW kettle.
One 1 kW immersion heater.
One 3 kW radiator.
One 1½ kW radiator.
One 1 kW radiator.
One ½ kW smoothing iron.

Total 10½ kW.

Allowing for ½ kW of lighting, this makes a total of 11 kW connected, or a probable maximum load of 6 kW. The actual number of units consumed per annum was 10 520 (average of two houses), and the load factor is therefore approximately 20 per cent. If these houses were individually supplied from a small plant instead of from the mains, it would be a simple matter to arrange for the plant to operate mostly at full load without the use of a large storage battery, as variations in load could be equalized by the thermal storage of hot water.

Fig. 5 shows costs for various types of generating

* *Electrical Review*, 1920, vol. 86, p. 675.

sets at 20 per cent load factor and working on full load. It will be seen that for a 6 kW plant the costs per unit are :—

	d.
Petrol engine	4·5
Paraffin engine	2·6
Town-gas engine..	1·70
Producer-gas engine	1·45

As the current for the Glasgow experiment was obtained at the low price of approximately 0·78d. per unit, it will be seen from the curves in Fig. 5 that only in the producer-gas or crude-oil sets of 20–30 kW would an "all electric" house supply be economical where the working cost per unit is between 0·8d. and 0·9d. If it is proposed to use a plant to furnish current for all domestic needs the number of units generated by the 6 kW plant would be allocated approximately as follows :—

	Units
Heating	8 000
Cooking	2 000
Lighting	500
Total	10 500 units

(7) The Utilization of Waste Heat from the Engine.

At the prices of current shown above for a 6 kW set it would not be economical to generate electricity for heating purposes, but a better plan than this would be to use as much as possible of the heat rejected by the engine. A study of tests made by some of the authorities referred to in Table 2, indicate that for a 12 h.p. engine the heat balance-sheet is approximately as follows :—

	Percentage of total heat supplied
Brake horse-power	28
Heat taken up by cooling water	28
Heat taken away by exhaust gases	32
Loss in engine bearings and pumping friction	5
Radiation loss from engine	7
Total heat	100

The heat from two of the sources of loss shown above is recoverable for domestic purposes, namely the hot water from the cooling jacket, and the heated exhaust gases, the latter of which will readily transfer the bulk of their heat to water in some form of calorimeter.

If the engine be located close to the house, then with suitably lagged pipes a quantity of hot water will be available for heating, washing and cleaning purposes, a small rotary pump being added if necessary to assist the circulation. As the 12 h.p. engine at approximately full load consumes 1·1 therms per hour, the total recoverable heat would be 0·66 therm. Allowing for one-third of this to be lost, 0·44 therm is available for heating purposes, as against 0·3 therm delivered as brake horse-power, or, after deducting dynamo and driving losses, the useful electrical energy is 0·22 therm. Thus for every kilowatt-hour of current generated, 2 kWh of heat which otherwise would be lost would be recoverable in the form of hot water. It would thus be possible to put down a plant to supply lighting, power, electrical heat for cooking and hot water for heating and domestic purposes, at quite a reasonable cost.

Out of a total of 10 500 units per annum, 2 500 are absorbed by the lamps and cooking apparatus, thus releasing the equivalent of 5 000 in hot water. Out of the remaining 3 000 units to make the required total of 8 000, it would only be necessary to generate 1 000 electrically. This would be conveniently used by electric radiators for "topping up" purposes. Calculating the working costs on this basis for a set designed to supply lighting, cooking and heating for the 10 500 units-per-annum house, the electrical load would be reduced from 6 kW to 2 kW. It would be necessary to include a storage battery for the lighting load, and it would be advisable to install one of sufficient capacity to carry the greater part of such load.

The approximate total costs for a set of 2 kW capacity using town gas at 7d. per therm and generating 3 500 units per annum, will be 2·2d. per unit. The equivalent cost per unit allowing for the use of engine waste heat will be (2·2d./3) + 15 per cent for extra battery costs = 0·8d. per unit, corresponding to the charge per unit made at Glasgow. Even when it is not desired to install a plant of sufficient size for purposes other than lighting, arrangements could be made to furnish a certain amount of hot water according to the output of the set.

In conclusion, the author desires to draw attention to the fact that the figures for working costs are based on prices of fuels obtaining at the time the paper was written, and these are subject to some variation from time to time, especially in the case of oil fuels. It is probable, however, that the general conclusions will not be very much affected unless some very large changes in price take place.

THE ATKINSON-TYPE REPULSION MACHINE AS A MOTOR AND GENERATOR.*

By F. J. Teago, M.Sc., Member.

(*Paper first received* 27*th November*, 1923, *and in final form*, 24*th January*, 1924.)

Summary.

The following notes are the result of experiments made by research students, under the direction of the author, on a 25-period single-phase Atkinson-type repulsion motor in the Laboratories of Applied Electricity, Liverpool University. The work involved in preparing Part I was carried out by O. J. Crompton, C. G. Ramsay and E. W. Young. That entailed in the preparation of Part II was performed by T. W. Dann.

In the first place a vector diagram for the motor, in line with the standard diagram for a single-phase series commutator motor, has been developed. It is then shown how, by means of brush shifting, the motor may be made to operate as a generator.

It is obvious that regeneration by means of brush shifting has limitations in its practical application. To obviate these limitations regeneration with a fixed brush-position and a reversed field coil was investigated. This was found to be a function of the speed and could not be varied independently. Finally, by injecting an E.M.F. into the armature short-circuit, with fixed brush-position and reversed field, it has been found possible to control the amount of power regenerated at any given speed.

Synopsis of Contents.

Introduction.

In the treatment of the graphical representation of the action of the simple repulsion motor, it is usual to split the single magnetic field of the motor into two components, as follows:—

(*a*) One component at right angles in space to the line along which the armature is split by the brushes. This component provides the magnetic field with which the armature current reacts to produce rotation.

(*b*) One component coincident in space with the line along which the armature is split by the brushes. This component induces the current in the armature which reacts with the magnetic field as previously mentioned.

The Atkinson type of repulsion motor is provided with two stator windings, and the brush gear can be so set that these two windings produce the two hypothetical components of a single-field motor. Under these conditions the brushes are said to be in the neutral position.

In the following notes the vector diagram of such a motor is evolved from experimental data, and, since the two hypothetical components of the single field actually exist in this case, the behaviour of the motor is capable of being expressed in terms of these two components and the results can be checked by actual measurements.

It must be clearly borne in mind that, in these notes, it is assumed that the two components of the magnetic field are permanently in space quadrature and that forces tending to distort this condition are negligibly small.

Notation.

The stator winding producing the flux in which the armature rotates is termed the field winding, whilst that which induces the torque-producing current in the armature is termed the transformer winding.

In the armature, the coils short-circuited by reason of the fact that the brushes bridge two neighbouring commutator segments are referred to as the auxiliary short-circuit, whilst the coils short-circuited by connecting the positive brush terminal to the negative terminal are termed the main short-circuit.

The following symbols are used throughout:—

V_S = total supply voltage.
V_F = supply voltage on field coil at speed.
V_C = supply voltage on transformer coil at speed.
$V_{F'}$ = supply voltage on field coil at standstill.
$V_{C'}$ = supply voltage on transformer coil at standstill.
Φ_F = flux due to field coil at speed.
Φ_C = flux due to transformer coil at speed.
$\Phi_{F'}$ = flux due to field coil at standstill.
$\Phi_{C'}$ = flux due to transformer coil at standstill.
V_T = main transformer E.M.F. in armature due to transformer flux, and is in quadrature with $\Phi_{C'}$.
V_R = main rotational E.M.F. in armature due to field flux, and is in time phase with Φ_F.
V_A = main resultant E.M.F. in armature.
V_t = auxiliary transformer E.M.F. in armature due to field flux, and is in quadrature with $\Phi_{F'}$.
V_r = auxiliary rotational E.M.F. in armature due to transformer flux, and is in time phase opposition to Φ_C.
e = auxiliary commutation E.M.F. in armature.
v = resultant of V_r and e.
I_s = supply current to field and transformer coils.
I_A = current in main armature short-circuit.
I_a = current in auxiliary armature short-circuit.

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

Part I.

(By O. J. Crompton, C. G. Ramsay and E. W. Young.)

The Atkinson-type Repulsion Motor.

In the Atkinson-type repulsion motor, assume that the field flux and rotational directions are as shown

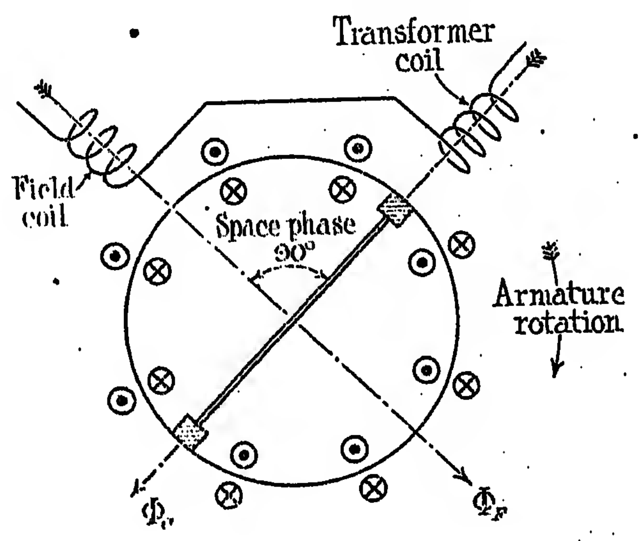

Fig. 1.

in Fig. 1. Then the induced armature current must be as shown by the outer conductors, and to produce this current the direction of the transformer flux must be as shown. The back E.M.F. generated by the rotation of the armature in the field flux is shown by the inner conductors.

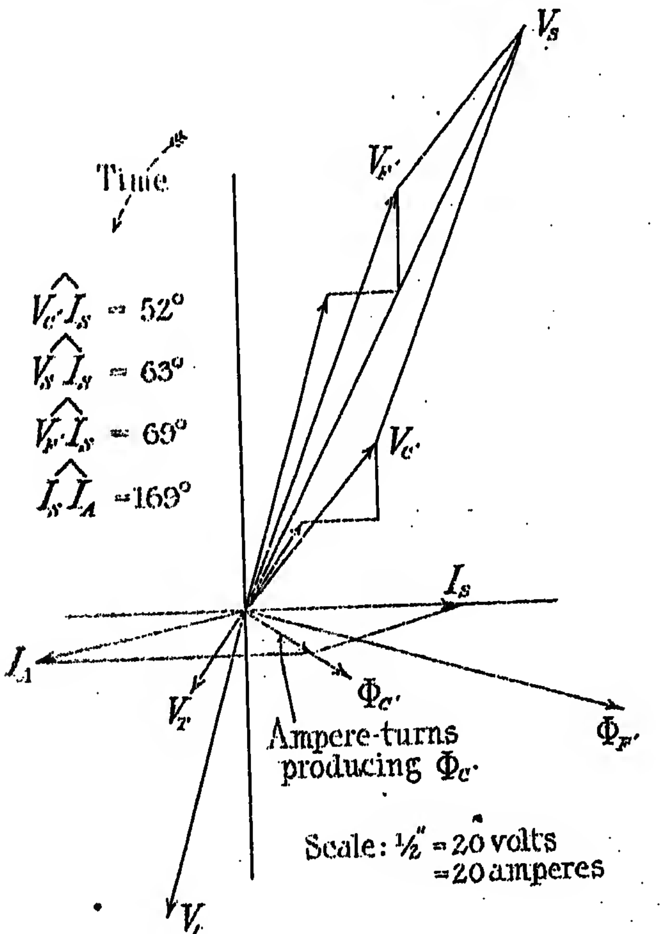

Fig. 2.—Vector diagram for motor at standstill.

Fig. 2 shows the vector diagram for the motor at standstill. The voltages V_S, $V_{F'}$ and $V_{C'}$ are meter readings, as are also the currents I_s and I_A, and these vectors are drawn to scale. The vector I_s has been chosen as a reference and drawn in a horizontal position, and the angles between this vector and the others are as indicated and were measured on an oscillograph of the falling-plate type.*

Fig. 3 shows the vector diagram for the motor at a speed of 450 r.p.m. V_S, V_F, V_C, I_s and I_A are meter readings and are drawn to scale. Their angles with respect to I_s were measured on the oscillograph.

Comparing Figs. 2 and 3 it is noticed that the time phases of the fluxes with respect to I_s change considerably as the speed changes. This point is dealt with later.

It is also seen that, although the angle between $V_{F'}$ and $V_{C'}$ remains unaltered and relatively small, the angle between V_F and V_C is considerable and is a function of the speed.

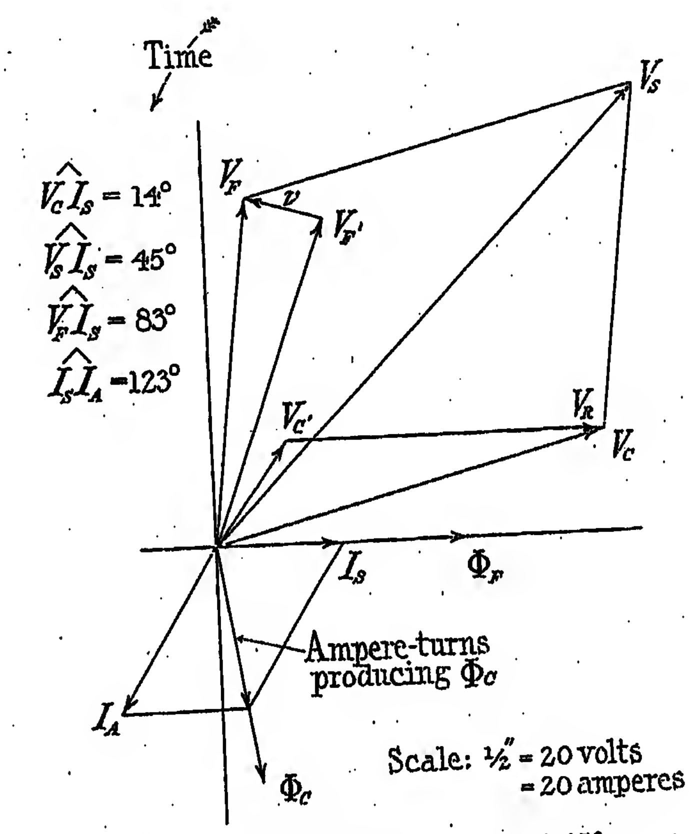

Fig. 3.—Vector diagram for motor at 450 r.p.m.

The voltage $V_{C'}$ at standstill.—As shown in Fig. 2, $V_{C'}$ is the vector sum of the component to balance V_T which is in quadrature with $\Phi_{C'}$, the component in phase with I_s to balance the resistance drop in the transformer coil, and the component in quadrature with the I_s to balance the leakage-inductance drop in the transformer coil.

Under these conditions, $V_{C'}$ cannot be very large, because V_T is small. This is so because V_T is produced by $\Phi_{C'}$ which is due to the resultant $I_s I_A$ ampere-turns. As can be seen from Fig. 2, these resultant ampere-turns are small, and therefore $\Phi_{C'}$ is small. The voltage $V_{C'}$ will, of course, be proportional to the magnitudes of the standstill values of I_s and I_A.

* The angle between I_s and $V_{F'}$, also that between I_s and $V_{C'}$, is practically independent of the value of I_s when the motor is at standstill in this case, but this may not be quite true in cases where there is saturation in the leakage flux paths, and the magnitudes of these angles must depend upon the design features of the motor under consideration. For convenience, although not strictly true, $\Phi_{C'}$ is shown in time phase with the ampere-turns producing it, and since $V_{F'}$ leads relatively to $V_{C'}$ therefore Φ_F is in advance of $\Phi_{C'}$, but no attempt has been made accurately to determine the angle between these two fluxes.

The voltage V_C at speed.—The transformer coil voltage at any speed is assumed to be made up of :—

(*a*) The voltage required to offset the E.M.F. V_R generated in the armature at that speed by the field flux due to the current I_s.*

(*b*) The standstill value of $V_{C'}$ corresponding to the current I_s.

To determine the component (*a*), the field coil only is excited with a current equal to I_s, the main short-circuit being open and the armature driven at the required speed. If the transformer coil were excited, then a transformer E.M.F. would be induced in the armature.

Experimentally it is found that the above method is correct (see Fig. 3), and, since Φ_F must be parallel to V_R, this method also provides a means of ascertaining the time-phase-angle between I_s and Φ_F at any speed.

That V_R is a component part of V_C can be easily seen when it is remembered that Fig. 1 shows that V_R is a back E.M.F. and would reduce the E.M.F. induced by the transformer flux unless V_C had a component to offset V_R.

The voltage $V_{F'}$ at standstill.—Owing to the relatively small number of ampere-turns in the auxiliary short-

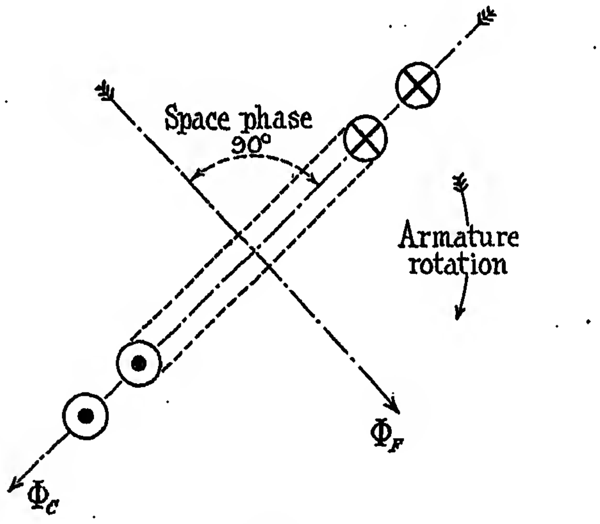

FIG. 4.

circuit compared with the ampere-turns due to the current I_s in the field coil, the flux $\Phi_{F'}$ is more nearly in time phase with I_s than is the flux $\Phi_{C'}$ (see Fig. 2). Also, as can be seen, the resultant ampere-turns producing $\Phi_{F'}$ are larger than those producing $\Phi_{C'}$. This tends to make V_t larger than V_T. $V_{F'}$ is made up of the component to balance V_t, together with the components to balance the resistance and leakage-inductance drops in the field coil, in the same manner as has been described in connection with $V_{C'}$.

Owing to the fact that $\Phi_{F'}$ is larger than $\Phi_{C'}$ and is more nearly in time phase with I_s, the voltage $V_{F'}$ is larger than $V_{C'}$ and is in advance of it, as shown in Fig. 2. These conclusions are confirmed by the experimental data obtained.

The voltage V_F at speed.—Fig. 4 shows the space position of the auxiliary short-circuit relative to the space positions of Φ_F and Φ_C. As in the case of any ordinary drum-wound armature, the auxiliary short-circuit is in space quadrature with the field flux, as shown.

The transformer E.M.F. induced by the field flux $\Phi_{F'}$ is shown by the outer conductors, and the current flowing would tend to rotate the armature backwards by reason of its interaction with the transformer flux Φ_C.

Actually, however, the auxiliary short-circuit is driven in the direction shown, since the torque due to the main short-circuit predominates. Thus the rotational E.M.F. due to the transformer flux Φ_C is as shown by the inner conductors. In Fig. 4, then, V_t and V_r act in the same direction, whereas in Fig. 1 V_T and V_R act in opposition, and this leads to the conclusion that, since in Fig. 3 V_R is in time phase with Φ_F, then V_r in Fig. 5 must be in time phase opposition to Φ_C, where

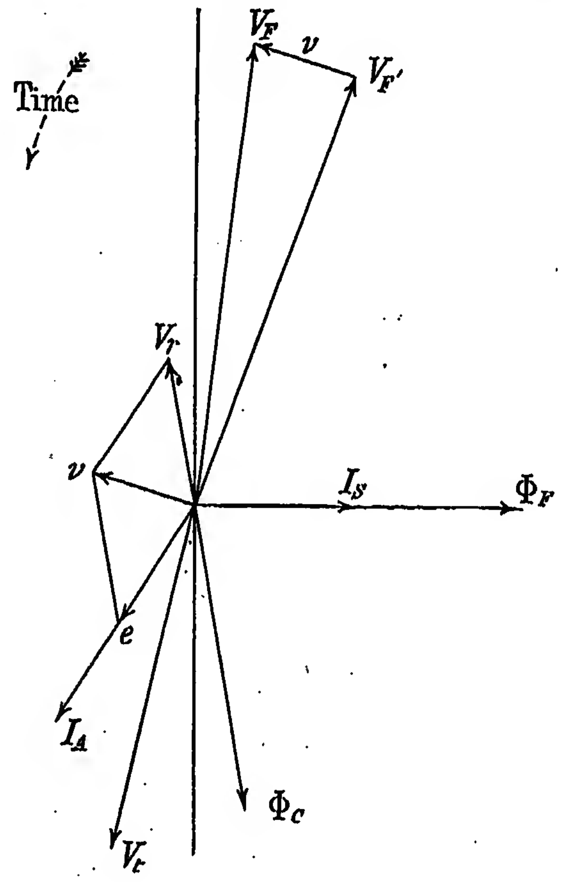

FIG. 5.

it is shown together with the commutation E.M.F. which is proportional to the current I_A.

Fig. 5 also shows v as the resultant of V_r and e, and that, in a manner similar to the case of the transformer coil voltage, the speed voltage on the field coil is made up of :—

(*a*) the voltage required to offset v, and

(*b*) the standstill value of $V_{F'}$ corresponding to the current I_s.

THE GENERAL CHARACTERISTICS OF THE REPULSION MOTOR.

The characteristics of the repulsion motor are much the same as those of the series motor; that is, the supply current and torque are maxima at the lowest speed. The armature current, however, does not vary with the supply current as it does in the series motor, but remains sensibly constant at all speeds (see Figs. 2

* I_s is assumed to be the supply current to the motor when operating against some particular torque at the particular speed under consideration.

and 3) unless the brushes are displaced from the neutral position. This can be explained as follows :—

Fig. 6 shows the experimentally determined magnitudes and time phases of I_s and I_A at 450 r.p.m. Fig. 6 also shows that the armature current I_A can be split up into two components which are practically in quadrature with each other.

One of the components $(-I_s)$ can be assumed to be induced in the armature by the transformer flux $\Phi_{C'}$ and to be equal to, except for the magnetizing current, the supply current I_s. This component, then, behaves precisely like the armature current of a plain series motor, and the torque is produced by the interaction of the current, $-I_s$, and the field flux Φ_{F}. The component I_R may be assumed to be produced by V_R, the E.M.F. due to the armature speed in the flux Φ_F. This current I_R is in quadrature with V_R except for a power component equal to its copper loss in the armature; it does not, therefore, appear in the supply current and, under these conditions, V_R is a pure back E.M.F., exactly as it is in the plain series motor and it increases in magnitude as the speed of the motor increases.

Thus as the speed of the motor increases, the $-I_s$ component of I_A decreases as it does in the case of the

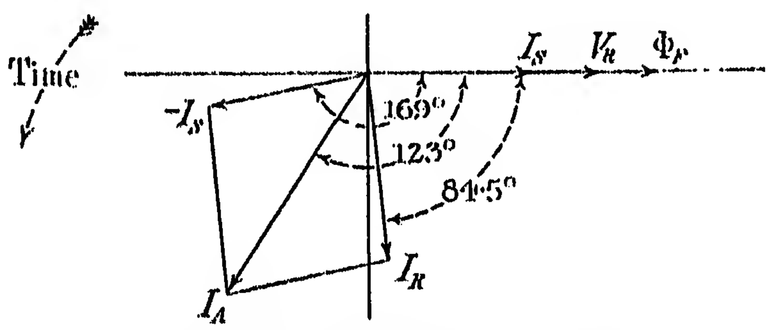

FIG. 6.—Experimentally determined magnitudes of I_s and I_A at 450 r.p.m.

plain series motor, whilst the I_R component increases because V_R increases, so that the resultant armature current I_A tends to remain of constant magnitude and move more into time phase with I_s.

If, however, it is preferred to regard I_A as the torque-producing current, then although this current is sensibly constant at all speeds, it must be remembered that the higher the speed the more nearly time quadrature exists between I_A and Φ_F. This, in conjunction with the decrease in Φ_F with increasing speed, explains why the motor has a series characteristic, and also why the motor fails to race, as the series motor does on no load.* Since the behaviour of the repulsion motor is very much like that of the series motor, it is desirable that its vector diagram should be drawn in line with the standard diagram for the series motor, and this has been done.

One great advantage of these diagrams (Figs. 2, 3 and 5) is that the time phase differences between I_s and $V_{C'}$ and $V_{F'}$ remain sensibly constant for all values of I_s, and this means that the standstill positions of $\Phi_{C'}$ and $\Phi_{F'}$ are fixed for all values of the supply current. Thus it becomes an easy matter to build up $V_{C'}$, the magnitude of which is given by the standstill value of the voltage on the transformer coil when taking a current equal to the particular current taken by the motor when operating at the speed for which the diagram is to be drawn. If the magnitude and time phase of V_C, the speed value of the transformer coil voltage, corresponding to this current is also determined, then the rotational E.M.F. V_R becomes a determinate quantity and, since the speed position of Φ_F must be parallel to V_R, it becomes an easy matter to find the amount of time phase-movement in the field flux which that particular speed has caused.

The construction for the field portion of the vector diagram is carried out in a similar manner.

The power factor of the repulsion motor increases as the speed increases, and this can be readily seen from Figs. 2, 3 and 5 when it is remembered that an increase of speed causes the voltage on the transformer coil to increase and approach I_s, whilst the field coil voltage is affected only slightly. Thus V_s approaches I_s as the speed increases, and it improves the power factor.

Part II.

(By T. W. DANN.)

THE EFFECT OF BRUSH MOVEMENT WHEN THE MOTOR SPEED IS UNRESTRICTED.

In the vector diagrams developed in Part I the brushes are assumed to be in the neutral position. If, with a repulsion motor of the Atkinson type, the brushes are rocked from the neutral, then the speed changes as shown in Fig. 7.

As might be expected from Part I, an increase in speed is accompanied by an increase in the power factor of the motor, whilst a decrease in speed lowers the power factor.

THE EFFECT OF BRUSH MOVEMENT ON THE VECTOR DIAGRAM WHEN THE MOTOR SPEED IS ARTIFICIALLY MAINTAINED CONSTANT.

The effect of brush movement upon the vector diagram for a constant speed of 450 r.p.m. can be seen by referring to Fig. 8.

Here it is noticed that a backward brush movement of two commutator segments increases the power factor from 0·707 to 0·934, whilst an equal forward movement decreases the power factor to 0·358.

Taking V_S as the fixed reference vector, these three diagrams show that I_s changes greatly both in time phase and in magnitude, that although I_A changes in magnitude its time phase-change is only slight,* and that the other vectors change very little either in time phase or magnitude.

With regard to the voltages V_F and V_C it might be pointed out that at standstill, for the same amount of brush rocking, they vary considerably, so that it is the speed which has the effect of maintaining them approximately constant.

It has been shown in Part I that variations in V_F

* Although the repulsion motor is said to have a series characteristic it must not be forgotten that the speed at no load is limited and that the speed of a plain series motor is unlimited, so that the repulsion motor cannot have a pure series characteristic.

* The power factor of the main short-circuit is practically independent of the brush position.

and V_C are accompanied by corresponding variations in the fluxes Φ_F and Φ_C, so that in the case under consideration it might be assumed that these fluxes remain of constant magnitude and time phase with respect to V_S, and if the fluxes are constant then the ampere-turns producing them are also constant. With respect to the transformer-coil voltage V_C, a statement such as follows is generally true :—

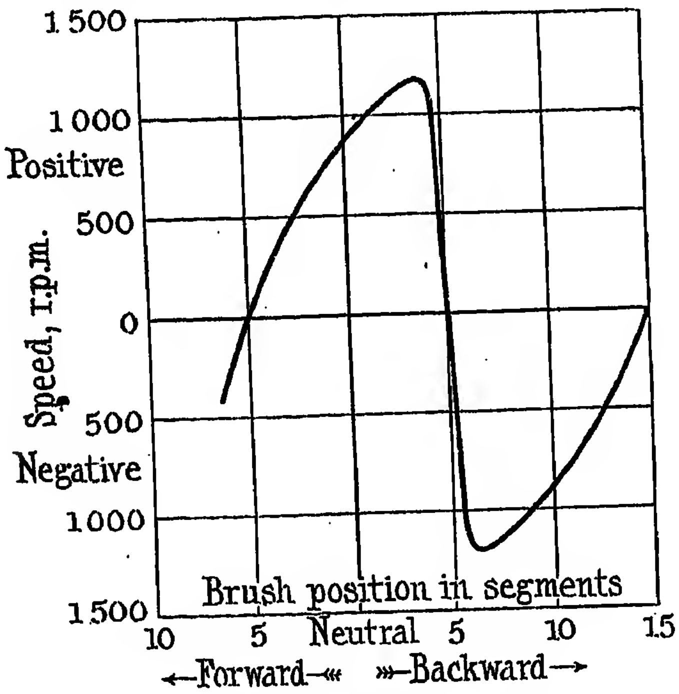

FIG. 7.

If the brushes are moved from the neutral position and the speed is artificially maintained constant, then the changes in I_s and I_A are such that their resultant is constant in time phase and magnitude.

Fig. 8, on the assumption that the variation in the magnitude of the angle between V_S and I_A is negligible, shows the general truth of the statement. In a similar manner it can be shown that the ampere-turns producing Φ_F remain approximately constant.

The power factor of the motor cannot be improved indefinitely by brush rocking, nor can it be decreased below a certain value, because the magnitude and time phase of the resultant of I_s and I_A are definitely fixed, and this fixes the limiting positions of I_s.

The variation in the magnitudes of the currents may be explained, in general, as follows :—

As the brushes are rocked backward the speed of the motor tends to rise and the increased resisting torque, necessary to maintain the speed normal, demands an increased supply current. Similarly, when the brushes are rocked forward a decreased supply current is taken.

REGENERATING BY BRUSH SHIFTING AT CONSTANT SPEED.

Fig. 8 shows that as the brushes are rocked forward the supply current diminishes, and its time lag is increased relatively to the supply voltage.

In the neighbourhood of five segments (45 electrical degrees) forward, this time lag becomes 90 degrees and the motor stops. If the brushes are moved further forward, then, owing to the reversal of the current in the armature, the motor reverses.

If, however, the speed of the motor is maintained artificially constant, and in the original direction, then as the brushes are moved forward the current passes through a minimum value, but continues steadily to increase its time lag relatively to V_s, getting gradually into phase opposition.

As soon as the current lags behind the voltage by more than 90 degrees the power in the circuit reverses and the machine begins to act as a generator.

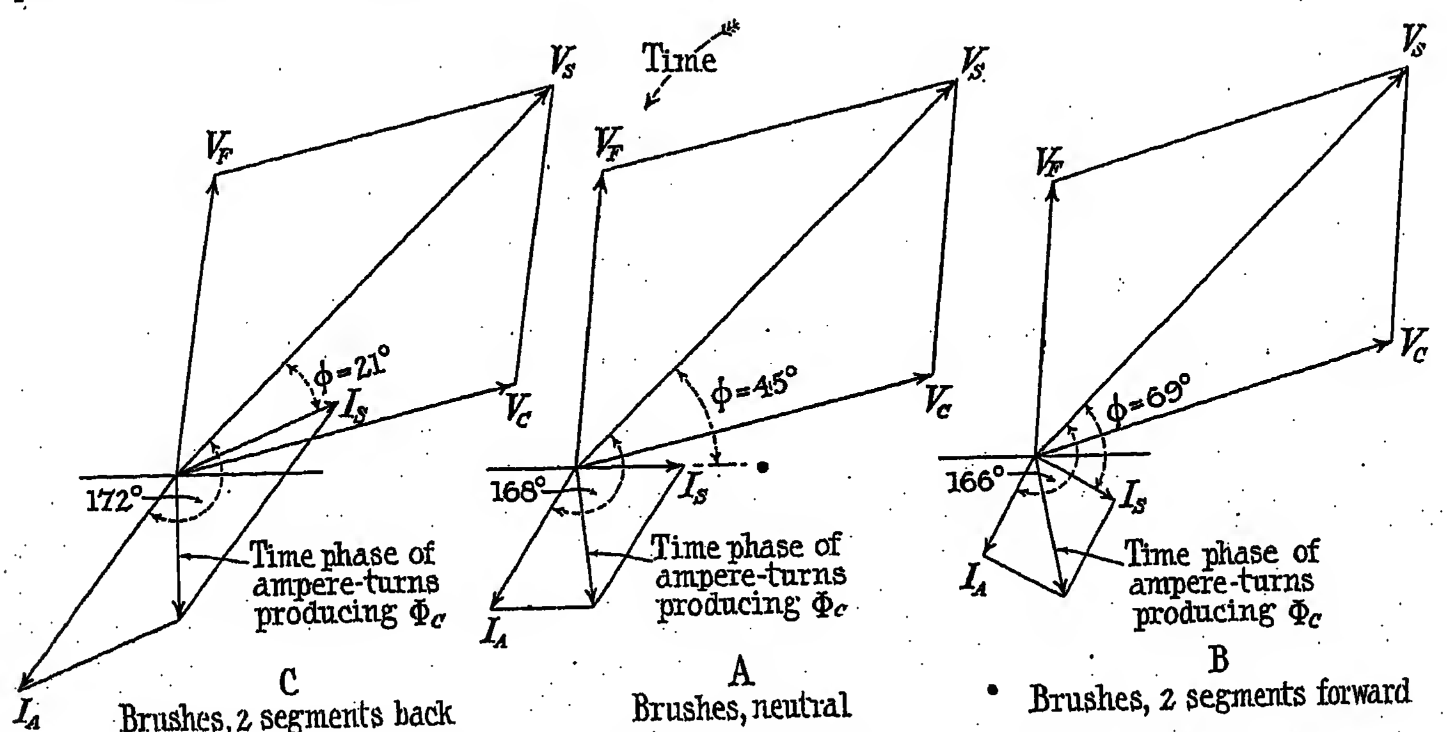

FIG. 8.—Effect of brush movement upon the vector diagram for a constant speed of 450 r.p.m.

Fig. 9 shows how, for a constant speed of 710 r.p.m., the current, power factor and power vary as the brushes are rocked forward, and Fig. 10 is typical of the vector diagram for the machine when operating as a generator under these conditions.

In a manner similar to that described in the case of the motor, the resultant ampere-turns producing Φ_C have to remain constant in time phase and magnitude, so that there is a limit to the power factor of regeneration, and regeneration at a leading power factor would only be possible where the inherent motor operation is at a leading power factor.

Regeneration is also possible when the brushes are rocked backward, but before the generating zone is reached in this direction very heavy current values, between three and four times the full-load current of the motor, are passed through.

In direct contrast to this, when the brushes are rocked forward a minimum value of the current is passed through and a rapidly rising power factor is obtained, so that regeneration from this side is gradual and progressive.

The rapid rise of the power factor over this part of the curve is very marked, and on taking a small overload

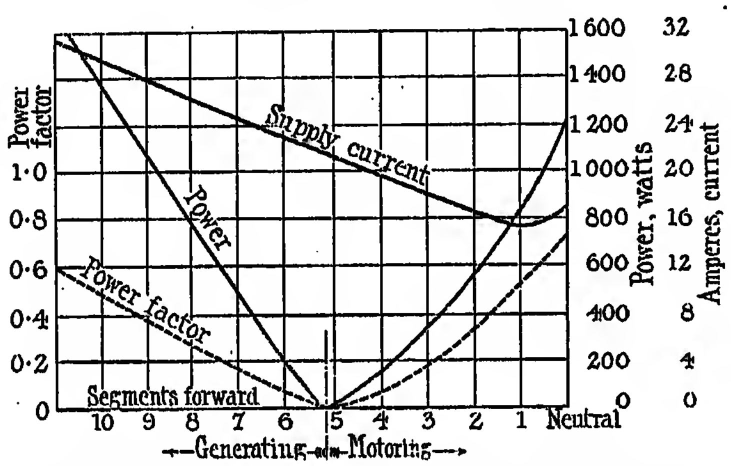

Fig. 9.—Variation of current, power factor and power with change in position of brushes at a constant speed of 710 r.p.m.

current it is possible to regenerate the full output of the machine.

Fig. 9 shows that at 710 r.p.m. with the brushes 7·5 segments forward the machine generates 50 per cent of its output as a motor, yet at 9·5 segments forward with approximately 14 per cent more current it regenerates the full motor output.

It is therefore possible to obtain regenerated power at any speed by merely regulating the position of the brushes on the commutator.

Regeneration with Fixed Brushes and a Reversed Field Coil.

To avoid moving the brushes in order to cause the machine to act as a generator, it was decided to reverse the field-coil connections, since a reversed field coil corresponds to a brush movement of 90 electrical degrees.

When the field coil is reversed the machine normally reverses its direction of rotation. If, however, the rotation is kept in the original direction by means of an auxiliary motor, then there is a fairly low critical speed, above which the machine acts as a generator (c.f. induction generator) having a power factor which increases as the speed increases.

The vector diagram for the machine acting as a generator under these conditions at 450 r.p.m. is shown by Fig. 10, and the critical speed is the speed at which the time phase-angle between V_S and I_s becomes 90 degrees.

At 225 r.p.m. the angle ϕ (Fig. 10) has a cosine of 0·074, which rises to 0·41 at 450 r.p.m.

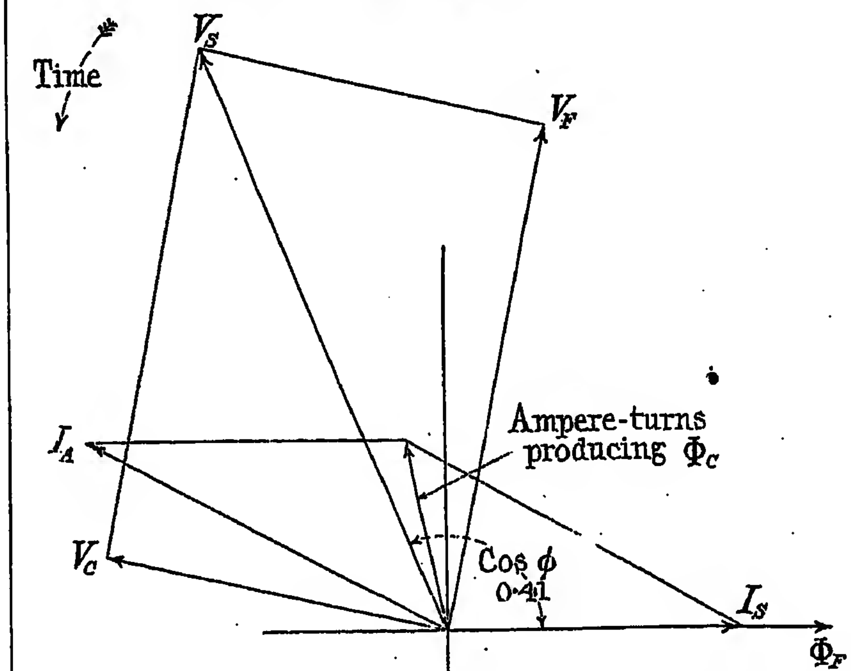

Fig. 10.—Vector diagram for machine acting as generator at 450 r.p.m.

In connection with Fig. 10, it should be remembered:

That the reversal of the field coil causes a reversal of the rotational E.M.F. V_R.

That a motor E.M.F. is less than its applied P.D., whereas a generator E.M.F. is greater than its terminal voltage.

That in the section on brush movement it has been

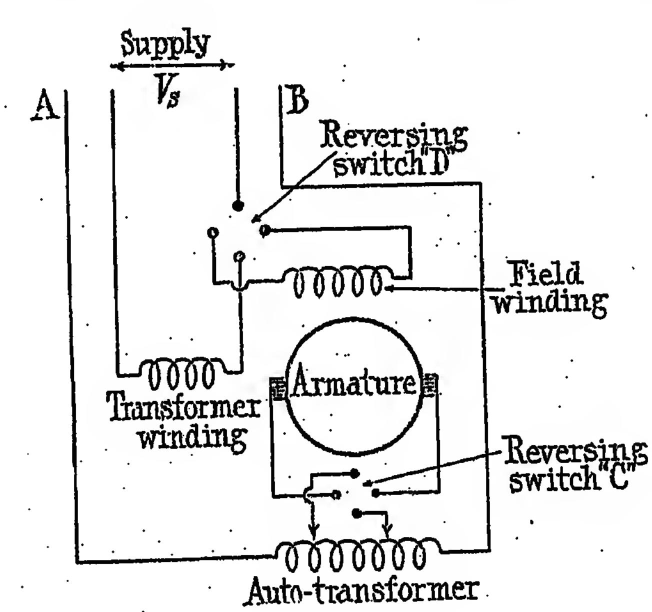

Fig. 11.

assumed that the machine changes from a motor to a generator when the supply current lags behind the supply voltage by more than 90 degrees. Fig. 10, therefore, represents generator conditions, because I_s lags behind V_S by more than 90 degrees.

That the field and transformer-coil voltages bear the same relative time phase-relationship to their fluxes as they do in Fig. 3.

It should be noticed that, at a speed of 450 r.p.m., Φ_C in Fig. 10 is in advance of Φ_F, whereas in Fig. 3 it lags behind Φ_F, and that this change is due to the time phase-change of I_A which is caused by the reversal of V_R.

The standstill conditions for Fig. 10 are the same as for Fig. 2.

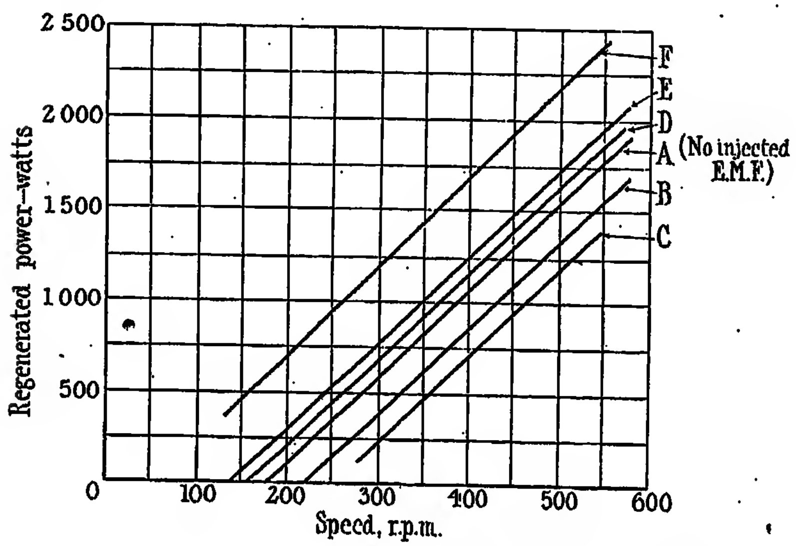

FIG. 12.—Variation in regenerated power with speed.

Regeneration with the field coil reversed is a very simple and convenient matter, but the amount of power regenerated at any one speed is a fixed quantity.

REGENERATION WITH THE INJECTION OF AN E.M.F. INTO THE MAIN SHORT-CIRCUIT.

When the repulsion motor with its field reversed is acting as a generator there is no control over the amount of power which may be regenerated at any particular speed.

With the object of modifying these limiting conditions, the motor was connected up as in Fig. 11. The lines A and B were connected across a supply and an E.M.F., the phase of which might be varied, was injected into the armature circuit.

By suitably varying the magnitude and time phase of the E.M.F. injected into the armature it is possible to obtain, at any speed, varying amounts of regenerated power.

The amount of power injected into the armature circuit is very small and the machine will regenerate 150 per cent of its full motor output when the power in the auxiliary circuit is 12 per cent of that in the main circuit. Fig. 12 shows the variation in regenerated power with speed for various auto-transformer tappings and for the different types of injection mentioned in the subjoined notes.

The particulars of the curves shown in Fig. 12 are as follows:—

Curve	Injected E.M.F. as percentage of V_S	Time phase-relationship between injected E.M.F. and V_S	Power factor of regenerated power at 450 r.p.m.
A	Zero	—	0·410
B	5 %	Phase opposition	0·336
C	10 %	Phase opposition	0·303
D	5 %	Quadrature lagging	0·520
E	10 %	Quadrature lagging	0·553
F	30 %	Quadrature lagging	0·627

In conclusion, the author wishes to thank Professor E. W. Marchant, D.Sc., for the many helpful suggestions put forward during the preparation of this paper.

INSTITUTION NOTES.

Council for the Year 1924–1925.

The scrutineers appointed at the Annual General Meeting on the 8th May, 1924, in connection with the ballot to fill the vacancies which will occur in the Council on the 30th September next, have reported to the President that 506 ballot papers were returned, of which 33 were spoiled, and that the result of the ballot is as follows :—

President : Mr. W. B. Woodhouse.

Vice-Presidents : Mr. S. Evershed and Mr. A. Page.

Hon. Treasurer : Mr. P. D. Tuckett.

Ordinary Members of Council : (Members) Mr. W. E. Highfield, Mr. Herbert Jones, Mr. B. Longbottom and Mr. E. H. Shaughnessy, O.B.E. ; (Associate) The Viscount Falmouth.

The ballot on this occasion was purely formal, no nominations other than those made by the Council having been received.

The Council for the year 1924–1925 will therefore be constituted as follows :—

President.

W. B. Woodhouse.

Past-Presidents.

A. Siemens.	Sir John Snell.
Col. R. E. Crompton, C.B.	C. P. Sparks, C.B.E.
Sir Henry Mance.	C. H. Wordingham, C.B.E.
J. Swinburne, F.R.S.	R. T. Smith.
Sir R. T. Glazebrook, K.C.B., D.Sc., F.R.S.	Ll. B. Atkinson.
	J. S. Highfield.
W. M. Mordey.	F. Gill, O.B.E.
S. Z. de Ferranti, D.Sc.	A. Russell, D.Sc., F.R.S.

Vice-Presidents.

Sir James Devonshire, K.B.E.	A. Page.
S. Evershed.	A. A. C. Swinton, F.R.S.

Honorary Treasurer.

P. D. Tuckett.

Ordinary Members of Council.

J. W. Beauchamp.	B. Longbottom.
R. A. Chattock.	S. W. Melsom.
F. W. Crawter.	G. W. Partridge.
Captain J. M. Donaldson, M.C.	Col. T. F. Purves, O.B.E.
	W. R. Rawlings.
D. N. Dunlop.	P. Rosling.
K. Edgcumbe.	E. H. Shaughnessy, O.B.E.
The Viscount Falmouth.	
A. F. Harmer.	Prof. W. M. Thornton, O.B.E., D.Sc.
W. E. Highfield.	
Herbert Jones.	

and

The Chairman and immediate Past-Chairman of each Local Centre.

I.E.E. Regulations for the Electrical Equipment of Buildings.

The Eighth Edition of the "I.E.E. Regulations for the Electrical Equipment of Buildings," formerly the "I.E.E. Wiring Rules," referred to in the Report of the Council for the year 1923–1924 (see page 530) has been approved by the Council and copies may be purchased at the offices of the Institution or from the publishers, Messrs. E. and F. N. Spon, Ltd., 57, Haymarket, London, S.W. 1. at the following prices: bound in cloth, 1s. 6d. net (or 1s. 8d. post free); bound in paper covers, 1s. net (or 1s. 2d. post free).

In the Report of the Council for the year 1920–1921 (*Journal I.E.E.*, 1921, vol. 59, page 348) it was stated that the Council proposed to arrange for the draft Rules to be discussed at meetings in London and at the Local Centres before they were finally issued. The Council have, however, been obliged to decide, with regret, that this course is impracticable. It has proved difficult to reach unanimous agreement upon the revised Regulations by a Committee consisting of a very large number of members representing diverse interests, and it has only been possible by numerous mutual concessions to issue a set of Regulations agreed by all these interests. The revised Regulations could not therefore at the present stage be altered in principle, and for this reason in the opinion of the Council no useful purpose would have been served by an open discussion of the Regulations before their publication.

Students' Premiums.

The following premiums, each of the value of £10, have been awarded by the Council for papers read before the Students' Sections during the past session :—

Author	*Title of Paper*	*Where read*
N. B. Hill	"Alternators for Operation on a Transmission Line"	Liverpool
A. I. Macnaughton B.Sc. (Eng.)	"Some Notes on Insulating Papers"	Glasgow
V. Mitchell	"The Electrical Equipment of Railways, with Special Reference to Signalling"	Bradford
O. Morduch and B. L. Metcalf	"Electrification Schemes in Russia"	Manchester
B. Nuttall	"Automatic Protective Apparatus for Alternating Current Circuits"	Manchester
A. C. Warren, B.Sc.	"Northolt Radio Station"	London

THE FUTURE OF MAIN-LINE ELECTRIFICATION ON BRITISH RAILWAYS.

By Lieut.-Colonel H. E. O'BRIEN, D.S.O., Member.

(*Paper first received 4th February, and in final form 10th March,* 1924; *read before* THE INSTITUTION *27th March, before the* MERSEY AND NORTH WALES (LIVERPOOL) CENTRE *17th March, before the* NORTH-WESTERN CENTRE *18th March, before the* NORTH-EASTERN CENTRE *24th March, and before the* SOUTH MIDLAND CENTRE *2nd April,* 1924.)

SUMMARY.

Extensive main-line electrification has hitherto been considered to be a rather remote possibility in Great Britain, it being supposed that the capital expenditure involved and the price of current would be prohibitive. The great superiority and simplicity of the electric as compared with the steam locomotive as a machine has not been realized. The author shows that the probable density of traffic in ton-miles on the main railway arteries is so great that the cost of energy, including all capital charges, will not be prohibitive, also that the cost of the electric locomotives will not be a capital charge, and, further, that when the reductions in the cost of locomotive operation and maintenance (due to the simple construction of the electric locomotive) are taken into account, the total cost of locomotive operation is substantially less for electricity than for steam. The conclusion is that though it has only been possible to base the argument on general statistics, the problem merits closer and more immediate investigation than has hitherto been accorded to it.

The presentation of another paper on this subject must be prefaced by an apology from the author for presuming again to approach a subject which has been dealt with so recently and so ably by other writers. The matter is, however, of such importance to both the railway companies and the electrical industry that it is desirable to reiterate the arguments in favour of main-line electrification in a form which, it is hoped, will appeal as much to railwaymen as to electrical engineers.

The author hopes to show that:—

(1) The cost of operating suburban electrical services is less than the average cost of the general steam-operated services, and very much less than that of a steam-operated suburban service;

(2) The modern electric power station is now able to produce electrical energy at such a price that the cost of current supplied to an electric locomotive is but slightly higher than the cost of coal supplied to a steam locomotive; and, finally,

(3) The design of electric traction motors and control equipment has made such advances that the total cost of operating electric locomotives is far below the similar cost for steam locomotives.

It is further sought to show how the relative density of traffic affects the cost of current, and that there is strong probability that on the main arteries of traffic the density is substantially higher than on the suburban lines already electrified.

An examination of the problem is most conveniently divided into two parts: first, the consideration of the relative value of the electric locomotive as a tractor as compared with the steam locomotive; and secondly, how that value is affected by the cost of electrical energy supplied to the electric locomotive in comparison with the cost of coal supplied to the steam locomotive.

In effect, the subject should be considered, first, from an almost purely railway standpoint, secondly, from an almost purely electrical standpoint, and, thirdly, in relation to the density of traffic. The solution of the question of the economic density of traffic which will give an adequate return on the capital expenditure involved is the key to the future of the electrification of British main lines.

Mr. Roger Smith * has already dealt with the subject, using the number of locomotives per mile of track as a basis, and Mr. H. Parodi of the Paris-Orleans Railway in a recent paper † has also used as a basis the coal consumption per mile of track. It appears to the present author, however, that for British conditions the subject may be more clearly considered by using the engine-mile as a basis, as this is a figure readily obtainable and already considerably used for comparative purposes in railway work.

For the benefit of those unacquainted with railway working it may be explained that the engine mileage of a system is the actual number of miles run by all the steam tractors of that system in a given period whether hauling freight, passenger or other trains, or without trains. Statistics of engine mileage are published in some detail monthly and annually by the Ministry of Transport; statistics of train-miles are also published, these being engine-miles run in connection with the haulage of freight or passenger trains but excluding shunting, light running and trains operated for service purposes.

It is true that the engine-mile, though a concrete fact, has a somewhat indefinite meaning, inasmuch as no value of work done attaches to it. The ton-mile is really almost as indefinite in this sense as the engine-mile, as in both cases all reference to the time factor is omitted. The average time factor or speed of trains can, however, be taken as a constant for any English main line, but the average weight of train, as will be seen later, varies somewhat. In considering averages (a method which is forced on the investigator by the existing statistical methods of English railways) deductions may, however, be safely drawn as to the probability of higher values than the average existing, when it is known that a large proportion of the whole represents lower values—the speed and weight of trains on branch lines will obviously be less than on the main line.

It will be necessary to consider quantitative figures, for the essence of the problem is financial, and the

* Société des Ingénieurs Civils de France (British Section), Presidential Address, 1923–24.

† "Electrification Partielle du Reseau de la Compagnie du Chemin de Fer d'Orleans," *Bulletin de la Société Française des Electriciens*, ser. 4, vol. 3, No. 23.

decision whether or not to electrify portions of the British main lines will rest with financiers rather than with technical experts.

At the outset it will be convenient to consider in some detail the disabilities of the existing method of railway haulage by steam in comparison with the advantages—and also the limitation of those advantages—which are to be gained by a change of method.

The steam locomotive as it exists to-day is in all essentials the machine designed by Stephenson, much enlarged and constructed with the improved materials now available.

The design has inherent disadvantages due to the constricted space available for the steam generator, which entails extraordinary rates of combustion, and for the low-speed prime mover, which entails high pressures on small bearing areas exposed to dirt and moisture. The machine is further very susceptible to weather conditions and variations in the quality of the fuel supply. The principal advantage of the steam locomotive lies in the independence of the tractive units so that the failure of one has no direct effect on the rest, while there is unlimited freedom of movement on rails so long as the machine has a supply of coal and water.

The cost of maintenance is therefore high but is probably decreasing, though very slowly, due to better appreciation by the operating staff of the value of close analysis of the causes of failure and by continued progress in the quality of the material used in construction.

The disabilities of the steam tractor may be briefly set out as follows :—

(1) Inability to give continuous service without considerable idle intervals.
(2) High cost of repairs.
(3) Low thermal and mechanical efficiency, and small range of maximum efficiency.
(4) Limited tractive capacity per unit.
(5) High weight per continuous draw-bar horse-power available.
(6) Liability to failure in service.
(7) Susceptibility to weather conditions.
(8) Irregularity of turning effort.
(9) Necessity for operation of each unit by two skilled men.
(10) Rapid increase of haulage cost with increased weight and speed of trains, particularly on gradients.
(11) Overload capacity cannot be given instantaneously and is limited.
(12) Exact allocation of current costs between various classes of traffic.

The limitation on the maximum continuous draw-bar capacity in horse-power of the steam tractor, results in a general use of the machine at or near its continuous capacity, and this, combined with the other factors previously referred to, is the principal cause of the high cost of maintenance. It is a well-known phenomenon of railway operation that just as fast as the chief mechanical engineer's department designs more powerful machines, so the increased capacity is absorbed, or more than absorbed, by the traffic department.

Before entering into the comparative advantages of the electric tractor in relation to the above, it is necessary to examine very briefly other possible improved forms of tractor.

The turbo-electric locomotive may be quickly dismissed : the weight per draw-bar horse-power is much higher than that of the steam locomotive, it requires more skilled attention, the first cost must be higher than that of an electric locomotive and very much higher than that of a steam locomotive, and a crew of two if not of three men is required. The possible advantages are a saving in fuel and, perhaps, reduced boiler repairs due to condensate being available for a portion of the boiler feed. The straight turbo locomotive seems to have more possibilities, but here again only a saving in fuel and a possible saving in boiler repairs can be offset against increased weight and complication.

The internal-combustion locomotive is still in swaddling clothes ; suffice it to say that only prolonged and expensive research shared by a large railway company and a manufacturing firm with ample resources is likely to result in the production of a practical tractor of 800 to 1 500 draw-bar horse-power capable of continuous service in traffic. If, and when, such a machine is produced costing no more than a steam locomotive, with a fuel consumption in money value of less than half that of the steam tractor, a possibility of multiple operation with a single crew and a demonstrated lower cost of repairs, then the electric locomotive will have a serious rival.

The electric locomotive compared purely as a tractor with its steam rival, leaving out of account all question of the cost of fuel or energy supplied for a given service, has the following advantages :—

(1) Capacity for almost continuous service in traffic.
(2) Low cost of repairs.
(3) High tractive capacity per unit.
(4) Low weight per continuous draw-bar horse-power available.
(5) Reliability in service.
(6) Complete independence of weather conditions.
(7) Even turning effort.
(8) High mechanical efficiency and large range of maximum efficiency.
(9) Possibility of operation as a unit or in multiple by one man.
(10) Reduction of signal movements and occupation of tracks due to elimination of necessity for turning and movements for obtaining coal and water and daily visits to sheds.
(11) Much greater flexibility of wheel base.
(12) Large overload capacity available instantaneously.

The disadvantages are the number of units which may be immobilized by a failure of energy supply, and the dependence of each unit for mobility on contact with the electrical distribution system of the track.

In a mixed system of electric and steam traction a further disadvantage is the necessity for changing from

steam to electric traction at the terminal points of the steam section. The economic length for electrification may not coincide with the natural economic length of run for a steam locomotive.

The question of the change of locomotive from steam to electric, and vice versa, has an important bearing on the financial aspect of main-line electrification. While such changes may be almost eliminated when a complete scheme of electrification has been carried out, the impossibility of dealing with an electrification of 1 000 or 1 500 track-miles except by stages, together with the fact that in general the maximum economic length of run of a steam locomotive is not more than 160 miles, may necessitate a considerable expenditure in the initial stages on temporary accommodation for steam locomotives at the temporary termination of each stage; nor will the expenditure be confined to locomotive housing alone, as accommodation will have to be provided temporarily for a large number of staff who will be displaced.

While given the conditions necessary for a successful electrification, viz. cheap current and requisite density of traffic, a limited scheme might not be a financial success, at the same time it will be clear that the full economies indicated in the paper could not be realized if it were necessary to retain a considerable percentage of the steam tractors in use with their concomitant services for water, coal, cleaning, etc.

Before considering the probable costs of main-line locomotive operation, force will be given to the arguments to be used subsequently by a comparison of the costs of steam and electric suburban services.

Suburban services operated at high schedule speeds with frequent stops are admittedly more costly to work than the average services on the main lines and branches of a railway; consequently, if a comparison be made between the average cost of operation per steam engine-mile on a typical main line and its branches and the cost of operation of suburban electrifications, the comparison will be of a very conservative nature by no means unduly favourable to electrical operation.

The average mileage per annum per steam locomotive in stock on the largest British system is approximately 26 000 miles per annum for passenger engines and 18 300 miles per annum for freight, the average being 21 100 miles per annum for the whole stock of 10 302 engines.

The cost of repairs per engine-mile, which is much lower than the cost of repairs per train-mile, varies on the various sections of the railway from 4·5d. to 6·9d., the average being 5·8d.

It must be borne in mind that these are averages and that large numbers of small tank engines and freight engines doing comparatively light work are included. The average mileage per annum is substantially less, and the cost of repairs per engine-mile is substantially heavier for the passenger and freight engines employed to haul the heavier trains on the main trunk routes, which would be the first to be electrified.

The existing methods of railway accounting do not, however, yield in a complete form such figures as would enable a definite quantitative statement to be made as to the amount by which such repairs are higher. These variations in repair costs are mainly due to differences in the weight and speed of the trains hauled, in the physical characteristics of the section such as curves and gradients, and in the purity of the water supply, which affects the boiler maintenance.

The average mileage per annum per train on the various suburban electrifications in Great Britain varies from 47 320 miles to 36 296 miles. This mileage per electric train per annum really is analogous to the mileage per steam locomotive per annum and may be used comparatively in considering relative costs.

The cost of repairs per train-mile varied from 2·1d. to 6·0d., the average being 4·18d., the variations in this case being due to differences in the design and age of the equipment and, to some small extent, to differences in the schedule speeds.

The steam locomotives probably averaged about 80 tons' weight in working order, and represented a present-day lowest market value of about £4 000 each and a maximum draw-bar horse-power of probably 800. The average steam locomotive of this weight would have been quite incapable of performing the electric suburban service, and the comparison really should be with locomotives weighing 120 tons, costing £8 400 each, and having a maximum draw-bar horse-power of 1 200.

The electric motor-cars, on the other hand, averaged about 60 tons for the tractor part of the train equipment including the weight of the motor bogies, cost about £8 000 per train at present market prices, and had a continuous draw-bar horse-power of 1 400.

Table 1 shows a comparison between

(1) The average cost of all steam services, passenger, freight and shunting, on a typical British railway system;

(2) The average cost of a high-speed electric passenger service;

(3) The estimated cost of operating the electric service by steam.

This conclusion is confirmed by Sir Philip Dawson in his paper on "Financial Prospects of Railway Electrification" where a diagram is given showing the relative costs per train-mile for suburban steam, main-line steam, and suburban electric services, the relative costs in 1921 being 61d., 51d., and 42d. per train-mile respectively on the London, Brighton and South Coast Railway.

It is therefore evident that, given a certain density of traffic, the cost of electric operation of suburban trains is markedly lower than the average cost of steam operation.

The above cost of steam-locomotive operation may now be compared with the probable cost if electric locomotives were substituted for main-line work. It is obvious on general principles that the result of this comparison should be much more favourable to electric operation than in the case of suburban traction dealt with above. The electrical equipment of the electric locomotives as a whole will be much less severely stressed on main-line work with comparatively long continuous runs than on the suburban work where

the frequent stops and high accelerations cause severe stresses on motors, control, gears and every other part of the equipment.

Before actually considering these figures it is desirable to give a brief comparison of the weights and performances of typical steam and electric locomotives. Table 2 gives a comparative statement of the leading dimensions for four typical freight and four typical passenger steam locomotives and for eight corresponding electric locomotives; these locomotives are also illustrated in Fig. 1, and some of their comparative speed and horse-power curves are shown in Fig. 2. The largest steam locomotives, freight and passenger, have not as yet been built, but are the largest practicable within the largest load gauge in this country; their range of action is extremely limited owing to the limitations of gauge and strength of bridges on many main lines. The electric locomotives are, with one exception, all built or building and would conform to the gauge and bridge strength of any main line in this country. It will be noted that, for the same weight, rather more than a 60 per cent increase in the continuous draw-bar horse-power is available. The latter fact has an important bearing on the cost of accelerating present services. Tests made on 500-ton passenger and 640-ton freight trains hauled by two steam locomotives run at average speeds over a line with heavy gradients, well in excess of the

* At 51·5 miles per hour. † Taken as one-fourth the adhesive weight. ‡ At 28·0 miles per hour.

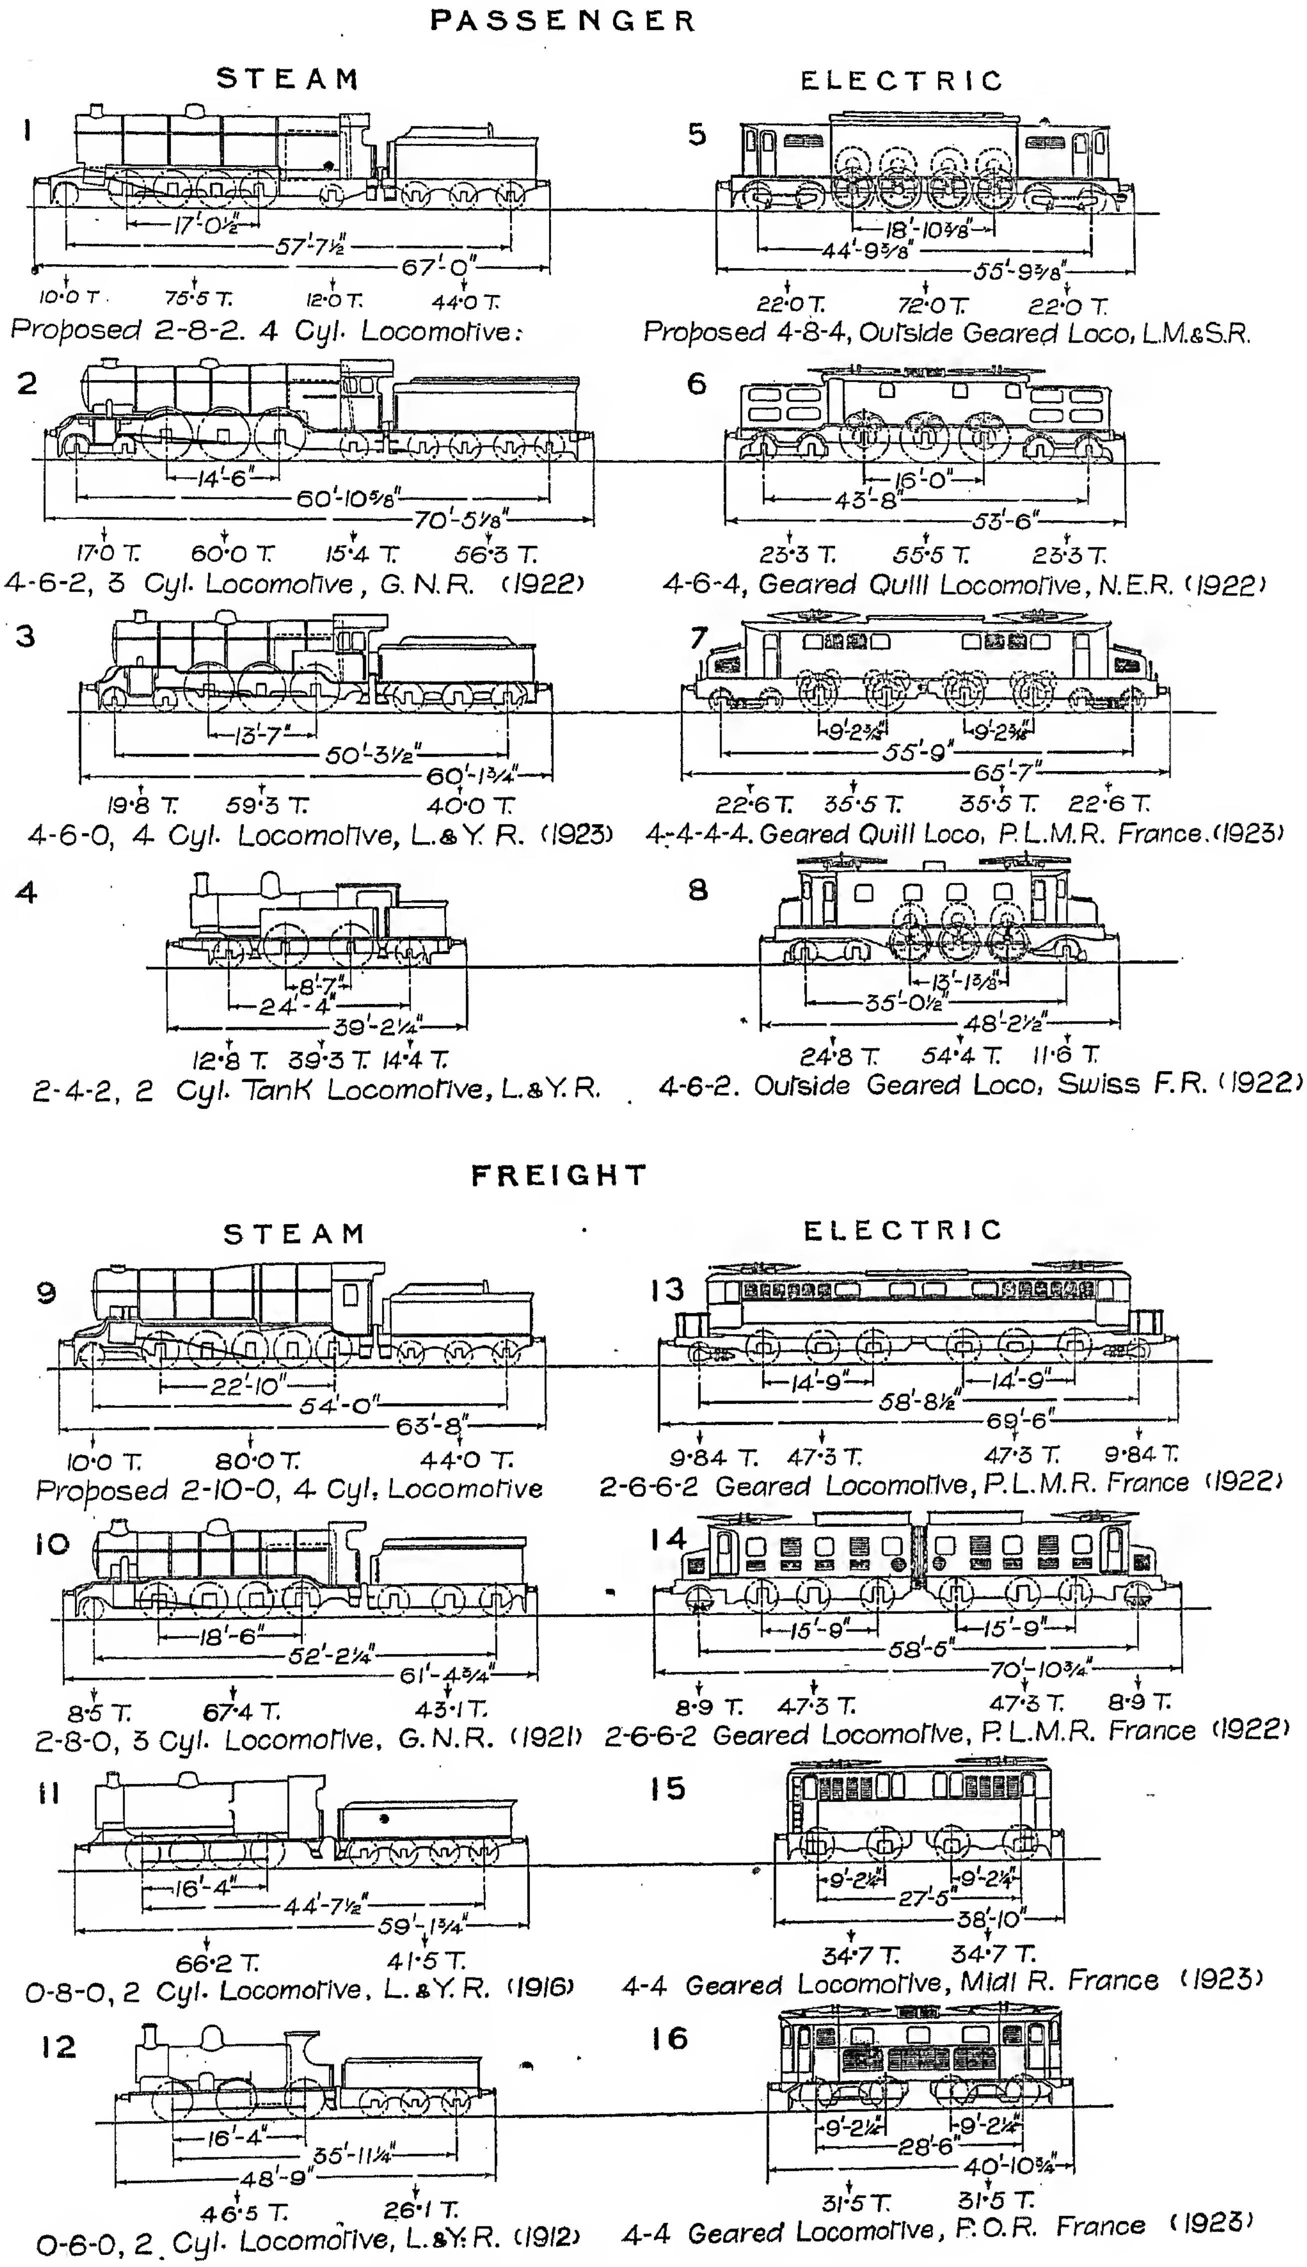

FIG. 1.—Comparative diagram of steam and electric locomotives.

average booked schedule speeds and yet without increase of maximum speed, showed that as soon as the maximum draw-bar horse-power required exceeded that obtainable from one locomotive, the ratio of both maximum and mean draw-bar effort to adhesive weight became very large.

The weight of the steam locomotives was nearly 50 per cent of the weight of the train hauled in the case of the passenger train, and 37 per cent in the case of the freight train; a slight increase in either weight or speed up the gradients would have made these figures 72 per cent and 56 per cent respectively. As the maximum draw-bar pull did not exceed from 8 to 9 tons for the mean speed, an electric locomotive of a total weight of 116 tons and 72 adhesive tons available for traction would have met all requirements. The necessary draw-bar horse-power can be produced by an electric locomotive of this weight.

The results of these tests are shown in Figs. 3 and 4. The aggregate maximum draw-bar pull of the two locomotives used was 27 tons, and the adhesive weight available for traction was 118·5 tons.

The maximum draw-bar horse-power recorded over one minute on the tests was 2 015 in the case of the freight train, and 1 921 with the passenger train. With the freight train, excluding gain due to increase of maximum speed on the level and down hill, the overall time for the 90 miles was reduced by 11 per cent and with the passenger train 10 per cent was gained, this saving in both cases being due solely to faster uphill running. Such faster speeds on up gradients can be attained by the steam locomotive only at the expense of heavy fuel consumption and exceptional wear and tear; with an electric locomotive much better results can be obtained.

Take the case of an up grade of 0·75 per cent, 30 miles in length, and a train of 750 tons trailing; the resistance due to the gradient is 17 lb. per ton, whilst the resistance for a goods train at 20 miles per hour is 8 lb. per ton, and at 40 m.p.h. is 15 lb. per ton, the total resistance therefore being 25 lb. per ton and 32 lb. per ton respectively. The train-resistance curves on which these and other figures in the paper are based are shown in Fig. 5. If the draw-bar horse-power required in the first instance is 1 000, in the second it is 2 560, but the time for ascending the gradient is 90 minutes in the first instance as compared with 45 minutes in the second. The horse-power-minutes are respectively 90 000 and 115 000, the draw-bar pulls being 18 750 lb. and 24 000 lb. respectively. Half the time is thus saved with an expenditure of only 27·8 per cent more energy and only 28 per cent increase in draw-bar pull.

The 750-ton train at 40 m.p.h. on this gradient could be dealt with only by a combination of three steam locomotives employing a crew of six men and weighing 348 tons, or nearly 50 per cent of the weight of the train. An electric locomotive weighing 116 tons and operated by a single man could perform the same duty with ease.

The gross weight of the steam-hauled train would thus be 1 098 tons, whilst that of the electrically hauled train would be only 866 tons. Assuming from Lawford Fry's curve that the resistance of the steam locomotive is 22 lb. per ton and that the electric locomotive has

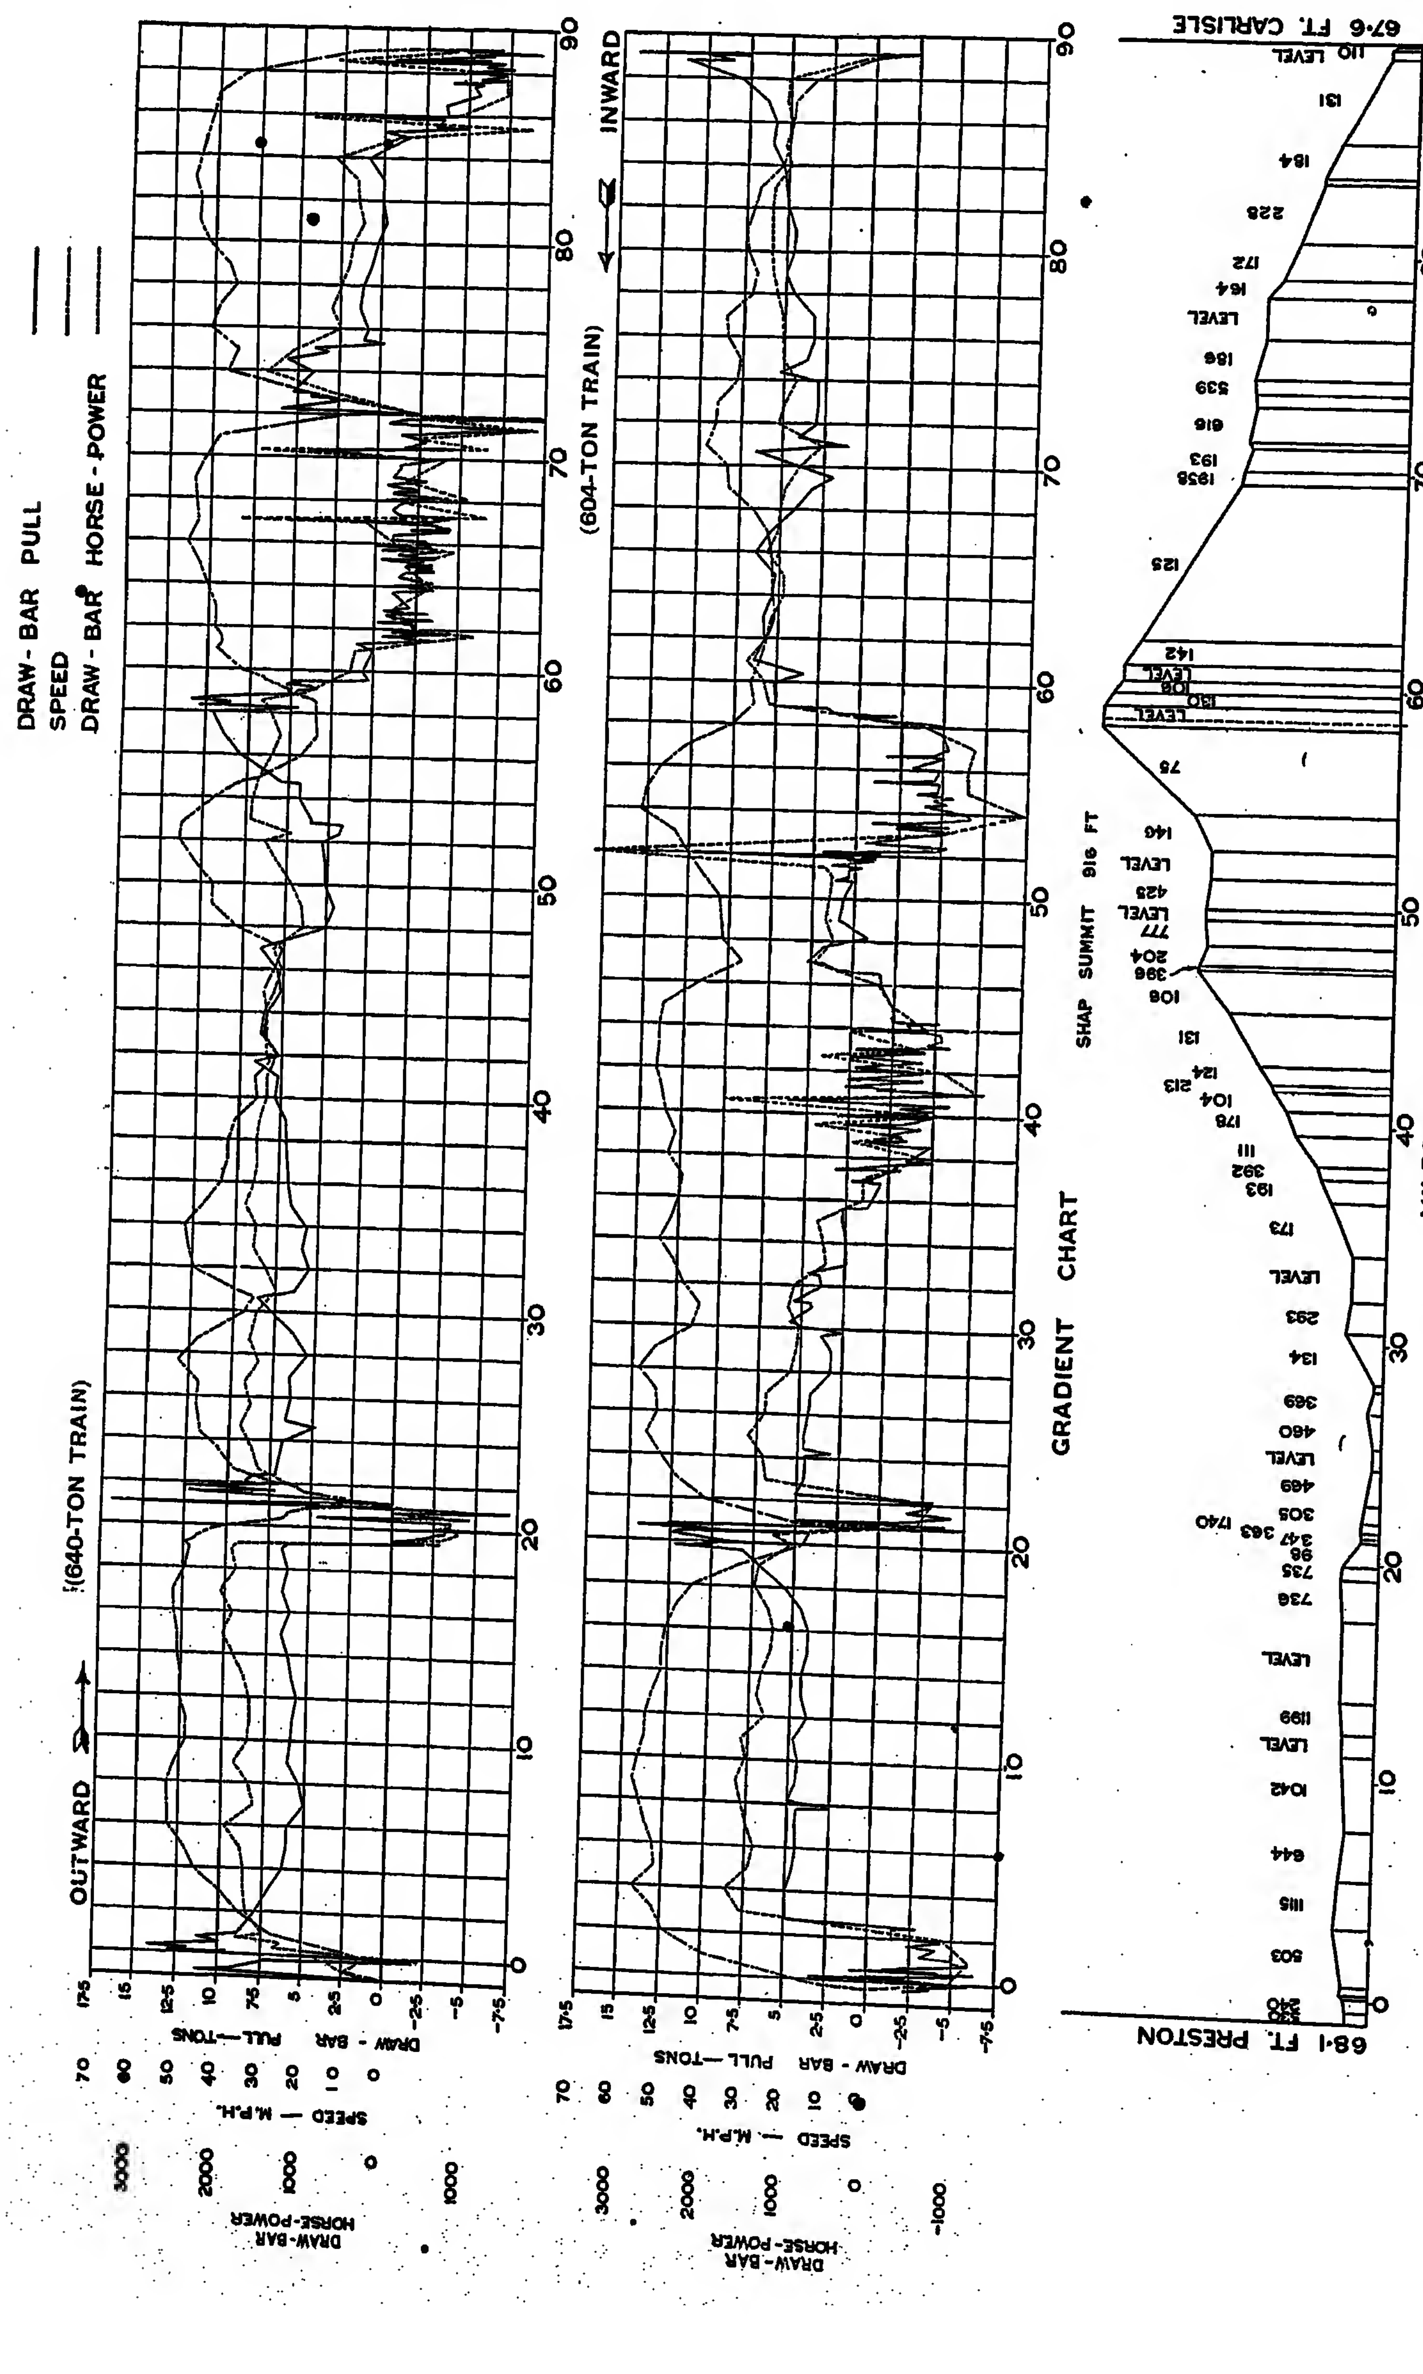

FIG. 4.—Double-headed run with heavy freight train over 90-mile section of main line.

a resistance of 10 lb. per ton, the gross h.p.-minutes for the steam train will be 166 000, as against 130 000 for the electrically hauled train, i.e. the steam-hauled train requires an increased energy input of 27 per cent. The cost of the three steam locomotives would be about £24 000 and the cost of the electric locomotive would be about £16 000. On arrival at the end of a 90-mile run including this gradient the steam locomotives would have to be changed for fresh ones, but the electric locomotive would be at once ready for another similar run. The electric locomotive would field. On this basis in a run of 100 miles containing 20 miles of 1 in 300 up grade and 20 miles of 1 in 300 down grade, excluding any gain due to acceleration at starting, about 20 minutes could be gained, 10 minutes due to 20 per cent higher speed on the level and 10 minutes due to $33\frac{1}{3}$ per cent higher speed on the grade.

Taking the same comparison with a 2–8–0 steam locomotive, the curves for which are also given, the steam-hauled speeds with 1 000-ton freight train would be 28 m.p.h. on the level and 18 m.p.h. on the grade. The same electric locomotive would give 43 m.p.h. on

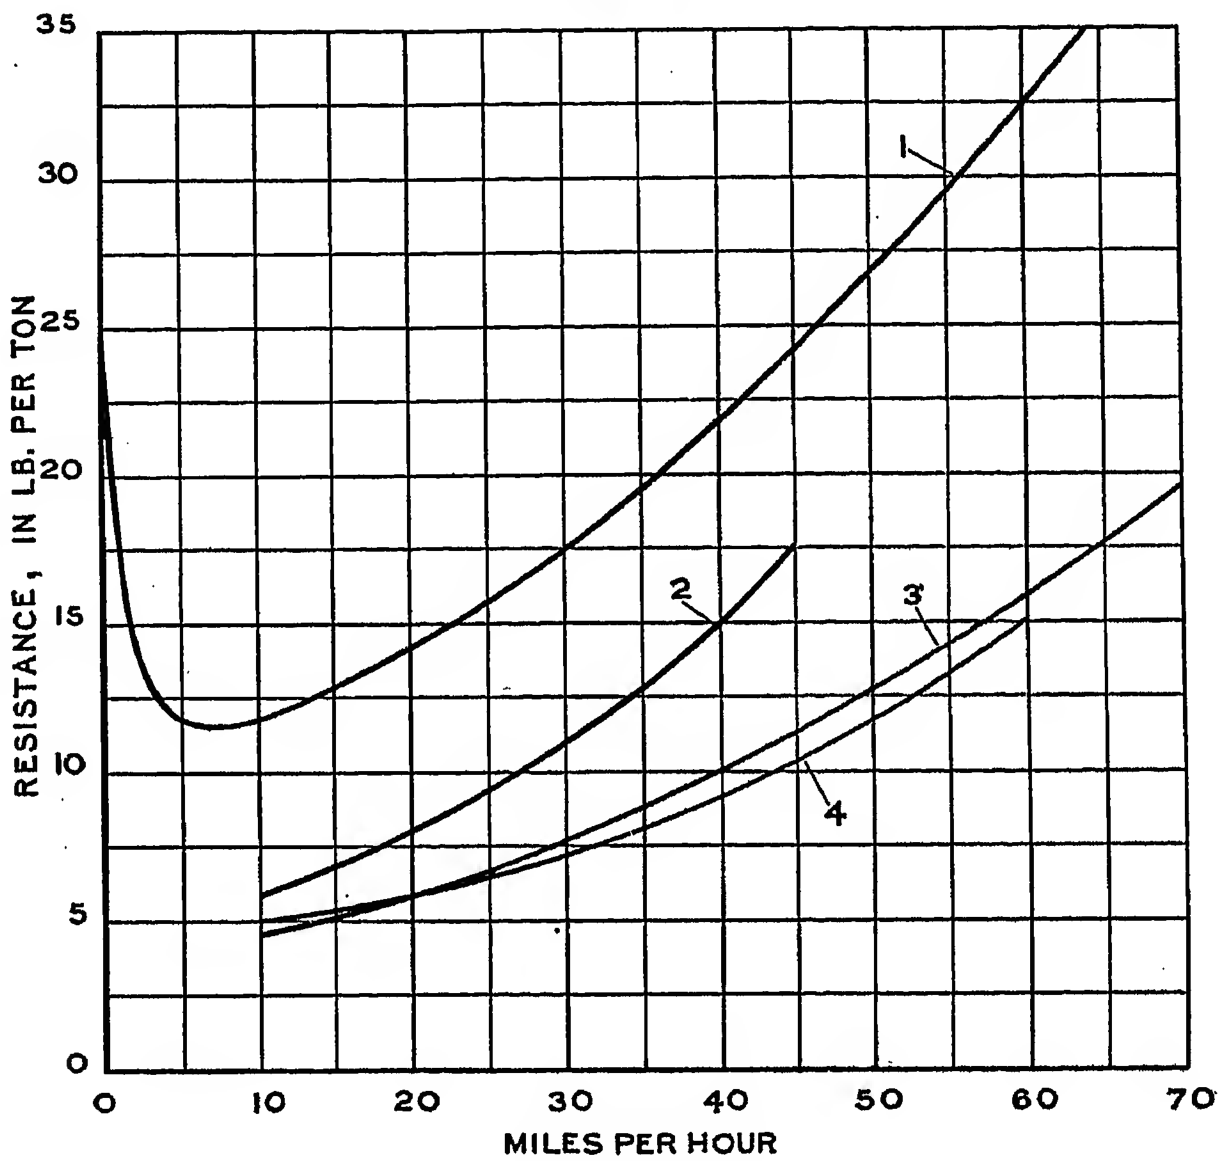

FIG. 5.—Resistance curves.

be equally efficient when working at the rate of 3 000 h.p., its one-hour rating, or at 750 h.p. if required to work a lighter train back, while the steam locomotives would be at a grave disadvantage in this respect.

Examination of curves given in Mr. Roger Smith's paper on "Some Problems of Railway Electrification" shows that the Great Western 4–6–0 steam locomotive referred to in this paper would have a speed of 55 m.p.h. on the level and 40 m.p.h. on a 1 in 275 grade with a 500-ton train. The speeds of Sir Vincent Raven's 2–C–2 electric locomotive with the same weight of train would be from 56 to 70 m.p.h. on the level and 47 to 58 m.p.h. on the grade, according to the shunt the level with full field and 39 m.p.h. on the grade. Even if the 20 miles of grade were continuous, this 20 miles would take only 30 minutes and the horse-power given out by the motors would be 2 350, which would be within their thermal capacity for this time.

The result of experience on suburban lines of the London and North Eastern Railway in this country, and on numerous electrified railways elsewhere (see Appendix 1), shows that the cost of repairs to an electric locomotive is from one-third to a quarter of that of a steam locomotive per engine-mile; and the same reduction in cost occurs in connection with sub-

sidiary services rendered at steam sheds, such as cleaning, coaling, washing-out boilers, etc.

Owing to the simplicity of construction of the electric locomotive and the high degree of excellence of manufacture now attainable, it is probable that the average mileage obtainable between general repairs to the electric equipment will exceed 200 000 miles. The facts that the London and South Western Railway on their suburban equipments and the London and North Eastern on their freight locomotives have never rewound an armature or field coil during 7 years' operation, and that the life of the modern commutator is at least 750 000 miles, are strong indications that the forecast given of the cost of repairs is correct.

The turning and changing of tyres and axle brasses, the renewal of brake blocks and the repairs to auxiliaries such as vacuum pumps, will be the principal causes of an interruption to continuity of service for any appreciable period. As neither these nor motor repairs will necessitate the return of the locomotive to the main repair shops, the capacity of these for steam-locomotive repairs will be considerably increased. The truth of the assertion is more evident if it be considered that 90 per cent of the cost of steam-locomotive repairs arises from the boiler or from crank axles, wheels and frames due to the reciprocating and variable stresses imposed on these latter.

Further, the experience of suburban electric services enables it to be said with absolute certainty that an electric locomotive can be available for traffic for 23 hours out of 24, and that a fortnightly examination of the electrical equipment will be sufficient.

The electric locomotive will therefore be capable of an annual mileage of 40 000 to 50 000 miles per annum, as compared with an average of about 20 000 miles for a steam locomotive; in fact, the mileage possibilities are only limited by the traffic requirements and the extent to which engine workings can be arranged to permit of continuous service. Universal experience indicates that one electric locomotive will at least perform the duty of two steam locomotives (see Appendix 1). At all times, and especially in foggy weather or at night, traffic movement will be greatly facilitated by the absence of any necessity for engines going out of service for coal, water, cleaning fires, tubes and smoke-boxes, or for turning. The liability to failure of the electric locomotive is also much less than that of the steam locomotive. It may be argued that the freedom of units from failure is counterbalanced by the possibility of failure of current supply, so that in the aggregate the time lost in this respect will be the same if not greater. The reliability of the electrical supply equipment is, however, so great to-day that the most modern suburban electrifications never suffer more than momentary interruptions due to circuit breakers operating.

The total cost of enginemen's wages will also be substantially reduced. Engine duties which represent time during which an engine is not in movement owing to its being required by its crew for examination, coaling, watering or cleaning fires, etc., account for 15 per cent of the enginemen's hours in passenger service and 12 per cent in freight service. These engine duties will be to a great extent eliminated with electric locomotives.

The necessity for double crews on double-headed trains also disappears, and with this from 3 to 5 per cent of the total cost of enginemen's wages.

The further absence of any real need for a second skilled man on an electric locomotive, at least for shunting engines and multiple-unit trains, combined with the better utilization of the machine which should be possible by re-arrangement of the engine workings, should enable the total cost of enginemen's wages to be reduced by 33⅓ per cent.

Dealing with the remaining costs, that for water disappears, that for lubricants will be at least halved owing to the disappearance of cylinder oil and oil for reciprocating parts, and clothing and other stores will also be halved owing to the greater cleanliness of the electric locomotive.

On a typical suburban electrification which has been in operation for nearly 20 years the cost per train-mile was:—

Lubricants	0·033d.
Other stores and clothing	0·030d.
Other wages at sheds	0·640d.
	0·703d.

The comparative costs are shown in Table 3, which compares the costs on one of the former railway systems carrying heavy main-line traffic and the estimated costs of electric locomotive operation for the same traffic.

TABLE 3.

Cost of Operation and Maintenance per Engine-Mile, excluding Locomotive Renewals and Fuel or Energy.

Other wages at sheds	2·658	0·620	75 % reduction (approx.)
	18·836d.	8·900d.	

On locomotive operation costs alone, excluding fuel, and almost quite independently of the density of traffic, there should be an economy of nearly 10d. per engine-mile.

The average density of traffic, which seriously affects the cost of the electric current supplied to the locomotive, would, however, preclude the realization of such a large economy in practice.

Before passing to the consideration of the cost of energy and how this modifies the very real economy affected by the electric tractor as a substitute for the steam tractor, some other points must be dealt with.

The weight of the main-line passenger and freight trains in this country is comparatively small. On a certain 100-mile section of the London, Midland and Scottish Railway with heavy gradients, an examination of the weights of the heavy through trains at the heaviest period of the year showed an average of 275 tons behind the locomotive draw-bar per passenger train, and of 410 tons per goods train; the maximum weight of passenger train only slightly exceeded 400 tons and was hauled by two engines. With rare exceptions the heaviest passenger trains do not exceed 350 tons, or goods trains 800 tons, trains of greater weight being almost invariably hauled by two locomotives. The combined maximum tractive effort of two steam locomotives such as are commonly used for these trains would be 16 tons for the passenger train and 21 tons for the freight train, and on occasions the combination might be such as to give 20 and 25 tons respectively. It is evident, therefore, that from a practical standpoint there is no objection to single electric locomotives with initial draw-bar pulls analogous to these combinations.

It is not realized by many engineers and others that the electric locomotive can be applied with both profit and facility to both fast passenger and freight services as well as to suburban work.

The General Electric Company in U.S.A. have recently completed and tested a 107-ton, 1 500-volt, high-speed passenger locomotive of the 2–C–C–2 articulated type for the Paris–Orleans Railway. This machine easily attained its guaranteed speed of 81 m.p.h., and a maximum speed of 105 m.p.h. was sustained during the final runs.

Brown, Boveri are also building for the Paris–Orleans Railway some 2–D–2, 1 500-volt locomotives capable of developing 2 580 h.p. for 1 hour, their weight being 92 tons, maximum speed 81 m.p.h., haulage capacity 600 tons behind the draw-bar up a 1 in 75 gradient at 40 m.p.h.; also a C–C freight locomotive developing 3 600 h.p. for 1 hour, its weight being 114 tons (all adhesive weight), maximum speed 50 m.p.h., haulage capacity about 1 000 tons behind the draw-bar up a 1 in 75 gradient at 25 m.p.h.

In order to consider the comparative costs of fuel and current the following basis has been taken:—Generation, three-phase at 11 000 volts; overhead three-phase transmission at 44 000 to 66 000 volts according to distance; conversion by mercury arc rectifier to 1 500 volts (d.c.), and distribution at this voltage by third rail, with overhead equipment in stations and station yards.

The author has endeavoured to arrive at a generally applicable graph expressing the cost of energy for electric traction as compared with steam, in pence per locomotive-mile, the energy being that required at the tread of the wheels of the tractor for propelling both the tractor and the train hauled by it (Fig. 8).

In the following pages the expression "gross ton-miles" refers to the total weight of tractor, train and train load; and "trailing ton-miles" to the total weight of train and train load behind the tractor.

The cost of coal for locomotive purposes has been assumed to be 23s. per ton delivered to the locomotive depot in wagons, equivalent to 7·40d. per engine-mile at 60 lb. of coal per mile, and the cost of a high-tension unit at the 44 000-volt busbars at the power station to be 0·40d. with coal at 15s. per ton. This figure for the price of locomotive steam coal is a conservative one, as will be realized from Table 4 which shows the price of coal as delivered to the locomotive shed yard for stations at varying distances from London, and also some comparative prices of coal for power-station purposes.

TABLE 4.

Typical Costs of Locomotive Coal delivered in Wagons to Locomotive Running Shed.

* *The Times Supplement* of 31st January, 1924, states that the average pit-head price in 1922 was 10s. 2¾d., and export coal 25s. per ton f.o.b.
† The average calorific value of the above coals is about 13 500 B.Th.U., with 9 to 10 per cent of ash.

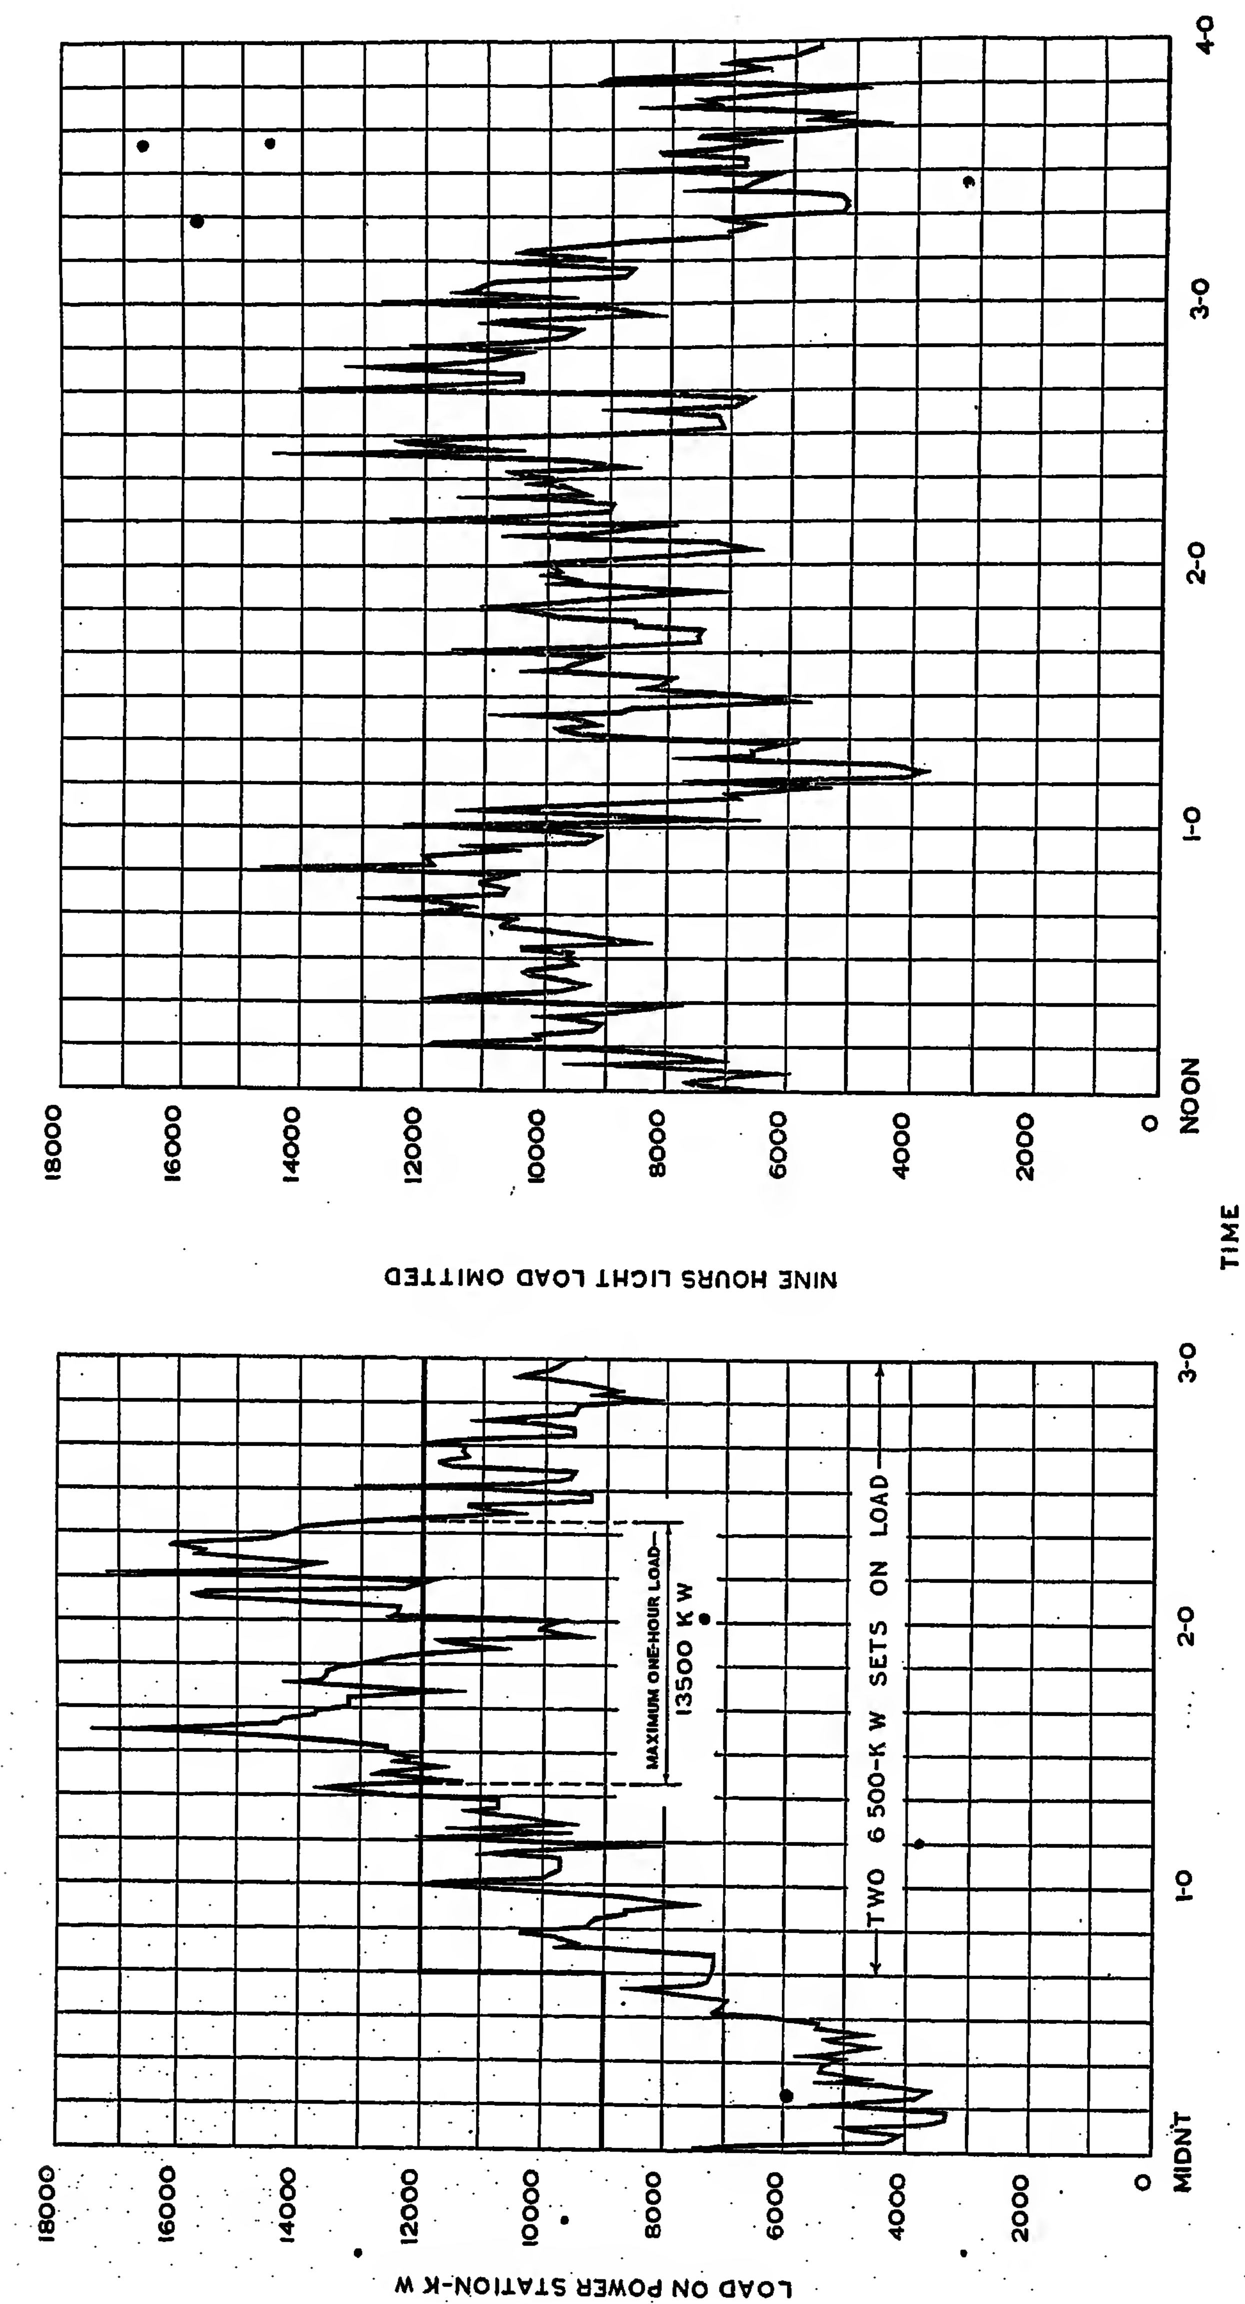

FIG. 6.—Load curve on power station for 100-mile section of main line.

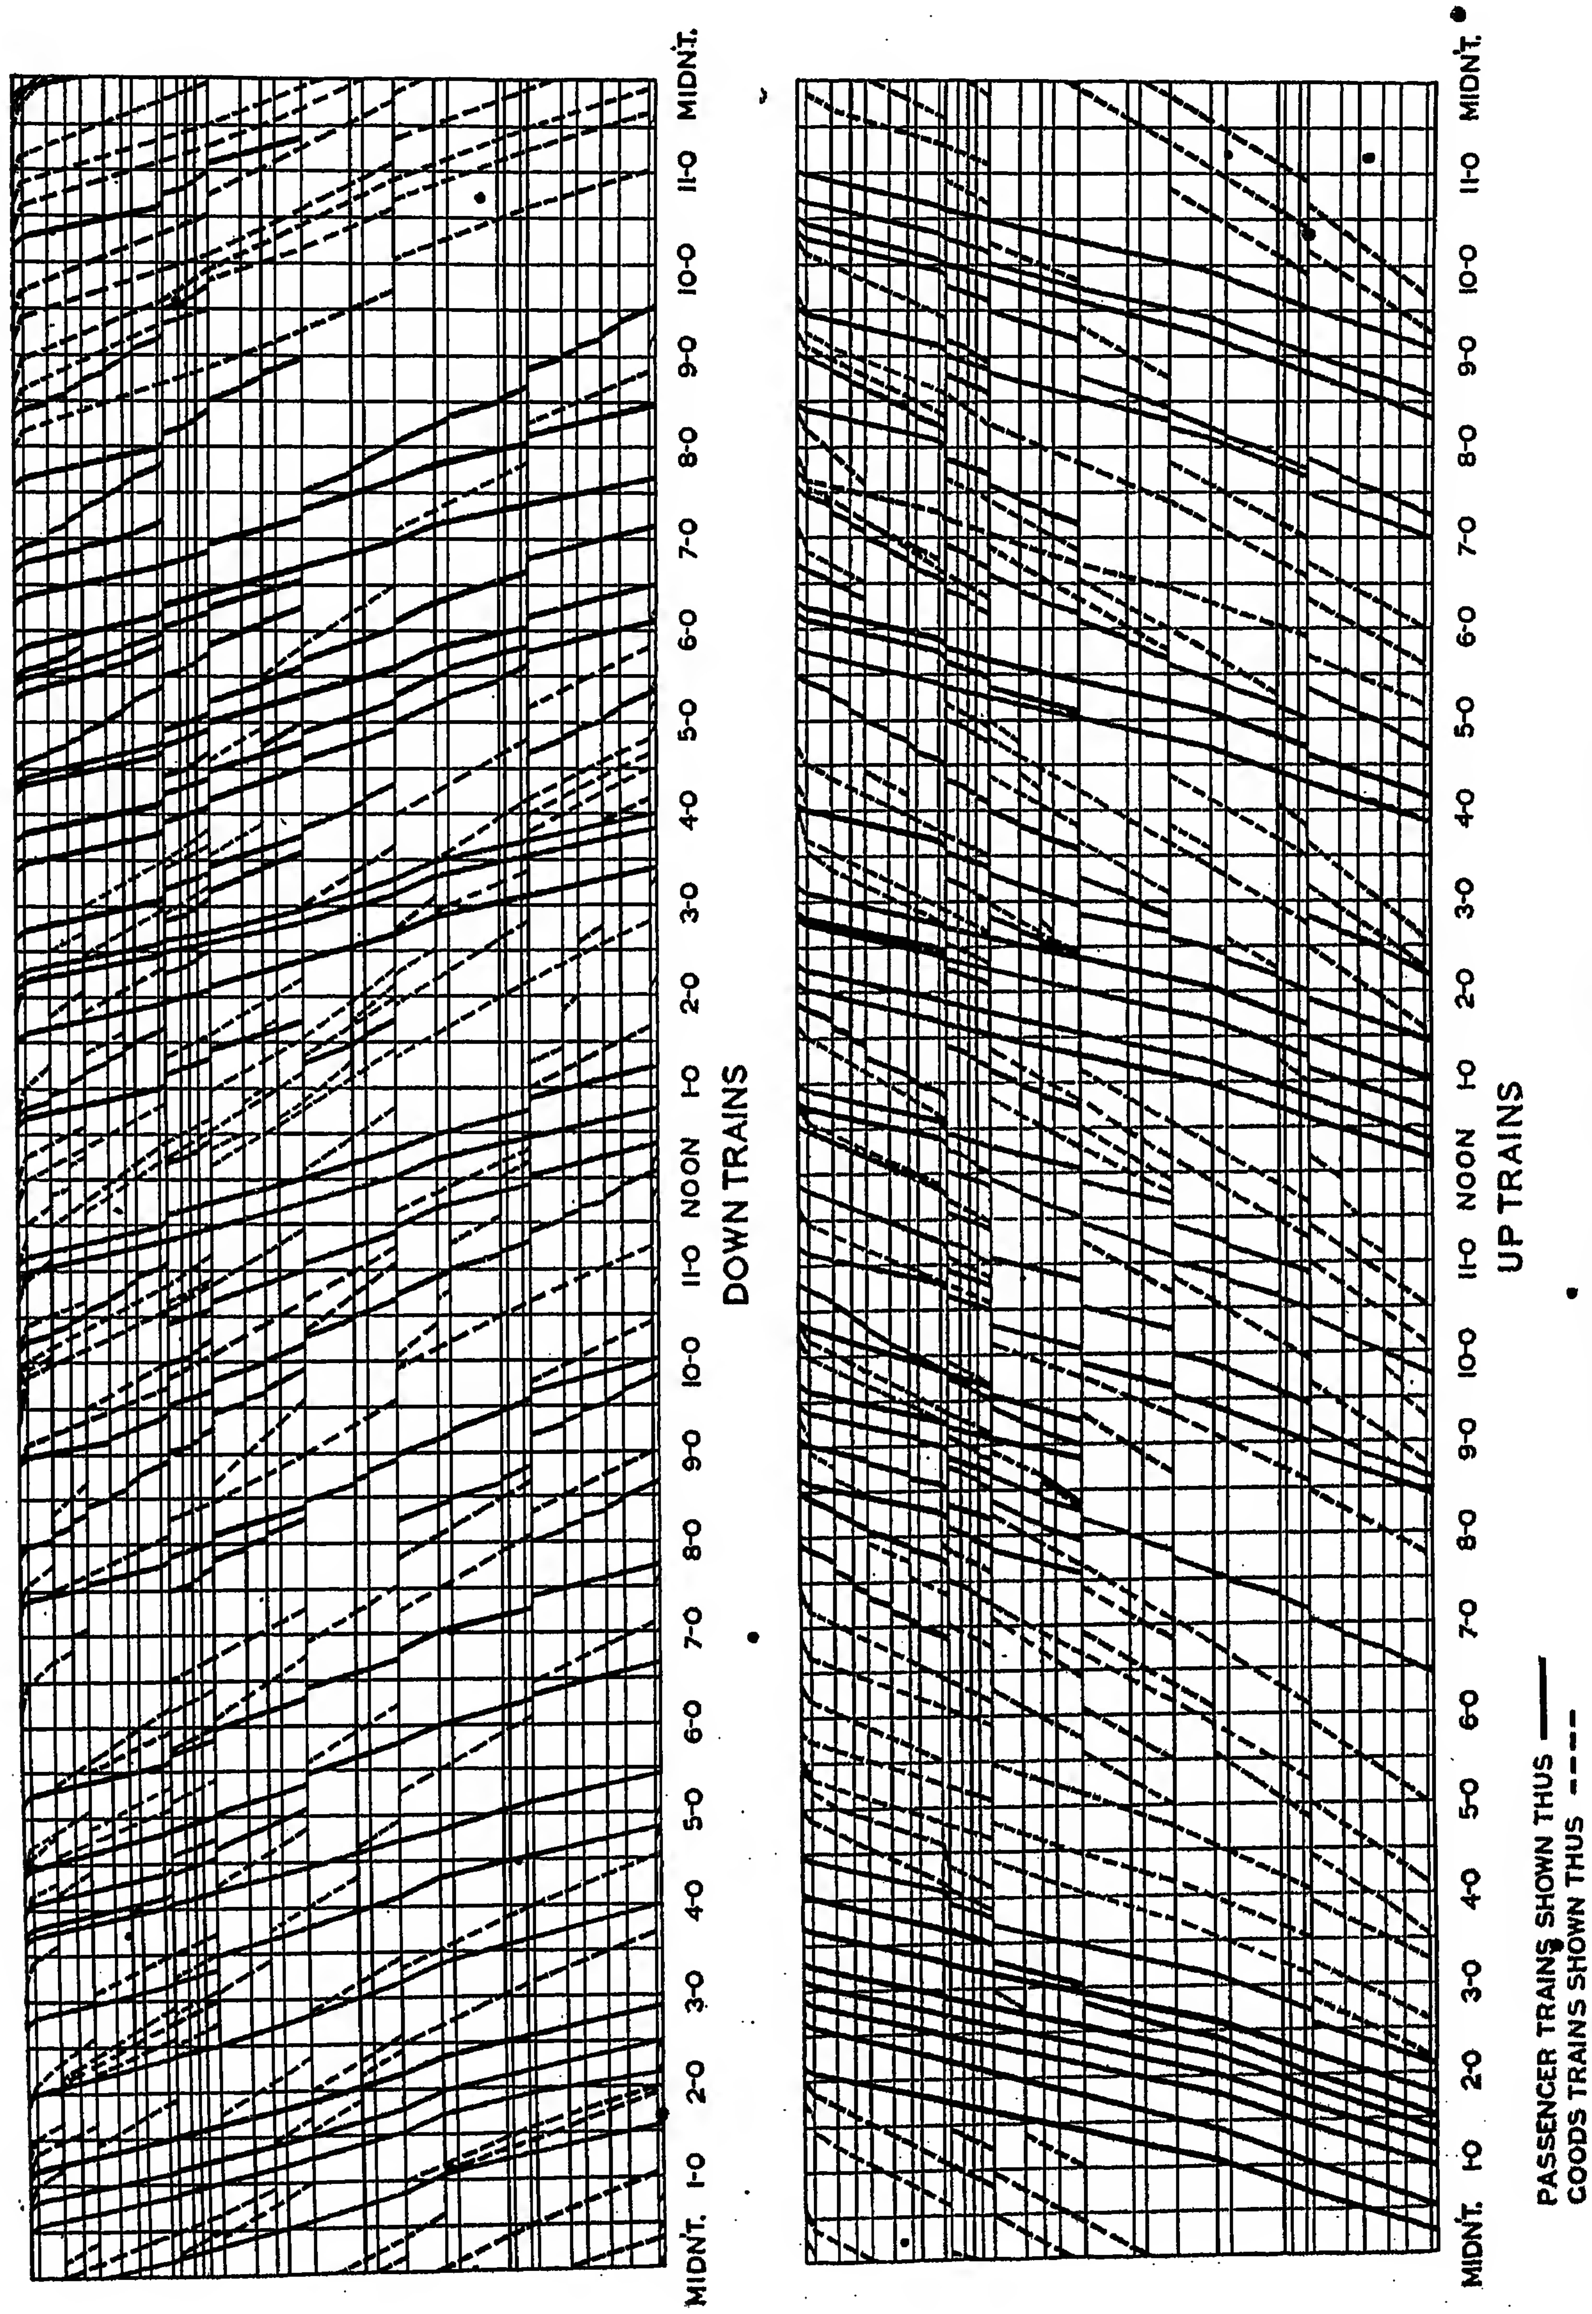

FIG. 7.—Graphical time-table for 100-mile section of main line.

It will be convenient at this point to refer to the load factor which would probably be obtained for such a supply, the load factor being defined as the ratio of the total units delivered to the high-tension feeders per

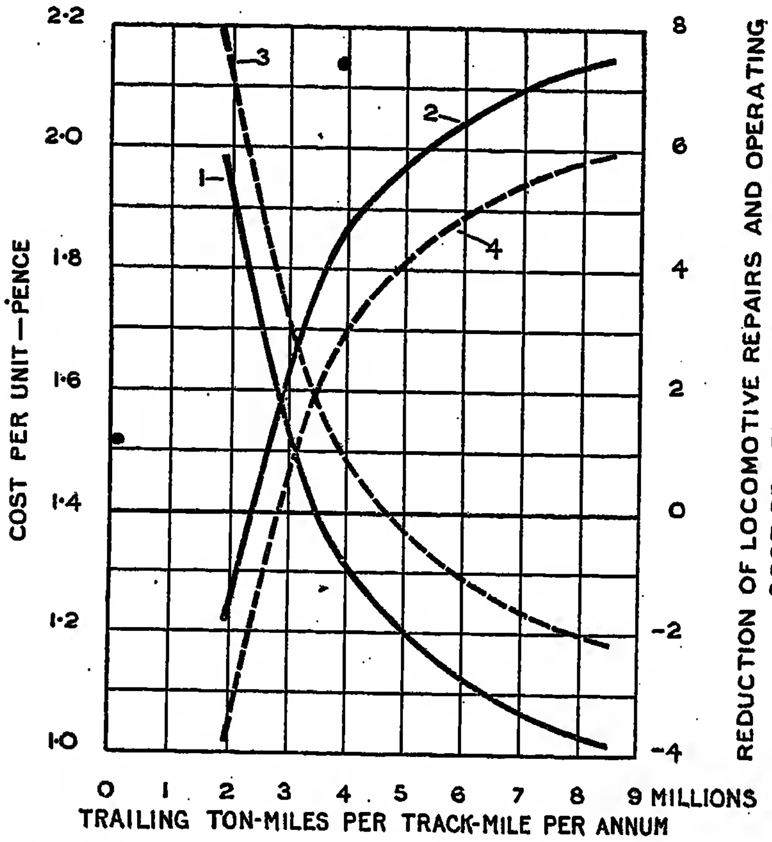

Fig. 8.

annum to the maximum hourly load multiplied by 8 760 (the number of hours in a year).

The load factor on the suburban electrifications of the L.M. and S. Railway, where there is practically no load from 12 midnight to 6 a.m. and where the load diminishes between 10 a.m. and 4 p.m. to between 66 per cent and 50 per cent of its rush-hour value, is of the order of 40 per cent. In all these cases the load factor is improved by the use of batteries operating in parallel with the converter plants, but tests made with the batteries eliminated show that the resultant load factor is only reduced by about 5 per cent by their absence.

Examination of the actual electrical load to be anticipated on a section of straightforward main-line double track with a density of 5 million trailing ton-miles per track-mile per annum indicates a load factor of about 50 per cent (see Figs. 6 and 7). It may be taken as a postulate that any length of main line worth electrifying will have a load factor of not less than this, and that where goods traffic and, particularly mineral traffic, predominate, the load factor will run up to as high as 70 per cent. These high load factors will naturally result in a low coal consumption and a low cost per unit whether the supply be generated at a railway company's own power station or whether it be purchased.

Table 5 shows in the first four columns some typical costs of generation in economical stations in Great Britain with load factors varying between 25 per cent and 30 per cent. These costs have been brought to a common basis, which assumes a rate of 8 per cent for interest on capital and depreciation combined and is further based on coal at 15s. per ton. It will be seen that the cost of a high-tension unit delivered to the feeders is about 0·46d., the average coal consumption of these stations being about 1·9 lb. per unit. The generating costs of a typical power station producing current for suburban traction, and of an assumed railway generating station working on the load produced by a main-line electrification, are also given on the same basis. From the load factor obtainable from a main-line electrification, and from

* Including handling and ash removal.

consideration of these results and those obtained at Blackburn, the probable cost per high-tension unit may be assumed not to exceed 0·40d.

Table 6 shows the average yearly efficiencies of transmission and conversion assumed, and these may be compared with those actually obtained in practice on the suburban electrifications.

The cost per high-tension unit of 0·4d. is increased therefore to 0·6d., on the score of efficiency alone, for the equivalent in energy of 1 000 watt-hours at the tread of the wheels. To obtain the actual cost of this energy the total units used must bear the further cost of operation, maintenance, interest and depreciation of the high-tension and low-tension transmission systems and the converting plant.

It may be assumed without any very great error that the low-tension 1 500-volt distribution system will for any given 100 miles of route remain constant whatever the density of traffic. Considerations of life of equipment and of stability and strength will dictate the use of a fairly large conductor, the substation spacing and size of substation equipment being varied to suit the density of traffic and varying almost directly as that density.

TABLE 6.

Efficiencies of Transmission.

* Assumed by author.

The cost of the high-tension transmission, if overhead, will also remain approximately constant per mile of route where it is derived from a single generating station supplying a division of main line from 50 to 150 miles in length, the voltage being varied to some extent to suit the load and the distance of transmission.

The watt-hours per ton-mile required for the types and weights of trains hauled on sections of British main line carrying dense traffic are not easily determined, nor are there any general statistics available as to the coal consumption per ton-mile, either gross or trailing, for steam locomotives.

The L.M. and S. Railway have, however, within the last two years carried out a number of dynamometer car tests with main-line trains, the results of which are given in abstract in Table 7. The dynamometer car is fitted with an integrator which records the horse-power-hours at the drawbar, and it is possible from these records, and from the published results of others, to deduce a figure for the watt-hours per trailing ton-mile which would be used by an electrically hauled train, and for the coal per ton-mile which would be used by a steam-hauled train for a general main-line service. It will be observed that the records have been made with very heavy and fast trains on routes with heavy gradients, and with both passenger and goods trains. The results are therefore probably on the high side.

The average figures of the tests are as follows:—

Max. draw-bar h.p. recorded for one locomotive	1 232
Max. speed on the level or on up gradient, m.p.h.	65
Lb. of coal per ton-mile gross, including all losses	0·175
Horse-power-hours per trailing ton-mile ..	0·036
Equivalent watt-hours per trailing ton-mile ..	26·8
Lb. of coal per draw-bar h.p.-hour, excluding shed duties	4·52
Lb. of coal per draw-bar h.p.-hour, including shed duties	5·89

In regard to the figure of 26·8 watt-hours per ton-mile, if the gross weight of train be taken at 320 tons, Mr. Roger Smith uses the figure of 26 and Mr. Parodi estimates it at about 30.

Figures taken from tests on other routes in Great Britain, given in Mr. Hughes's paper before the Institution of Mechanical Engineers on superheating and compounding, tend to show, allowing for the fact that all the figures examined are test-results made presumably with engines in first-class condition with picked drivers, that the figure of 0·175 lb. of coal per ton-mile used as the basis of calculating gross train weight is probably a fair approximation to the truth.

A rough check on the accuracy of these figures is given by multiplying the coal per ton-mile thus experimentally obtained by the estimated gross ton-miles for a 100-mile section of main line carrying traffic very similar to that of the tests. The annual coal consumption thus obtained only differed by 1·6 per cent from the actual coal consumption for the year 1922.

Except as regards suburban electrified lines, gross ton-mile figures do not exist: the only figures available in the Ministry of Transport statistics, or easily obtainable from the railway companies' own records, are engine-miles divided under various heads such as passenger, freight, shunting, light, average freight train load, coal per engine-mile for passenger, freight and shunting services, and the number of wagons per freight train.

To obtain a fairly reliable estimate of the ton-miles per annum for any railway system it is first necessary to obtain figures for the average weight of each class of train.

From the coal per engine-mile and the coal per gross ton-mile as ascertained by test, it is possible to estimate the gross weight of each class of train. An arbitrary estimate of the weight of locomotive enables a deduction to be made for this, leaving the trailing weight of each class of train.

In the case of freight trains the average trailing load thus obtained may be checked by taking from

NOTE.—For detailed explanation of basis of figures in above table see Appendix 4.

the statistics the number of wagons per freight train and the average net tons of load per train; by assuming an average tare weight for the wagons the trailing tons weight of freight train may thus be ascertained. The figures obtained by these two different methods may be further examined in the light of the actual average weights of both passenger and freight trains taken over 2 days at a period of the year when traffic is fairly heavy on a 100-mile double-track section of main line carrying mainly through traffic, and with an average weight of train for the same section obtained in a different way. Details of the methods of arriving at these figures are shown in Table 8. These figures show a fair measure of agreement and are sufficient to demonstrate that the assumption, for the purpose of calculating ton-miles per mile of single track of an average trailing train weight for all classes of traffic of 250 tons, is fairly correct and, if anything, gives the advantage to the steam locomotive when the figure is used as a basis for traffic density and the units per engine-mile.

Table 9 shows how, on the basis of the cost of electrification of 100 miles of double track, the cost of the equivalent of 1 000 watt-hours at the tread of the electric locomotive wheels in relation to the density of traffic in trailing ton-miles per mile of track per annum is built up. From the assumption that the gross train weight, i.e. that of the locomotive plus the trailing load, is 320 tons, the units required per engine-mile and the cost of current per engine-mile are deduced; it will be noted that this cost of current includes all fixed charges. It appears that the cost of current will always be higher per engine-mile than that of coal per engine-mile delivered to the locomotive running shed, but that at any density of traffic equal to or higher than 2 300 000 trailing ton-miles per track-mile per annum, the lower costs of operation of the electric tractor more than compensate for this increase in the cost of energy.

Table 10 shows the application of this current cost to the whole cost of locomotive operation and the consequent reduction which may be expected in the total cost of locomotive operation per engine-mile in relation to the density of traffic.

Fig. 8 shows in graph form the cost per unit at the locomotive wheel and the reduction of cost per engine-mile due to electrification. It also shows the corresponding costs if the cost of current is taken at 0·5d. per unit instead of 0·4d. and the cost of track equipment increased by 10 per cent. The figures have been taken on a very conservative basis so that it may be assumed that, even discounting to some extent the reduction in operating costs, main-line electrification is worth carrying out at a density of 3 000 000 or more trailing ton-miles per track-mile per annum.

It will be noticed that no addition has been made to the cost per engine-mile for electric working to cover any capital charges on the new locomotives that would have to be provided to replace steam locomotives. This charge does not arise, because the whole cost will be borne by the Renewal Fund. The ratio of the cost of the electric locomotive to the cost of the steam locomotive for equal draw-bar pull and draw-bar horse-power is less than 1·7 : 1 on the average, but, as the

Units per engine-mile are based on 250 trailing and 320 gross ton-miles per engine-mile. This low figure is due to the inclusion of shunting-miles in engine-miles. Units per engine-mile = 320 ton-miles × 30 watt-hours per ton-mile = 9·6.

Transmission costs are based on overhead conductor, in duplicate, varying in size from 0·05 sq. in. to 0·1 sq. in. Pole line exclusive of copper, taken at £2 000 per mile. H.T. circuit 80 miles at 44 000 volts, 3 phase. Step-up transformers are based on the maximum hourly load of power station in each case with 50 per cent load factor: 4 in service and 2 stand-by taken at £1 per kW.

Substation costs based on £12 per kW installed.

Substation wages based on partial automatic operation.

Track cost based on £2 000 per mile and 10 per cent for special work and 60 miles of sidings (23 per cent of total track-miles).

Cost of track equipment for sidings taken at half main-line cost.

Ten per cent added for special work at junctions on main line.

annual mileage per electric locomotive will be double or more than double that of the steam locomotive, the total cost of the new electric rolling stock will not be as great as that of the steam locomotives which are replaced. For particulars as to relative cost reference should be made to Appendix 2.

The application of these figures of traffic density with the consequent costs to the actual traffic densities of British railways is a matter of some difficulty. To assist in giving a correct picture of traffic densities, Table 11 has been prepared. This shows the traffic densities on some of the principal former railway systems in engine-miles per mile of single track, exclusive of sidings; the same for certain electrified lines; the coal per engine-mile; the average weight of train based on coal per engine-mile and the experimental figure of 0·175 lb. of coal per gross ton-mile; and the consequent density of traffic in trailing ton-miles per track-mile per annum. More detailed figures for one of the systems referred to are also given in Appendix 3.

It will be seen that, taken as a whole, most of the systems fall within the category of possible successful main-line electrifications.

As each of these large systems includes many branch lines with very sparse traffic which could not be profitably electrified, it follows that the main traffic routes must have much higher traffic densities and that electrification on the score of reduced costs for locomotive maintenance and operation alone will be remunerative.

The figures given in the paper indicate that main-line electrification is a probable source of largely increased revenue, and that a thorough investigation of the possibilities of electrification in connection with the main arteries of railway traffic is very desirable.

The author has confined himself strictly to the economies obtainable under Abstracts B and C of the railway accounts, omitting the cost of engine renewals which is assumed to be the same.

It is not within the ambit of a railway electrical engineer to discuss the possible traffic economies which may accrue due to main-line electrification, or the possibilities of accelerated schedules and the consequent growth of traffic, but a substantial increment to the increased net profits indicated is undoubtedly obtainable from traffic sources.

It is necessary also to emphasize the fact (already taken into account by the French Government and railway managements) that an extensive electrification brings a cheap and abundant supply of electricity to large areas of the country now devoid of such supplies.

Assuming that after full investigation of the operating conditions on a considerable section of main line comprising, say, 1 500 miles of track, it was found that the author's broad conclusions were fully justified so that the method of electrification became an immediate problem, there would be several difficult points to consider.

Such an electrification covering possibly 500 miles of route would not be supplied by a single generating station, but would usually be supplied from at least six, and probably from eight, generating stations; consequently the length of high-tension transmission lines would not bear as large a ratio to the route mileage as has been used in Table 9. The use of cables would raise the price of current to a prohibitive figure, and therefore overhead transmission is practically compulsory. Such transmissions, however, are not desirable on the railway itself, not only on account of difficulties in finding a route for the transmission line but also on account of the undoubted interference troubles which would arise in connection with telegraph, telephone and signal circuits. The power company or municipal stations giving the supplies will therefore be obliged to construct overhead transmission lines to the points chosen by the railway company for their substations. The existing electricity supply areas are such as to make it probable that a number of Special Orders would be required, and it would seem that some legislation is desirable which would facilitate the construction of such transmission lines for railway-supply purposes.

The track equipment will in the main be on the third-rail system, but considerations of continuity of contact at junctions, particularly with reference to freight locomotive operation, will necessitate short lengths of overhead distribution, thus involving the provision of both collector shoes and bows on the locomotives. As the overhead collector must be clear above the structure gauge, the bow in its "up" position fouls the structure gauge, and means will therefore have to be provided whereby the bow automatically rises to meet any stretch of overhead trolley and automatically falls when it leaves it, or, alternatively, every overbridge and tunnel will have to be equipped with a dummy trolley. Unless means are provided for making the bow dead when the third-rail shoes are alive, these dummy sections will have to be insulated for the full line pressure.

The cost of electrification of sidings is of importance. It will be observed from column 5 of Table 11 that the mileage of sidings on a railway system with heavy traffic represents from 20 to 30 per cent of the total track mileage. In addition to these railway-owned sidings there is a large mileage of privately owned sidings over which railway companies' locomotives work. It has not yet been possible to determine whether sidings would be more economically dealt with by electrification with overhead conductors or by operation with storage-battery locomotives. Probably both methods would be adopted. In some cases the cost of the overhead work for the sidings would be nearly as high as for the main track. The work carried out at Melbourne in connection with Flinders-street and that done on the Newport–Shildon line, however, give grounds for assuming that it is probable that as a whole the cost per mile of electrification of the sidings would not exceed half that of the main tracks.

The provision of electric locomotives capable of the maximum utilization of traffic, which is of the utmost importance in view of their capacity for continuous traffic, is perhaps the most difficult problem of all. Its solution is, however, facilitated by the approximation of the speed of freight and passenger trains made possible by electric traction.

The advantage of the increased speed possible with

freight trains hauled by electric locomotives was very clearly brought out by Mr. Watson in the discussion on Sir Philip Dawson's paper on "The Financial Prospects of Railway Electrification" read before the Institute of Transport on 7th May, 1923. Mr. Watson stated that there were two speeds of passenger trains between New York and Newcastle, and five speeds for freight trains; in consequence, there was a large waste of engine time by trains of lower priority having to give preference to those of higher priority. Electrification was going to reduce these seven speeds to three: 90 per cent of the train mileage would be run at two speeds only, namely, 60 m.p.h. for fast expresses and 30 m.p.h. for stopping passenger trains and freight trains.

The speed of freight trains is in general limited by (1) the brake power available, and (2) the efficiency of axle-box lubrication. In regard to the latter, the existence of a very large number of grease-lubricated axle boxes is the limiting feature. Maximum speeds of 45 m.p.h. are, however, usual even with these grease boxes, and the average speed can obviously be raised very considerably. The electric locomotive can be braked in new designs to a greater extent than the average of the steam freight locomotives now in use. The utilization of field control also permits of a very wide range of speed with a comparatively small percentage of weight variation in the motors.

Standardization of design and the use of a minimum number of types will therefore be essential conditions of success. From the experience gained in France and elsewhere it would seem that three types should suffice for the new conditions which will be brought about by electrification: (1) B–B type for shunting and local freight services; (2) B–B type for ordinary freight; (3) 2–D–2 type for fast freight and express passenger work. The whole locomotive design can be common for the first two types, with the exception of motor, pinion and gear case.

The 2–D–2 type will be utilized when required on full field in the series-parallel motor combination for the services performed by the two B–B types. All types will have four-motor equipments, field control and rheostatic brakes. The determination of the proportionate number of each type to be built will, however, be a matter of extreme difficulty and will finally be decided on an empirical basis. The control of the 2–D–2 type will be used on all types and will be operable in combination with the control used on the multiple-unit trains.

To improve brake control on routes with heavy gradients, electrification makes it possible to equip a certain number of freight brake-vans with collecting shoes, vacuum reservoir, and vacuum pump and vacuum brake gear, thus giving, in case of a break-loose on a rising grade, the goods guard a control over the train much superior to that possible under steam conditions.

The problem of dealing with train-heating is not easy, but the electrically heated boiler used by Sir Vincent Raven on his electric express passenger locomotive will probably have to be used in the initial stages. As electrification progresses trains which circulate exclusively in the electrified area will be fitted with electric heaters, but the present system of lighting will continue. Incidentally, the substitution of electric heaters for the present steam system will eventually effect a substantial economy as compared with the present steam-heating system.

Most difficult of all of solution is the problem of making the main-line express or freight locomotive perfectly safe to operate with one man. This will be a matter for future consideration and, obviously, at the outset of the electrification locomotives handling heavy trains or trains running long distances without a stop will be operated by two men as at present. It may be mentioned that locomotives under 1 000 h.p. are to-day operated by one man on the Loetschberg Railway.

It is evident that such far-reaching changes in the equipment of British railway systems will of necessity bring with them many radical alterations in methods of operation. If the fullest advantage is to be taken of the capabilities of the new system of traction, operating officers will have to adjust their methods to these new conditions.

In conclusion, it will be realized that those in whose hands rests the operation and financial success of a public utility corporation such as a railway naturally shrink from the vast responsibility of expending many millions on the trial of a system of traction so novel and unfamiliar to them, and very rightly are unwilling to embark on such an enterprise without the certain prospect of success. The evidence of certain success has not as yet been put before them, and all the author can hope is to have made a prima facie case for full investigation.

The author wishes to acknowledge the assistance he has received from the writings of many other workers in the field of electric traction, particularly the papers of Sir Vincent Raven, Mr. Roger Smith, Mr. Parodi and Mr. Bachellery.

Summarized Conclusions.

(1) The density of traffic on most of the suburban electrified lines in Great Britain at the present is about 20 000 train-miles per track-mile (excluding sidings) per annum.

(2) The cost of locomotive operation as detailed under Abstracts B and C of the Railway Accounts, excluding locomotive renewals, is less per train-mile for the electric suburban services than per engine-mile for the average of all the steam-hauled services on the larger of the former British railway systems, including all branch lines.

(3) The density of traffic on these systems, including all their branches, in engine-miles per annum approaches the density in train-miles per track-mile, excluding sidings, per annum on the suburban electrified lines, but in ton-miles is greater owing to the greater average weight of train.

(4) As a considerable proportion of the total track mileage is made up of branches with sparse traffic, the density of traffic on the main trunk routes in ton-miles per track-mile per annum must be very much greater than on the electrified suburban lines.

(5) Owing to the standing charges on the capital

expenditure on high-tension transmission lines, sub-stations and track equipment, and the losses in transmission and conversion, current, even if purchased at the generating station busbars at 0·4d. per unit, is more costly than coal as supplied to the tenders of the steam locomotive at the locomotive running sheds.

(6) The cost of current, converted to tractive effort at the electric locomotive wheel-tread, being greater per electric engine-mile than the cost of coal per engine-mile for the steam locomotive, the extent to which this cost is greater depends on:—

(*a*) the density of traffic in ton-miles per running track-mile per annum,
(*b*) the ratio of the siding mileage to the running track mileage,
(*c*) the number of junctions.

(7) The electric locomotive as a tractor compared with the steam locomotive is superior in every way except mobility as a self-contained unit.

(8) In considering operating costs, the total of enginemen's wages will be less due to:—

(*a*) elimination of engine duties,
(*b*) elimination of double crews for double heading,
(*c*) elimination of movements for turning, coaling and watering,
(*d*) utilization of one man instead of two on local trains composed of multiple-unit stock, and on shunting engines.

(9) Shed wages, other than repair wages, will be almost eliminated, as the locomotives will no longer go to the sheds except for repairs and for a fortnightly inspection.

(10) Repairs both at the sheds and at the main repair works are reduced to about one-third of the present cost per engine-mile, due to the elimination of reciprocating parts and the boiler.

(11) The capacity of the existing locomotive repair works and locomotive running sheds is therefore increased.

(12) Water is no longer required, and the cost of it therefore disappears.

(13) Simplification of design of electric locomotives has so lowered their prime cost that the replacement of the steam locomotive by the electric locomotive is a revenue charge.

(14) The capabilities of the electric locomotive for maintaining its normal speed on gradients and in unfavourable weather will permit of a substantial reduction in timings without increase in the maximum speed and with a small increase, of the order of 5 to 10 per cent, in the cost of energy only.

(15) The number of large generating stations in this country is now such as to permit in most cases current to be purchased by the railway companies, and offers the further advantage that an extensive electrification will not be dependent on a single generating station.

(16) The load factor of these purchased supplies should be such as to make the price of current very low.

(17) The figures given in the paper indicate that after paying all fixed charges on capital expended, the railway companies should obtain a further net profit representing from 5 to 10 per cent on the capital expended in electrification.

(18) Apart from the question of development of traffic due to increased facilities, main-line electrification is likely to be more profitable to the railway companies than suburban electrification.

(19) In the paper, only the net profit arising from more economical working of locomotives has been taken into consideration; there will be additional profits arising from:—

(*a*) elimination of necessity for bridge renewals for heavier axle loads,
(*b*) slight reduction of wagon stock due to quicker wagon movement and elimination of locomotive coal traffic,
(*c*) reduction in painting and longer life of bridges and stations,
(*d*) reduced wear and tear of permanent way,
(*e*) reduced wages of goods guards due to reduction in goods train-hours by quicker movement,
(*f*) elimination of necessity for expenditure on loops and widenings,
(*g*) increase in the capacity of the line.

APPENDIX 1.

Data on Reduction in Number of Locomotives by Substitution of Electric Traction, and Reduced Cost of Repairs.

On the New York, New Haven and Hartford Railway, which has 550 miles of electrified track, in 1921 the electric passenger locomotives averaged 33 000 miles per locomotive failure, the average detention per failure being 18 minutes. The annual mileage per locomotive was nearly 60 000. The freight locomotive mileage per locomotive failure was approximately 22 500. These locomotives frequently made two round trips in 24 hours, mileage 272, whereas under steam operation the daily locomotive mileage was from 100 to 120. During the years 1915–1921, 16 electric switching locomotives were in actual service over 70 per cent of the total time, and during 1916 they realized over 77 per cent. These locomotives are operated 24 hours per day, and consistently make 140 miles on the basis of a running speed of 6 miles per hour. They have replaced steam locomotives in the ratio of 1 to 2 and have realized a coal saving of 65 per cent. On the Pennsylvania electrified lines in New York, main-line electric locomotives realized 78 600 miles per detention on account of locomotive troubles, and during one year there was a total train delay of only 55 minutes due to failure of motive power. These locomotives are now averaging about 4 500 miles per month. On the Norfolk and Western Railway two 300-ton electric locomotives now haul trains of 3 250 tons at 14 miles per hour, whereas previously three Mallet steam locomotives were required,

the speed then being 7 miles per hour. Twelve electric locomotives were purchased to replace 24 Mallet engines and still handle the service, although when placed in traffic 33 Mallet locomotives would have been required, and the volume of traffic has also further increased. During 1922 these engines made an average mileage of 37 820, more than 100 miles per day per engine. On the New York, Westchester and Boston Railway during the heavy snowstorms of 1919–1920, when the service on many steam roads was seriously disorganized, operation of the suburban service was 100 per cent perfect. In 1919, the average mileage per car was over 42 000, and the average car-mileage per minute of delay 2 700. On the Philadelphia suburban service of the Pennsylvania Railway approximately 600 trains per day are now operated, as compared with 160 under steam conditions. During the year 1919 over 2 883 000 car-miles were run, with an average of over 48 000 car-miles per detention. Figures taken from the Interstate Commerce Commission Accounts for 1919 give a comparison, brought down to a common basis of 100 tons on the driving wheels, of repairs per locomotive-mile for steam locomotives and direct-current electric locomotives. The cost of repairs and engine-house expenses for steam are 49·8 cents per locomotive-mile, as compared with 9·77 cents per locomotive-mile for the electric, or approximately 2s. per mile for steam as compared with 5d. for electric. If the actual figures per locomotive-mile are taken without considering the weight on the drivers, the cost for steam is about 1s. 8d., as against 6d. for the electric. As further evidence of the extremely low cost of repairs to be anticipated with electric locomotives, the 2–C–1 outside-gear alternating-current electric locomotive of the Swiss Federal Railways was examined after 80 000 miles running, and no wear could be found on the gears nor were any adjustments or repairs required to either motors or gears. This of course is a result unattainable with a steam locomotive, which would have required a heavy general repair after running this mileage from new. From the standpoint of the electrification of British main lines, however, the most important evidence on this crucial question of the cost of repairs comes from Sir Vincent Raven in his paper on electric locomotives read before the Institution of Mechanical Engineers in November 1922.

The North Eastern Railway alone in this country, with the exception of the Metropolitan Railway, has had experience of the actual cost of repairs for locomotives working main-line traffic. On the Newport–Shildon line the 5 electric locomotives which replaced 13 steam had a mileage of over 60 000 miles per annum, and the cost of repairs and shed wages was less than one-seventh of that of steam locomotives doing similar work. In fact these electric locomotives were at least 50 per cent more powerful than steam locomotives of similar weight. The shunting locomotives which have been in use on the same railway for 18 years corroborate these figures, the cost of repairs and shed wages being only one-sixth of that of steam locomotives doing the same class of work.

The Metropolitan Railway operates a number of trains hauled by electric locomotives of the B–B type between Baker-street and Harrow, and the cost of maintaining these is fairly comparable with that of maintaining the steam locomotives which haul the same trains from Harrow onwards. In this case, in spite of some abnormal expenditure on the electric locomotives, the cost of these for repairs, inspection, shed wages, lubricants, stores and clothing was less than one-third of that for the steam locomotives.

APPENDIX 2.

Cost of Replacement of Steam Locomotives by Electric Locomotives.

It is an almost essential condition of successful financial results in main-line electrification that the provision of the electric locomotive stock should be chargeable to revenue. This would be impossible were it not for the greater annual mileage obtainable from the electric locomotive.

Locomotive or other machinery renewals, if paid for from revenue, should be made on a basis of replacing like with like. The locomotive renewals effected annually on a railway should leave the total haulage capacity of the locomotive stock unaffected. Variations in prices should not affect this principle and, taken year by year, the sum expended on renewals should fluctuate. In actual practice this is inconvenient and, in many cases, it is usual to set aside a fixed sum, making adjustments for minor fluctuations in prices by deferring renewals in dear years and accelerating them in cheap ones, while unforeseen extreme fluctuations such as those caused by the war are dealt with specially and in relation to other factors such as fluctuations in receipts arising from the same cause.

For the purpose of this paper, however, the author assumes in the first instance that electrification is being carried out solely to reduce working expenses and that, consequently, the haulage power of the locomotive stock will not be increased in the aggregate, at any rate appreciably.

From the figures given below it will be seen that the assumption is not necessary because, if on a mileage-per-annum basis one electric locomotive can replace two steam locomotives, the cost of replacement of equal haulage power will be less for electric than for steam locomotives.

Apart from any question arising from an accountancy point of view in connection with the ratio of pre-war and present-day costs, the provision of the electric locomotives necessary will therefore not be a charge against capital.

The 4–6–0 four-cylinder steam locomotive, No. 3 in Table 2, is a typical express passenger tractor; its weight empty is 92 tons, and its current market value at present prices at £80 per ton is approximately £7 500. Its electrical equivalent type might be taken as No. 8 in the same table, namely, weight 90 tons and 2 100 horse-power on 1-hour rating, the cost of which would be approximately as follows :—

		£
2 100 h.p. of motors at £2·5 per h.p.	..	5 250
Control and cabling at £1·2 per h.p.	..	2 520
Vacuum pumps, motor-generator, etc.	..	1 000
55 tons of locomotive structure at £75 per ton		4 125
		£12 895

i.e. £143 per ton.

$$\text{And ratio} \quad \frac{\text{Electric locomotive cost}}{\text{Steam locomotive cost}} = \frac{1 \cdot 72}{1}$$

If the steam passenger locomotives averaged 26 000 miles per annum, then for the fixed charges to be the same the electric locomotive mileage would have to be 44 750 miles per annum; excluding Sundays and 26 days per annum for examination and repairs, the daily mileage would have to be 156.

The steam and electric freight engines may be compared on the basis of the 0–8–0 shown as No. 11 in Table 2, and the 4–4 electric Midi Railway No. 15 in the same table. The weight of steam locomotive empty is about 78 tons, and its current market value at £80 per ton approximately £6 240. The cost of the electric locomotive, weight 70 tons, will be approximately as follows:—

		£
1 400 h.p. of motors at £2·2 per h.p.	..	3 080
Control and cabling at £1·5 per h.p.	..	2 100
Vacuum pumps, motor-generator, etc.	..	1 000
48 tons of structure at £75 per ton ..	..	3 600
		£9 780

i.e. £140 per ton.

$$\text{And ratio} \quad \frac{\text{Electric locomotive cost}}{\text{Steam locomotive cost}} = \frac{1 \cdot 56}{1}$$

If the steam freight locomotive averaged 18 300 miles per annum, to obtain equality in fixed charges the electric locomotive would have to average 28 550 miles per annum, or 100 miles per day on the same basis as the passenger locomotive.

This electric locomotive could haul 720 tons, trailing, up a 1 in 100 grade at 26 m.p.h. The test load was 254 tons up 1 in 30 at 28 miles per hour.

If the 0–6–0 steam freight locomotive, the empty weight of which is 56 tons and the cost at present prices £4 480, were replaced by an electric locomotive 0–4–4–0 of similar draw-bar h.p., viz. 800 h.p. at the 1-hour rating, the cost of the electric locomotive would be:—

		£	Weight, tons
Four 200-h.p. motors, control and cabling		4 400	18
2 bogies and gear cases	..	1 125	14
Structure 25 tons at £75 per ton..	..	1 875	25
		7 400	57

i.e. £130 per ton.

$$\text{And ratio} \quad \frac{\text{Electric locomotive cost}}{\text{Steam locomotive cost}} = \frac{1 \cdot 65}{1}$$

The tractive effort of the locomotive at 30 m.p.h. would be 12 000 lb., corresponding to a haulage capacity of 290 tons up a 1 in 100 grade, and 570 tons on a 1 in 300 grade at 32 m.p.h.

If it is correct that double the mileage can be found by the traffic department for a day's work for an electric locomotive as compared with a steam locomotive (for there is no doubt about the capacity of the electric locomotive to treble the steam-engine mileage if necessary), there is then, on the basis of replacing like haulage capacity with like, a very considerable margin for building larger electric locomotives to replace the steam locomotives, and at no greater cost than would have been involved in normal steam-locomotive renewals.

The question of the allowance to be made in the future for the obsolescence and life of the electric locomotives is also of interest. The usual assumed life of a steam locomotive is 40 years. There seems little doubt, judging from the results obtained on the Liverpool and Southport line and on the District and other early electrified lines, coupled with consideration of modern improvements in design, that the life of the electric locomotive will be just as great as, or greater than, that of the steam locomotive. It is probable, indeed, that whereas the steam locomotive 40 years old consists of hardly more than the original brake rods and, possibly, frames and wheel centres, the rest having been renewed, after 40 years the electric locomotive will exist *in toto* as built. As regards obsolescence, after a certain stage has been attained in the development of a new invention a measure of finality is arrived at and obsolescence is slow until some further complete innovation replaces the original. The older a method the higher should be the rate of obsolescence. There is therefore no sound reason for assuming at the outset any different life or rate of obsolescence for electric locomotives than for steam, though after more extensive experience the life may be increased and the rate of obsolescence reduced.

APPENDIX 3.

The question of the density of traffic is of such importance in connection with the cost of current for main-line electrification purposes that it is desirable to set out in some greater detail the comparative figures for the year 1922, in connection with the traffic density on one of the former large independent railway systems which carried the heaviest traffic and one of the suburban electrifications.

Coaching train-miles ..	..	..	..	20 480 890
Coaching shunting-miles	..	..	..	1 466 705
Freight train-miles ..	..	..	..	22 085 909
Freight shunting-miles	..	..	..	12 087 646
Assisting coaching-miles	..	..	..	632 846
Assisting freight-miles	..	..	..	2 943 450
Light mileage	..	..	..	2 605 576
Departmental mileage	..	..	..	2 041 550
Total engine mileage			..	64 344 572

No. of single-track miles exclusive of sidings	3 568
Miles of sidings	1 831
Freight and coaching train-miles, excluding shunting, light, departmental and assisting miles	42 566 799
Train-miles only per track-mile, exclusive of sidings	11 900
Total engine-miles per track-mile, exclusive of sidings	18 000
Shunting-miles, coaching and freight per siding-mile	7 400
Coal per engine-mile, passenger services ..	47·14 lb.
Gross weight of passenger train based on 0·175 lb. per ton-mile	270 tons
Coal per engine-mile, freight services ..	58·35 lb.
Gross weight of freight train based on 0·175 lb. per ton-mile	334 tons
Gross coaching train ton-miles, 20 480 890 × 270	5 530 millions
Gross freight-train ton-miles, 22 085 909 × 334	7 380 millions
Total gross train-ton-miles on running lines excluding sidings (average gross train weight 304 tons)	12 910 millions
Gross train-ton-miles per track-mile per annum, excluding sidings	3 620 000
High-tension kWh per track-mile, excluding sidings, at 45 watt-hours per ton-mile ..	163 000
High-tension kWh per substation per annum with 10 miles of 4-track route fed from one substation	6 570 000

Comparative Figures for Suburban Electrified System.

	1922
Train-miles	2 264 732
Ton-miles	360 433 418
Average train weight (tons)	159
High-tension kWh used for traction ..	43 335 972
Track-miles electrified	121
Train-miles per track-mile	18 700
Ton-miles per track-mile	2 980 000
High-tension kWh per track-mile	362 000
Average high-tension kWh per substation per annum (average suburban electrification)	5 500 000

These figures clearly show that, excluding shunting, assisting, light and departmental mileage, the average train-ton-mile per track-mile density on the large steam-operated system is 20 per cent greater than on the electrified suburban system, but that owing to the lower energy consumption per ton-mile for the former the electrical demand density is only 45 per cent of that for the electrified suburban lines.

As the load factor on the substations for the steam-operated system would be much better than the load factor for the electrified suburban lines, owing to the all-night freight traffic which does not exist on the latter, the kilowatts of substation plant per track-mile required for the steam-operated system would be less than half of that required for the electrified lines. An average figure for electrified suburban lines with this traffic density is about 180 kW of rotary converter plant per track-mile, and the amount of converter plant required for main-line work will therefore be about 90 kW per track-mile; but the provision necessary for the power for shunting mileage will probably raise this figure to 120 kW.

As, however, the suburban electrification figures given above represent track, most of which is operated at 600 volts, and the main-line electrification would be carried out at 1 500 volts, it is fair to assume that the distance between substations would be at least three times as great for the main line. In these circumstances the total annual output of the main-line substations would be higher than for the suburban system, though the maximum loads would be smaller owing to the better load factor.

APPENDIX 4.

Notes in regard to Table 7.

Steam Locomotives.

Results.—The results are all calculated from figures obtained from dynamometer-car records.

Tractive resistance.—The total tractive resistance of the train in lb. per ton on the various runs is obtained by dividing the average tractive effort whilst doing positive work, by the weight of the train hauled.

The resistance of the train on the level has been taken from curve 4 in Fig. 5 (derived from recent tests on L.M. and S. passenger stock—weight of train 435 tons); and that of goods trains on the level from curve 2 in the same figure.

The resistance due to gradient, etc., is the difference between the total resistance and that on the level.

The total tractive resistance of the engine in lb. per ton is obtained by taking the resistance on the level at the average speed whilst doing positive work (as given in Fig. 5, curve 1), plus that due to gradient obtained as above.

Horse-power and h.p.-hours.—Draw-bar horse-power and draw-bar h.p.-hours are taken from the dynamometer car records, the energy to overcome the total tractive resistance of the engine being added to give the gross horse-power and gross h.p.-hours.

Ton-miles.—The total ton-miles include the weight of engine and tender (gross ton-miles), and the trailing ton-miles exclude the weight of engine and tender.

Coal consumed.—The coal consumed between terminal stations (excluding shed duties) and the total coal used (including shed duties) are given. The average of the laboratory tests over a period of two years on classes of coal similar to that used in these tests gave a carbon content of 58·23 per cent, volatile matter 32·74 per cent, ash 9·62 per cent, sulphur 2·48 per cent, evaporative power 13·88 lb. of water per lb., calorific value 13 481 B.Th.U.'s per lb.

Mechanical efficiency.—This is obtained by dividing the draw-bar horse-power by the gross horse-power.

Thermal efficiency.—This is equal to

$$\frac{\text{h.p.-hours} \times 33\,000 \times 60 \times 100}{\text{B.Th.U.'s in fuel per lb.} \times 778 \times \text{coal consumed}}$$

and is considered in the table under the following conditions :—

(*a*) Gross h.p.-hours and coal consumed (excluding shed duties).
(*b*) Gross h.p.-hours and total coal consumed (including shed duties).
(*c*) Draw-bar h.p.-hours and coal consumed (excluding shed duties).
(*d*) Draw-bar h.p.-hours and total coal consumed (including shed duties).

Electric Locomotives.

Results.—The same energy is required to haul the trains as in the case of the trains hauled by steam locomotives. The author has taken the case of a 116-ton electric locomotive, this being more than capable of dealing with requirements.

Tractive resistance.—The total tractive resistance of the electric locomotive is obtained by the addition of the following :—

(*a*) Resistance of the locomotive as a vehicle, taken from Fig. 5, curve 3. This curve is an average of the results given by Mr. Carus Wilson and Mr. Carter, and does not include the resistance of gears and motor bearings (this resistance being included in the overall efficiency of 66·6 per cent from power station to tread of driving wheel).
(*b*) Resistance due to gradient, etc.

Coal consumption.—The coal consumption at the power station is arrived at by taking the total h.p.-hours required for the engine and train, converted to kilowatt-hours, and an overall efficiency of 66·6 per cent has been taken to obtain the equivalent kWh at the power station.

A figure of 1·98 lb. of coal per kWh output from the station has been used (Dalmarnock power station, March 1923), the calorific value of the fuel being taken as 11 000 B.Th.U.'s per lb.

Description of runs.

16 *Passenger runs*—Manchester to Blackpool.

On the outward runs the respective heights above sea-level of start and finish were 110·28 ft. and 68·62 ft., the first 5 miles being a stiff up gradient of approximately 1 in 130, whereas on the return run the length of approach to this maximum point was 14 miles.

5 *Goods runs*—Crofton to Mytholmroyd, one way only.

The respective altitudes were 142·44 ft. and 328·7 ft., this giving an average up gradient of 1 in 695.

Passenger runs. 141 miles—Crewe to Carlisle and return.

Outward run—altitude at Crewe 161·86 ft., altitude at Preston 68·1 ft., highest point at top of Shap 916 ft., altitude at Carlisle 67·6 ft. The approach to Shap on the outward and return journeys is shown clearly in Figs. 3 and 4.

Passenger runs. 90·1 miles—Preston to Carlisle.

Goods runs. 90 miles—Preston to Carlisle.

The Pennsylvania Railway Company, from their rotary testing plant at Altoona, publish the results of tests on various steam locomotives as shown in Table 12. The columns giving the thermal efficiencies are calculated on the dry coal consumed during the test. It will be noticed that these figures are higher than those given by the author, this being probably due to :—

(*a*) Higher boiler pressure—250 lb. per sq. in. (against 180 lb. per sq. in.);
(*b*) The resistance at given speeds of leading, trailing and tender wheels has not to be overcome on a rotary test plant;
(*c*) No resistance due to curves, wind pressure, or track depression;
(*d*) The tests were carried out with full throttle opening and later cut off;
(*e*) Dry fuel.

Table 12.

Pennsylvania Railway Tests on Steam Locomotives.

APPENDIX 5.

ESTIMATE OF REDUCTION IN COAL CONSUMPTION TO BE EFFECTED BY ELECTRIC TRACTION ON ALL RAILWAYS IN GREAT BRITAIN.

Total engine-miles of standard gauge in 1922 in Great Britain = 504 916 311

Average coal consumption per engine-mile for all services = 54·04 lb.

$$\text{Therefore total coal consumed} = \frac{504\,916\,311 \times 54\cdot04}{2\,240}$$
$$= 12\,193\,776 \text{ tons}$$

or, say, 12 195 000 tons, costing £14 815 177.

Total standard-gauge mileage in Great Britain, excluding sidings = 35 088

If the coal consumption is 54 lb. per engine-mile and 0·175 lb. of coal per gross ton-mile, then gross weight of train is 54/0·175 = 308·5 tons

Total ton-miles per annum = 308·5 × 504 916 311
= 155 400 millions

Watt-hours per ton-mile = 30

Efficiency = 66·6 per cent

Therefore watt-hours per ton-mile at power station = 45.

Coal consumed = 1·98 lb. per unit.

Therefore total coal

$$= \frac{155\,400\,000\,000 \times 45 \times 1\cdot98}{1\,000 \times 2\,240} = 6\,180\,000 \text{ tons}$$

Average saving per annum in coal = 6 010 000 tons.

COAL CONSUMED ON RAILWAYS IN GREAT BRITAIN IN RELATION TO THE COAL RAISED IN GREAT BRITAIN, 1922.

Total coal raised in Great Britain in 1922 = 249 607 000 tons

Coal used for railway operation = 12 193 776 tons

Coal used for railway operation represents 4·9 per cent of coal raised.

Coal saved by electrification of railways = 6 010 000 tons.

Coal saved by electrification of railways represents 2·4 per cent of coal raised.

DISCUSSION BEFORE THE INSTITUTION, 27 MARCH, 1924.

Mr. R. T. Smith: The author claims that the density of main-line traffic is greater than that of the corresponding suburban traffic, and he states one reason for this to be the fact that trains on a busy main line are running throughout the 24 hours, whereas on the suburban lines they are limited to 17 or 19 hours. He gives his unit of comparison of cost as the engine-mile. Personally I have always considered that any unit of comparison for electrification should be on the basis of the engine, but I doubt if the engine-mile is the most convenient unit. As the author points out, it takes no account of speed, or weight, or number of stops. It is extraordinarily difficult to manufacture any unit which will allow a satisfactory comparison to be made between the cost of different traffics. Probably the best unit would be some such compound unit as "ton-miles per engine-hour." Although I have not worked out the author's figures on that basis, I have found that such a unit gives much more uniform results. However, properly interpreted the engine-mile is quite a satisfactory unit of cost. The author's unit of density is the trailing ton-miles per mile of track per annum, but the engine-miles per track-mile per annum, from which his unit is derived simply by multiplying by an assumed constant weight of train, appears to me to be really a more convenient unit to deal with. It is very inconvenient to deal with a unit which is in millions. Table 7 gives actual steam-locomotive test figures compared with partly assumed and partly actual electric locomotive figures, and the comparison between steam and electric locomotives in Fig. 8 for various traffic densities is based on certain assumptions which are now, I think, quite agreed among electrical engineers. On pages 749 and 750 the author summarizes the conclusions which he draws from the figures given, namely that it would pay to electrify main lines above a certain density of traffic, which comes out at above 3 million trailing ton-miles per mile of track per annum. The author omits to mention, however, the great traffic advantage of the speed characteristic of the electric motor as compared with that of the steam engine. This has been specially brought out on the Italian State Railways, where nearly all the electrification is three-phase with two fixed speeds, although four speeds can be used where necessary. It was thought at first that uniform speed was a disadvantage, but it was found that the constant speed and the fact that, for most of the traffic, the speed of the slow freight traffic was half that of the fast traffic, was most satisfactory. It has been pointed out that one of the advantages of electrification on main lines even with direct current is that all the passenger traffic can be run at practically one speed and all the freight traffic at half that speed. In view of these and other advantages, and the fact that France contemplates electrifying in its complete programme 5 600 miles of track (or one-third of the whole of the railways in France), that Italy contemplates electrifying 2 800 miles of track, and that Switzerland within a few years will have electrified 1 000 miles, how is it that we have comparatively no main-line electrification in this country? The first and obvious answer is that in all those countries, even in the greater part of France, coal is an import, while there is sufficient water power to run the railways, and it is worth while to do so from the national point of view simply to prevent the import of coal. Apart from that, however, I cannot but feel that electrification is going on in those countries largely because it has become the fashion. Railway electrical engineers are, I think, more or less convinced that beyond a certain density it would pay to electrify main lines in this country; but the traffic officers are not yet convinced, and a good many of the traffic officers do not want to be bothered with it. I am quite convinced that if any one traffic

officer could be induced to put his heart into the thing —because, it is to be noted, nearly all the real troubles devolve on the traffic officers, and it is they who will have to change their methods—and if the fashion could be set by one railway starting any considerable amount of main-line electrification, the rest of the railways would follow suit.

Mr. F. Lydall: The question of the unit of comparison to be adopted is an important one, and I should like to support the author in bringing forward the unit of "trailing ton-miles per track-mile." It is true that it is rather a clumsy expression, especially in comparison with the simple straightforward unit of "engine-mile," but, after all, one cannot get very far in considering any scheme without leaving aside the engine-miles and studying the actual ton-mileage. Ton-mileage represents the work which is to be done; the engine mileage can only do so on a convenient convention that to every engine is allotted a certain tonnage haul. Therefore, whatever may be the general practice, the unit of ton-mileage to be hauled must be used and developed. The author gives certain figures of average tonnage behind the draw-bar, and those of us who follow the developments in other countries, especially in the United States, must be struck by the extraordinary difference that there is between these weights and those which are hauled on other lines. Railway engineers in the United States are getting accustomed to talking of loads of 2 000 to 5 000 tons. The figures given by the author for British railways are perhaps a quarter or a fifth of those. I suppose it is not unreasonable to hope, however, that some day, even in this country, we shall develop to a point at which we shall have a substantial increase of the loads which the author has mentioned. We cannot go on for ever economically hauling 200 or 300 tons of goods with a single engine, a guard, and all the other necessary accompaniments to a complete train. When the time comes for the average load to be doubled, trebled, or even quadrupled, any comparison on the basis of engine-miles at that time with figures of engine-miles at the present time will be completely fallacious. On the other hand, the comparison on the basis of trailing ton-miles will remain exactly the same. The author sets out very convincingly the relative advantages and disadvantages of electric and steam locomotives. Practically the only disadvantage of the electric locomotive that he mentions is that a large number of units may be immobilized owing to the failure of the electric supply. That is perfectly true, but the whole question is what weight to attach to that particular disadvantage: how often have a large number of electric locomotives been immobilized for this reason? I had occasion about three years ago to consider such a point as this, and I was able to obtain, through the kindness of the engineers of the Newcastle Electric Supply Co., some information as to the operation of the Tyneside lines of the North-Eastern Railway which receive power from the Newcastle Supply Co.'s system, and also the mineral line between Shildon and Newport. The records were for a period from 1905 until 1920 and the result was that, on the average, so far as the Tyneside line was concerned, there was interruption of traffic, due to disturbance in the high-tension supply to the substations, on the average only once every two years, and the duration of those interruptions was quite short—a few minutes only. The experience with regard to the Shildon and Newport line for five years was much better, and therefore it was not considered worth while to go through all the records and take out the figures. I have no doubt that the record for the last five years only would be considerably better than that. I think, therefore, that one may claim that on a modern power system, developed in modern ways with protective apparatus and an extensive network, and so on, the interruptions of supply causing stoppage of traffic can be regarded as being genuinely negligible. I should like to ask the author what curve 1 in Fig. 5 represents. I take it that the train resistance of a steam locomotive is derived from the difference between the indicated horse-power and the draw-bar horse-power. On the other hand, I suppose that the train resistance of an electric locomotive is derived from the difference between the brake horse-power exerted by the motors at the treads of the driving wheels, and the draw-bar horse-power. Again, the resistance of a 10-ton wagon (curve 2) at one particular point is given as 15 lb. per ton at 40 m.p.h. This question of train resistance is a very difficult matter, owing largely to the diversity of conditions under which the tests have been made, and the difficulty of correctly interpreting the results obtained. I had an opportunity in South Africa a few years ago of carrying out some very careful tests on goods trains, under conditions rather different perhaps from those customary in this country, but I found that there was a very marked difference indeed between the train resistance of a goods wagon when it was fully loaded and when it was empty. A goods wagon in South Africa is usually a four-wheeled, double-bogie wagon. On the occasion when I made the test the average load per axle varied between 11 short tons and 3·4 short tons; that is to say, the 11 tons represented a loaded 44-ton wagon and the 3·4 tons represented the same wagon empty. The train resistance of the loaded wagon was only about 8 to 9 lb. per ton at 40 m.p.h. The resistance of the same wagon when running light at the same speed was between 24 and 26 lb. per ton. The difference between these figures shows that a good deal of care has to be taken in referring to the train resistance of wagons, because the weight of the wagon itself varies so much. I should be glad if the author would indicate under what conditions curve 2 (which refers to the 10-ton wagons) was taken. Again, curve 4 represents the train resistance of a 435-ton passenger train. In my experience, the train resistance there shown corresponding to 60 m.p.h., viz. 15 lb. per ton, seems to be rather high. Possibly the author has intentionally included a considerable margin for bad weather conditions. A test was made some few years ago on the New York Central Railway with one of their gearless locomotives and 9 passenger cars. At 80 m.p.h. the train resistance was 11·4 lb. per short ton, which is very much lower than the figures given by the author. These figures of train resistance are of great importance when studying the electrification of a main line, because they vitally affect the calculation of energy con-

sumption. On a straight run, with no complications, no curves, no starts, no stops and no gradient, the watt-hours per ton-mile at the draw-bar are directly proportional to the train resistance. In fact, watt-hours = (train-resistance in lb. per ton × 2). For example, if the train-resistance is 10 lb. per ton, the number of watt-hours per ton-mile is exactly 20. In Appendix 1 the author gives some valuable information in regard to the mileage worked by electric locomotives, and the corresponding reduction which is possible in the number of locomotives on an electrified line compared with steam-working. A statement was recently issued, with regard to the electric locomotives on the New York, New Haven and Hartford Railway, to the effect that for the last 17 years, 41 single-phase locomotives constructed by the Baldwin and Westinghouse Companies had each of them on the average worked more than 70 000 miles per annum. On the St. Gothard line some electric locomotives doing three shifts per day of 24 hours—that is to say, assuming there is not far short of 8 hours per shift, they practically work all round the clock—accomplish 435 miles in the 24 hours. The Chicago, Milwaukee and St. Paul Railway has published certain figures which are not mentioned by the author. Mr. Storer stated in 1921 that the record for a continuous 24-hour run on one of the passenger locomotives supplied by his company to this railway was 766 miles. Soon after that a statement was made in the *Railway Gazette* to the effect that "the electric passenger locomotives put into service a year ago make 440 miles run with one engine. During this run they stop at Deer Lodge and change crews. The locomotives are taken off for shop inspection after a mileage varying from 3 000 miles to 5 000 miles, that is, they are inspected every 8 or 10 shifts. Under this operation locomotives have been making records of from 10 000 to 11 000 revenue miles per month." Those figures, of course, are very high compared with any figures that can be obtained in connection with steam locomotives. The only conclusion one can come to with regard to electric locomotives is that the mileage which they can run in the year depends mainly upon the opportunity they have for doing work. If traffic arrangements are suitable, the electric locomotive can, I have no doubt, do anything up to 100 000 miles per annum. If the traffic arrangements are not suitable, it is obvious that, due to long periods of lie-over, fluctuation of traffic and so on, the mileage per locomotive is proportionately reduced.

Mr. F. W. Carter: The author mentions on page 739 that his costs of fuel, and so on, are based on three-phase generation, overhead line transmission, conversion by mercury-arc rectifier, and third-rail distribution to train. Of course some of these factors might be varied without making any particular difference to the results given in the paper. The author mentions on page 748, however, that overhead transmission lines should be taken separately to the substations and not run along the track. I think that the expense would thereby be considerably increased. The author takes the cost of third-rail track equipment in Table 9 as £2 500 per mile, which is, I think, a reasonable figure as it includes special work, but I am not sure whether it includes the moving of the signal rods and other obstacles, which often adds considerably to the cost of the electrification. Whether one uses a third rail or an overhead line is largely a matter of opinion, and probably both will be used on main-line railways in different parts of the country. In Table 5 the author gives the cost of electrical energy delivered to the high-tension lines. Is the last column but one, headed "Typical railway power station supplying suburban electrification," based on an actual case or are the figures estimates? In Fig. 8 the author gives certain curves showing the reduction in operating expense in electrical working as compared with steam, the price of energy being assumed to be 0·4d. and 0·5d. per unit, and I am pleased to see that even in the latter case he makes out a very good case for electrification on most of our main-line railways. In Table 6 he gives efficiency figures which do not agree with Mr. Roger Smith's and Mr. Parodi's figures as regards transformation and conversion. I think, however, that the author's figures are probably the more correct, i.e. that the efficiency of transformation is higher than is generally supposed. Take, for instance, a unit consisting of a rotary converter, with transformers, which is in service represented typically by one hour without load, one hour at one-tenth load, one hour at half load and one hour at full load, with overall efficiencies given in the table below. The total energy output (i.e. load × hours) is 1·6 and the input 1·774. The average efficiency of transformation is therefore 90·2 per cent, with a load factor of 40 per cent.* The main value of the paper in my view

Load	Efficiency	Loss	Time	Output	Input
	%				
0	0	0·030	1	0	0·030
$\frac{1}{10}$	76·0	0·032	1	0·1	0·132
$\frac{1}{2}$	92·0	0·043	1	0·5	0·543
1	93·6	0·069	1	1·0	1·069
		Total ..	..	1·6	1·774

lies in the connection that it establishes between steam and electric working, largely as a result of the careful train tests recorded in Table 7.

Mr. J. S. Highfield: I agree with Mr. Roger Smith that it is a matter of the first importance to interest traffic officers in the value of electrification from a traffic point of view. The author's figures showing the saving in cost by electrification are, of course, of great importance, but, even taking into consideration all that Mr. Lydall has said in regard to the long life of electric locomotives and their capacity to run so many hours of the year, I do not think it at all likely that electrification will be adopted merely to reduce the working expenses. Of course, part of the saving consists in reducing the consumption of coal to approximately one-half as compared with steam locomotives, and this, possibly, might be held to be a matter of national importance, but I do not think so. Therefore, we must

* F. W. Carter: "Railway Electric Traction" (page 382).

look to other reasons than merely the saving in cost for carrying out main-line electrification. If we consider suburban railways, the main reason for electrifying was to enable the lines to carry heavier traffic. Either the traffic grew from natural causes or, alternatively, it was considered that the electrification of a particular line would lead to greater traffic, and this has proved to be true in every case where suburban railways have been electrified. We have no examples of main-line electrification in this country, but if we study the causes that have brought about main-line electrification on the Continent, we find that, in Northern Italy for example, the chief causes were, first, the desire to use water power; secondly, that the load which many of the bridges could carry was strictly limited and, consequently, the weight of steam locomotives could not be increased to deal with additional traffic; and thirdly, that electric locomotives enabled greater loads to be carried at higher speeds without the expense involved in strengthening the bridges. In France, again, there was the desire to use water power to provide a broadcast system of electric distribution for other purposes, and this system naturally worked in well with the development of water power for railway purposes. There was, in short, a combined desire to supply the country with cheap electricity developed from water power and to run the railways without the necessity of importing coal. Also in Japan, where the gauge is 3 ft. 6 in., the easiest method of increasing the carrying capacity of the lines was to electrify in all cases. Therefore, there were extraneous reasons for carrying out electrification, apart from the mere saving in cost. I understand that in all these cases numerous other advantages have resulted, such as increased carrying capacity and increased speed. I think it likely that main-line electrification in this country will ultimately be forced on the railways in order to enable existing terminals and tracks to deal with the heavier traffic and at increased speed. No doubt the increased speed and facilities generally will again react by increasing the traffic.

Mr. A. E. Jackson:* The author gives on page 729 a definition of the engine mileage on a system as the actual number of miles run by all steam tractors whether hauling trains or running light. I should like to ask him whether the steam-locomotive engine-mile mentioned in Tables 1 and 3 is the gross mileage (i.e. all mileage including running for locomotive requirements) or whether it is a net mileage. It would not be fair to compare the cost per gross steam-engine-mile with the cost per electric train-mile. I take it that the last column of Table 1 should in any case refer to the net train mileage. In Table 3 the cost per engine-mile of superintendence is compared for steam and electric working, and it is stated that there is "No change"; but surely if the electric locomotive performs double the mileage per day that a steam locomotive does, the cost of superintendence would be reduced, if not by half, at any rate to a very great extent. With regard to the general question of electrification, the author on page 755 says that the resulting saving in coal is over 6 million tons per annum. If that is so, it seems to me that this is really a national question apart from all other aspects. It may be noted that this quantity of coal would be capable of generating some 7 000 million units of electricity per annum.

* In addition to making these remarks, Mr. Jackson read Sir Philip Dawson's contribution to the discussion (see page 758, col. 2).

Mr. R. Brooks: One very important point which the author makes, and one which I had not quite appreciated before, is that the density of main-line sections is very much in excess of the traffic density on suburban sections which have already been electrified most successfully. The question of standardization has already been mentioned in the course of previous discussions. In most cases the criticism was aimed largely at the manufacturers, but I think that early standardization is to be avoided. Closely bound up with this question of standardization is the matter of simplicity of equipment. It seems to me that very soon we shall be prepared to sacrifice, for the sake of getting simplicity and robustness of equipment, a great many of the refinements which are being demanded at the present moment. After all, we use electrical equipment for the sake of getting efficient transportation, and our whole energies should be directed towards obtaining an equipment which will have the minimum of parts and the minimum of complexity to achieve that object. The author mentions different types of locomotives which may be used to meet the different services, and deals solely with four-motor combinations. This is sound in so far as obtaining a standard type of control is concerned—and that is very important. One has to consider the different capacities of the motor which will have to be controlled and, although it may at first sight seem difficult, it should be perfectly possible, with a properly-designed line of apparatus, to retain the advantages of the unit form of construction—to retain the major elements of the equipment exactly the same, and simply vary the copper content to meet the different requirements of current capacity. The author's summarized conclusions give a very clear picture of what may reasonably be expected from the electrification of main lines. When we consider how conservatively he has arrived at his figures, and the fact that he has not claimed any of the traffic advantages which have always followed the suburban electrifications, we cannot help feeling that his conclusion in the body of the paper might perhaps have been expressed somewhat more strongly than it has been. We have got beyond the region of general considerations and general investigations, and the time should soon be ripe for our railway authorities to investigate particular sections with a definite view to electrification. In conclusion I submit that the electric locomotive is no longer an experiment. Where it has been adopted under proper conditions it is an established and unqualified success, and further hesitation seems to me to savour too much of that over-caution generally attributed to my own countrymen. The record of the work already done justifies the belief that the success which has followed electrification elsewhere may also reasonably be expected in this country.

Sir Philip Dawson (*communicated*): I am sorry that the author has not given calculations for a concrete case and that the figures arrived at are only of a general

nature based on assumptions similar to those contained in another paper by Mr. Roger Smith, dealing with the same subject. I also regret that in treating the problem of main-line electrification the assumption that there is only one system available as regards type of current, working pressure and contact system, has once more been made. All who have investigated in detail the subject of main-line electrification know that much higher line pressures than those contemplated by the author are essential if the system is to be applied in a general way. Also it is to be regretted that in referring to electrification in Europe the author only quotes French practice, having regard to the limited experience so far obtained in that country and to the very extended experience in all varieties of main-line electrification available in Italy, Austria, Switzerland, Germany and Sweden. The map exhibited at the meeting shows the extent of railway electrification in these countries as compared with that in France. Until further experience is available I should also myself hesitate to regard the mercury rectifier as being necessarily the right thing to adopt in connection with main-line electrification in this country. The introduction of the transverter may materially alter conditions, and I am not at all sure that it will not militate in favour of high-tension a.c. traction. As, however, the object of this paper is, I take it, to show that main-line electrification may not only prove desirable but may be essential, and not merely to favour one system against all others, I endorse all that the author has put forward in favour of main-line electrification in this country. I am convinced that there are many main-line sections on British railways where electrification would prove a great financial success. It is unfortunate, but nevertheless true, that grouping has reacted unfavourably on the prospects of electrification, to the great disadvantage of the public and of our industries. The moving spirits of those railways which but for the grouping would have been in the course of carrying out not only suburban but also main-line electrification have disappeared. Sir Henry Thornton and Lord Claud Hamilton had decided to electrify the whole suburban area around Liverpool-street. Sir Vincent Raven and his advisers had prepared a complete scheme for electrifying the main line from York to Newcastle. The late Lord Bessborough, Mr. Charles Macrae and Sir William Forbes had told their shareholders that they intended to electrify not only the whole of their suburban system but also the main line to Brighton, Worthing and Eastbourne. Indeed, the adoption of the single-phase system was based on the express intention to electrify the main line. Before the war the Caledonian Railway was considering the electrification of its system around Glasgow. Now that grouping is completed, we find that the London and North-Eastern Railway not only has no intention of electrifying the main line from York to Newcastle but do not intend to electrify the suburban sections around Liverpool-street and to Tilbury, and the Chairman of the North-Eastern Railway Company, although not satisfied with conditions on the suburban lines, can see no immediate cure except by carrying out widenings and reverting to the policy of railways 20 years ago in the early days of tramway and motor-omnibus competition. Having regard to the importance of the problem, a few conclusions resulting from a complete investigation that I carried out in co-operation with the Locomotive, Goods, Accountancy and Traffic Departments of the London, Brighton and South Coast Railway, and approved by all the departments concerned, may not be without interest, particularly as this investigation was subsequently checked by the highest Continental authority on this subject, who sent over a staff of engineers and, after investigating the whole problem, confirmed the conclusions at which I had arrived. This double investigation took nearly two years to complete and was carried out in the greatest detail, involving the preparation of a complete scheme for electrification in all its details. All the figures were based on statistics for 1920 and 1921 and the summer of 1922. The investigation comprised (*a*) the electrification of the whole suburban system, all goods and main-line trains being run by steam; and, alternatively, (*b*) the electrification of all services in the suburban area and on the main line as far as Lewes, Brighton and Worthing. The basis on which calculations for the capital and operating costs were made was that the seat-miles per annum should be increased by 140 per cent for the suburban and 70 per cent for the main line, this being obtained by more frequent services and by operating the trains at the various hours of the day to meet the passengers to be accommodated. It was shown that an increase in gross receipts of 58 per cent on the suburban and 29 per cent on the main line would give a return of over 8 per cent on the capital involved, and for an increase of 100 per cent on the suburban and 50 per cent on the main line—which the management was convinced would be achieved—a return of 15 per cent would be obtained. The plant provided and the operating costs included, for both cases, an increase in travelling facilities of 140 per cent on the suburban and 70 per cent on the main line. The capital expenditure provided for:—

- The electrical equipment of all tracks and sidings; the transmission lines and substations; altering telephones and telegraph circuits and signalling system, comprising in all the equipment of (in round figures) 500 miles of single track.
- All the motor coaches and electric locomotives required, no allowance being made for the value of the steam locomotives going out of service.
- Wiring of trailer coaches and electrical equipment of driving trailers.
- Necessary additional repair shops and carriage sheds.
- Alterations to tracks, stations and bridges rendered necessary by electrification.
- Additional track facilities, junctions and other permanent way and station alterations required to handle increased traffic.

Engineering and unforeseen expenses were added to the total costs mentioned above, and interest during construction was also provided for. The total figure on the above basis came out (at costs then prevailing) at, in round figures, £11 800 000. A comparison was first made on the basis of electricity replacing the existing steam services, no increase being

provided for. This is an absurd assumption and unfavourable to electrification, as the reduction in the capital cost is relatively small compared with that required to increase the traffic as provided for in the estimates. Even under these conditions, however, a net annual saving in total operating costs of £626 700 was shown over steam. If it were possible—which it is not (without the heavy capital expenditure required for very greatly increasing the track facilities)—to increase the steam services to the same extent as the electric services provided by the full scheme, then there was shown a saving in operating expenses of £1 608 000 in favour of electric haulage. On the basis of electrifying the suburban and main line already referred to, a balance sheet was drawn up supposing that the proposals had been in operation in 1921, allowance being made for increase in maintenance of ways and works, carriages and of all portions where electric equipment as well as the increased service would increase the expenditure. This showed, based on 140 per cent increase on suburban and 70 per cent on main-line facilities, an increase in net receipts above those with the existing steam plant of over two million pounds. The most interesting part of the investigation was that it proved conclusively that by far the best paying portion of the whole proposition was the electrification of the main line to Brighton, as will be shown by the following figures:—

The ratio of the capital required for the suburban electrification to the additional capital required to electrify to Brighton was 7 : 4.

The ratio of the total operating costs of the suburban to the main-line service was 7 : 3.

And the ratio of the net receipts arising from an increase in gross receipts of twice as much on the suburban as on the main line was 7 : 6.

This shows that the increase in the net receipts on the main line is in a greater ratio in actual money than the capital and operating costs, and the main line is therefore by far the most remunerative portion of the electrification. In taking, for purposes of comparison, the average steam locomotive costs over the whole railway, there is, I think, a great danger of drawing false conclusions and, further, of presenting the case of main-line electrification in a much less favourable light than it would appear had the comparison been made with the actual costs of steam-working on those portions of the system for which electrification could be profitably considered. I think it is unfortunate that anyone casually looking at Tables 10 and 11 would draw conclusions adverse to main-line electrification, due to the fact that the figures are based on averages over the whole system, and no one at the present time would contemplate the electrification of all the railway systems of the country. The investigation which I carried out showed clearly that it was not safe to base conclusions on average steam locomotive costs, and that, including the cost of drivers and stokers and also of guards and shunters, there was a very large difference in the locomotive costs per train-mile for suburban, main-line, local goods, shunting and main-line goods trains. On the line that I had under consideration the passenger traffic was by far the greatest. The total passenger traffic on the line proposed to be electrified amounted to just over $9\frac{1}{2}$ million train-miles, as compared with $1\frac{3}{4}$ million train-miles for goods. The local lines accounted for 835 million ton-miles for passenger and 129 million ton-miles for goods services; and the main line for 1 237 million ton-miles for passenger and 415 million ton-miles for goods services. It may be of interest to state that the electrification of the main line as proposed only involved two substations in addition to those required for the purely suburban services. The results recently published by Dr. Wechmann, the Chief Electrical Engineer of the German Federal Railways operating the electrified line Halle–Madgeburg–Leipzig, fully confirm the great financial benefits to be derived from main-line electrification over level country and where electric power is generated by steam. The results which I have investigated in the United States and those achieved on the Continent of Europe, where main-line electrification is much more advanced than in America, clearly demonstrate the great benefits which under suitable conditions may be expected in this country. Incidentally, it may be mentioned that the electrification of the Liverpool-street terminus in London would render free for building purposes an area of some 10 acres in the heart of the City of London of a monetary value which cannot be ignored. The electrification of the Birmingham area would also render it possible to build over the approach to New-street Station, and many other similar examples will at once suggest themselves. Such advantages indirectly resulting from electrification are well realized in America, as evidenced by the Pennsylvania and New York Railway terminal buildings in New York City.

Mr. F. Gill (*communicated*): The author hurts a good cause by saying: "It is an almost essential condition of successful financial results in main-line electrification that the provision of the electric locomotive stock should be chargeable to revenue" (see Appendix 2). While there are probably errors in the detailed application of what follows, it shows the correct approach to this part of the problem. Taking the first cost of the freight electric and steam engines in this appendix, viz. £9 780 and £6 240, and assuming that 100 of these steam locomotives are to be superseded at the same time, such an operation would need £978 000, less what was obtained from the sale of the old steam locomotives, and it would apparently be an impossible proposition, as well as an unsound one, to charge this amount to revenue. A company is entitled to charge to capital that which fairly represents its assets; at the end of the assumed transaction, therefore, the first cost of the displaced steam locomotives should not be represented in the capital account and the entire first cost of the new electric locomotives should be so included. Taking the same 100 locomotives, this requires that the capital account be increased by (£9 780 — £6 240) 100 = £354 000. The facilities (i.e. mileage) obtained by reason of the change has nothing whatever to do with this question of what it is proper to charge to capital. Let us make the following assumptions for each steam locomotive: First cost £6 240; life 40 years; age 15 years; residual value

10 per cent; interest 5 per cent per annum; sale price at 15 years £2 080. Then the rate required for interest and depreciation (other charges such as taxes, insurance, etc., can be added as required) will be 5·7452 per cent per annum. At the end of 15 years

the amount in the depreciation fund for each such steam locomotive is	£ 1 003	
and the unexpired value of the capital is	5 237	
		£6 240
The selling price is	2 080	
There remains a *wastage*, due to the change (for which provision must be made), of	3 157	
		£5 237
and for 100 such locomotives the present loss due to this wastage is		£315 700

To put the 100 electric locomotives into service requires an expenditure of £978 000, obtained as follows:

From depreciation fund for 100 steam engines, each 15 years old	£ 100 300	
From sale of 100 steam engines ..	208 000	
From fund which is to cover wastage	315 700	
From new capital	354 000	
		£978 000

The operation of the electric locomotives has to be sufficiently advantageous to pay off this present wastage loss, viz. £315 700, and its carrying cost, as well as support the charges due to increased capital, viz. £354 000. How long will it take to pay off the present wastage loss? The answer is, in rather less than 8 years; thus:—

Present loss for 100 steam locomotives superseded	£315 700
Added capital charges:—	
£354 000 at 5·7452 per cent per annum = £20 338	
Present value (5 per cent) 8 years, £20 338 × 6·46321	131 449
Total present value 8 years	£447 149
Against this we have:—	
Saving of, say, 4·74d. per engine-mile (see Table 10, 4 000 000 ton-miles) for 36 600 miles (double that for the steam locomotive, page 752) = £722·85 per electric locomotive per annum.	
Present value (5 per cent) 8 years for 100 locomotives = 100 × 722·85 × 6·46321..	467 193
Present value of net saving in 8 years ..	£20 044

If these figures are correct, we may summarize thus:—

To change 100 of these steam locomotives the additional capital required is	£354 000
The immediate wastage charge to be financed (ultimately chargeable against revenue) is	£315 700
This wastage charge, its carrying cost and the added capital charges (for the period) will be cleared off in	8 years
After 8 years there will be a net saving per annum of	£51 947
After paying off the wastage fund, the savings to the 20th year have a present value of	£331 674

[The author's reply to this discussion will be found on page 774].

Mersey and North Wales (Liverpool) Centre, at Liverpool, 17 March, 1924.

Mr. B. Welbourn: The author has very wisely, I think, kept clear of all technical details in the paper and has taken it for granted that British engineers and firms are capable of undertaking the electrification of the British railways from start to finish as and when the demand arises. The real text around which the paper is written is the paragraph in which the author says: "It will be necessary to consider quantitative figures, for the essence of the problem is financial, and the decision whether or not to electrify portions of the British main lines will rest with financiers rather than with technical experts." The electrical engineers of this country have been convinced for some time past that a strong case can be made out for the electrification of the main lines which carry considerable passenger and goods traffic, but I am not so sure that the mechanical engineers and traffic officials of the railway companies, who have to advise their directors, are yet fully converted from their natural prejudices in favour of the steam locomotive and that they believe that a change would be financially justified. I assume that one of the author's objects in initiating this further discussion on the subject is to obtain additional information and, with this object in view, I propose to give the following particulars of some of the benefits derived from the electrification of the Chicago, Milwaukee and St. Paul Railway which were supplied to me in America in 1922. The particulars of this electrification seem to me to be of very great importance, as it is the only example in the United States of America of the conversion of a portion of a transcontinental line. A route of 650 miles, equivalent to 850 miles of single track, has been equipped for 3 000-volt d.c. operation, and the following are some of the results:—

(*a*) The trains operate with one-third less crews than formerly with steam.

(*b*) 42 passenger, freight and switching locomotives replaced 120 steam locomotives on the Rocky Mountain and Missoula division and, in 1917, handled 50 per cent more business than the steam locomotives handled in 1915.

(*c*) 15 per cent of the company's freight cars on the division were released from hauling locomotive coal and were set free for earning purposes.

(*d*) Two years' recent steam locomotive figures show that they run a daily average of 73·4 miles and spend

89 days per annum in the shops, while 15 to 28 per cent of the running time is taken in going to the ashpit on mountain grade work. The electric passenger locomotives are maintaining an average of 11 000 miles per month.

(*e*) In 1921, steam locomotive maintenance cost 33 cents per engine mile and the corresponding figure for the electric locomotive was 22 cents.

(*f*) The savings in locomotive charges are of the order of 20 per cent. In 1915, the last year of steam working, the total locomotive charges including all fixed charges were $1·2034 per 1 000 ton-miles, whereas the corresponding figure for the electric locomotive in 1917 was $0·9825.

(*g*) The smoothness in running both up and down hill on heavy grades is very noticeable as compared with steam haulage.

(*h*) The savings in brake shoes, wear on tyres and wear of the rails on curved track are quite appreciable.

(*i*) The combined demand of the Chicago, Milwaukee and St. Paul Railway and the Butte, Anaconda and Pacific Railway is 71 000 h.p. and the power factor exceeds 90 per cent.

(*j*) After allowing for all transformation losses, 11 per cent of the regenerated current is returned to the supply system.

(*k*) Where regenerative control is employed, the electric locomotive driver has much more confidence in his locomotive than in a steam locomotive, because he has the whole of the air-brake system in reserve for emergencies.

Mr. R. Livingstone: Having regard to the great care which has been taken by the author in the preparation of his facts, it is gratifying to note that main-line electrification is now confirmed as being economically sound. It is natural for those associated with the manufacture of the apparatus required for the electrification of railways to be optimistic in their views on the economies effected, as they are not involved should the financial results be less than expected. At the same time, while this may be the tendency it is a short-sighted policy for any manufacturer to encourage the use of apparatus unless he is convinced that satisfaction will eventually be obtained by his customer and that the line of progress is sound from an engineering and commercial point of view. I fully appreciate the necessity in a paper of this kind of being conservative in one's estimate of the possible saving due to electrification, as in this country we cannot claim to have experience of the work involved in changing over and the cost of running a main-line electrification. We, as manufacturers in this country, have, however, been associated with main-line electrifications in New Zealand, Japan (for the Imperial Government Railway) and France (for the Midi Railway), in addition to which we are at the present time carrying out electrifications in France (Paris–Orleans), Holland (Noord Zuid), Spain (Cataluna), Canada, Japan, Morocco, Southern Railways, G.I.P., and South America (Campos de Jardao). The success of these various electrifications has more than come up to our expectations and, due to a fuller knowledge of the problems associated with main-line electrification, we feel that it is not now necessary to be as conservative in our engineering estimates as would be the case had the experience been confined to work done in this country alone.

Comparative costs.—Reference is made in the paper to the present-day market value of the steam locomotive, and an estimate is given of the cost of replacing these locomotives by electric locomotives. As, however, the railway companies build locomotives only for their own use, their costing system is not one which is used by manufacturing concerns who have to judge their results on all costs which are incurred in manufacture. I am very doubtful whether a modern steam locomotive could be manufactured and sold by a trading concern at a price of £50 to £70 per ton (see page 731). It would appear that the steam locomotives are not debited with a proper proportion of the overhead charges of the railway organization. If, however, it is possible to build a complete steam locomotive at such a low figure as £50 per ton, there is no reason why a figure of £75 per ton should be taken for the electric locomotive structure. I think, however, that the steam locomotive figures are probably on the low side, and that the cost of the electric locomotives are obtained from competitive figures. On checking the figures given for the cost per ton for electric locomotives I find that, although there are slight variations in the make-up, the average cost of the larger electric locomotives is about £130 per ton, i.e. slightly under the figure assumed in the paper. It is possible, of course, to have variations of this figure due to variations in the specification, but the comparisons given in the paper are, at any rate, in favour of the steam locomotive, rather than in favour of the electric locomotive, and still prove an economical case for electrification.

Power of electric locomotives.—The possibility of obtaining large power in proportion to the adhesive weight of an electric locomotive has already been thoroughly established. It may be of interest if I indicate here the amount of power which can be obtained in a motor mounted directly on a locomotive axle. We have built four 3 ft. 6 in. gauge locomotives of the 4–6–0–0–6–4 type for the Imperial Government Railway of Japan, having a total weight of 99 tons and an adhesive weight of 74 tons, on which we have been able to obtain 306 h.p. per motor at the 1-hour rating, i.e. a total h.p. for the locomotive of 1 836. These locomotives give a maximum draw-bar pull of 42 000 lb. and are arranged for double heading. We are also supplying for the Montreal Harbour railway, which is standard gauge at 1 200 volts, locomotives of the 0–4–4–0 type weighing approximately 90 tons with an adhesive weight of 90 tons, on which we are installing four 430-h.p. motors (1-hour rating). This locomotive will give a maximum draw-bar pull of 30 tons taken at one-third of the adhesive weight, but the motors are sufficiently powerful to give a draw-bar pull of 45 tons. Samples of modern electric locomotives are given in Table A as an indication of the maximum draw-bar pull possible.

Additional traffic.—It has been the general experience of railway services that passenger traffic increases after electrification, and, while this might not apply to any large extent to main-line electrifications, it would

TABLE A.

Contract	Type	Gauge	Weight: Total	Weight: Adhesive	One-hour rating	No. of motors per loco.	Total	Tractive effort: Full field	Tractive effort: Shunted field	Gear ratio	Diam. of driving wheel	Line pressure	Max. tractive effort
		ft. in.	tons	tons	h.p.		h.p.	lb.	lb.		in.	volts	lb.
New Zealand	0–4–4–0	3 6	48	48	170	4	680	14 200	—	68/15	$44\frac{7}{8}$	1 500	32 000
Yamanote	0–4–4–0	3 6	60	60	275	4	1 100	20 000	16 000	73/18	49	675	40 000
I.G.R. Freight ..	0–4–4–0	3 6	58	58	306	4	1 224	15 000	12 000	68/23	49	1 500	36 000
I.G.R. Pass.	0–4–4–0	3 6	59	59	306	4	1 224	12 500	10 000	65/26	49	1 500	32 000
I.G.R. Express Pass. ..	4–6–0–0–6–4	3 6	99	74	306	6	1 836	16 500	13 500	65/26	55	1 500	42 000
Montreal Harbour ..	0–4–4–0	4 $8\frac{1}{2}$	90	90	430	4	1 720	42 000	—	85/15	50	2 400	60 000

certainly apply to the suburban portions of these electrifications. Such increased traffic would certainly have a bearing on the minimum economic traffic density for electrification, as shown in Fig. 8. In addition to this, the reduction in many other charges associated with railway working—such as reduced fire insurance, reduced accommodation for rolling stock, etc., together with the fact that the author's estimates are already conservative—would indicate a minimum traffic density of approximately 3 million ton-miles per track-mile per annum as the density at which main-line electrification becomes economical. This figure would cover the majority of the railways given in Table 11.

Mr. J. Dalziel: It cannot, I think, be gainsaid that the author has put forward a sound case for railway electrification. He has the advantage of access to a mass of information not available to everybody, and his knowledge of the subject and his railway experience have enabled him to interpret and to utilize fully this information. That the author's investigations show a more favourable case for electrification from the financial point of view than some of us have hitherto been able to attain is no doubt due in part to the closer estimates that he has been able to take out in the light of the information at his disposal, and in part also perhaps to his being able to put a valuation on advantages which we have hitherto had to pass by. I do not think, however, that he can be accused in any quarter of using figures that he cannot fully substantiate or that railway and electrical engineers generally would not be prepared to accept. That the paper is centred on finance and takes technics largely for granted not only is wise but marks a stage in the literature of electrification. That finance is the core of the whole matter is indisputable. Briefly, the difference between an electric and a steam locomotive, so far as traffic operation is concerned, is that the electric locomotive has behind it the whole capacity of the power station and so can draw therefrom, as and when it requires it, power to a vastly greater extent than is the case with a steam locomotive, the power capacity of which simply finds its limit in the steaming capacity of its boiler. An electric engine, therefore, can take heavier trains and handle them faster, especially up gradients, and can do so without necessarily being heavier than, or even as heavy as, a steam engine. It is now nearly 14 years since in a paper before the Institution of Civil Engineers I showed that an electric engine up the 1 in 90 gradient of the Midland Derby–Manchester line could take a train nearly 40 per cent heavier than the maximum steam train at nearly three times the speed. This illustrates another aspect of electrification and another reason which may in some cases govern its adoption, viz. that of traffic advantage. Apart from the basis of economy on which the author argues, a scheme which offers traffic advantages, or in other words an added facility for doing business, may be adopted for these advantages, and they may exercise a more powerful leverage towards the adoption of electricity for traction than even the promise of fairly substantial economy. Clearly there are certain lines which are approaching, or may before long approach, their limits of traffic-carrying capacity, and on which it will be easier and cheaper to get the required increase of capacity up to

double or more by means of electrification than by putting down additional road bed and tracks, the added electrification capacity coming, of course, from the above-mentioned ability to handle heavier trains at higher speeds. The question of load factor raised in the paper is a very important matter in relation to the costs at which current can be purchased, and I am sure that the paper does not set the railway figures too high; in an analysis which I made of sections of the late Midland Railway I found figures as high and even higher. On a mixed-traffic main line the goods traffic moves mainly overnight, the passenger traffic in the daytime, and there is no dead period as on a suburban line. A four-track line is of course higher in load factor than a two-track line, also the longer the stretch of line dealt with from one power house the higher the load factor; in fact the load factor of a single train could clearly be 100 per cent if the section were long enough. I entirely agree with the author that the full results from electrification cannot be obtained unless steam be completely eliminated on the electric section. If it is retained to even a very small extent a great many services will have to be retained which could be wiped out with full electrification, and these will be increasingly costly in proportion to the work they perform as that work becomes less. The lack of a tender on an electric locomotive is felt only in the one respect of braking; this means in effect that as the tender by its weight helps very appreciably to control the stopping of a train on gradients, its elimination means a reduction in stopping power with an electric locomotive and presents a certain amount of difficulty in respect to the case for the latter. In my own paper already referred to I suggested, as does the present author, the fitting of a power pump in the brake van so that a few of the rear-end vehicles could be controlled by power brakes and so make up for the loss of the tender. In my case I proposed an axle-driven pump and I think that that would perhaps suffice. If so it would be somewhat simpler and cheaper than an electrically driven one with its concomitant apparatus, though it might require a larger reservoir. Referring to the author's remarks on page 748 in regard to track equipment, I should like to ask why, since he must have short lengths of overhead conductors to help his third rail, he does not fully accept overhead conductors which will do all that he requires both on the main line and in sidings without requiring any assistance from a third rail. It seems to me that the proposed auxiliary lengths of overhead conductors with automatically raised and lowered bows will result in a very great amount of breakages of bow gear, expecially at some bridges. In connection with line equipment both of the overhead and third-rail type whether worked at 1 500 or, more especially, 3 000 volts, I should like to ask what drop may properly be accepted on an uninsulated track return. It is a very important point which materially affects substation spacing and the amount and capacity of the return cables to be provided. The 7-volt electrolysis standard does not, of course, enter into the matter outside city areas.

Professor E. W. Marchant: One of the advantages of main-line electrification is the reduction which it effects in unnecessary manual labour. The stoker on the Euston–Liverpool evening train has to shovel in 3½ hours more than 5 tons of coal on to the grate of the fire-box, throwing some of the coal 10 ft. or more. This is a very exhausting operation and automatic stokers are useless. This unnecessary labour would be done away with altogether if electric traction were employed. The author makes no reference to regenerative braking. The amount of saving by regeneration has been discussed at various times and I understand that in some cases it is as high as 10–15 per cent; possibly the gradients on our railway lines are not steep enough to enable it to be used with advantage.

Mr. J. A. Morton: If one accepts the author's axioms then neither the logical argument as built up in the paper, nor his conclusions, can be escaped. One of his principal axioms is that electricity can be assumed to cost 0·4d. per unit. The paper does not state the basis cost of installed plant on which this price is figured. A figure of 8 per cent for interest and depreciation is taken. This appears to be low and should, I think, have an extra 2 per cent added to it for maintenance. The price of coal also seems low at 15s. per ton, especially when account is taken of the coal figures in Table 4. Assuming the generating plant to cost £20 per kW installed, 10 per cent for interest, depreciation and maintenance, and coal at 2 lb. per unit, then in a modern generating station one would expect that current could be generated at 0·4d. per unit, even with coal at, say, 22s. 6d. per ton. If the price of coal were assumed to be 30s. per ton this would become 0·5d. per unit, and I think that the author must have had this figure in his mind as being nearer the mark in view of the 0·5d.-per-unit curves in Fig. 8. To this figure the author adds 50 per cent to cover the loss in transmission from the power station to the wheel of the locomotive (see Table 6), but this is not sufficient because the load factor of the losses is less than the station load factor, as shown by Mr. J. R. Beard * in 1916. With a 50 per cent load factor at the power station, the load factor of the losses would be nearer 35 per cent, and the extra for this would probably be about 0·05d. per unit. In this way one gets a figure of 0·8d. as the cost per unit, as against the 0·6d. taken in column 16 of Table 9. Even allowing for this, however, it can be seen from Table 10 that any traffic density about equal to 3 000 000 trailing ton-miles per track-mile would be a paying proposition. On the other hand, some reductions might, I think, be made in the author's estimates. In connection with Table 9 it seems to me that the transmission line might be worked at 66 000 volts just as well as at 44 000 volts, in which case the losses on this line would be nearly halved. It also appears that £2 000 per mile for the 44 000-volt pole line, exclusive of copper, is much too high, and that £2 000 per mile for the cost of track equipment is on the safe side. This might be cheapened as to siding equipment by using creosoted wood poles and ordinary tramway suspension arrangements instead of catenary suspension. Where necessary these wood poles on sidings can be stayed, as I see no objection

* "Design of High-Pressure Distribution Systems," *Journal I.E.E.*, 1916, vol. 54, p. 125.

to staying along the siding tracks. This would cheapen the siding track equipment very considerably. The proportion of siding tracks is considerable. It also seems to me that for main-line working the distribution pressure might well be raised to 3 000 volts. This would of course mean overhead trolley equipment instead of a mixture of third-rail and overhead equipment, the third rail being omitted altogether. At 1 500 volts the substations would, I suppose, have to be spaced 10 or 12 miles apart, whereas at 3 000 volts they could be spaced two or three times this distance, with a consequent saving. On financial grounds I think that the author's general conclusions are sound. There are, of course, other than financial considerations, some of which are referred to in the appendixes. Amongst others may be mentioned: Less wear and tear of the engineering staff after the electrification is carried out; time saved to the general public in transit (and time is money); cheaper fares and transport and therefore cheaper goods; the electrification would provide work for unemployed men; and our coal supply would be conserved. I suggest that, instead of the railway companies obtaining further net profit as mentioned in item (17) of the summarized conclusions, the fares and transport costs should be reduced.

Mr. W. L. Box: One of the most serious matters is the choice of the line voltage. A decision as regards a standard voltage should be arrived at, as with varying voltages difficulties will arise, especially where main-line and suburban traffic are intermingled. The author refers on page 738 to motors on the South-Western Railway being in service for 7 years without an armature or field coil having to be rewound. As there must have been during this period between 200 and 300 motors in operation, this is an excellent record, and I should like to know if equally successful results have been obtained on the London, Midland and Scottish Railway. On the line with which I am associated some new box-type motors have been in operation for 2½ years and none of these have burned out. On page 738, figures relating to lubrication are given. In this direction we have effected a very great saving in oil consumption by the adoption of the latest type of motors, and the following figures of motor lubrication (including gears) were obtained:—

Old type (oil-ring lubricated) 12·24 pints per 1 000 train-miles (or 0·0229d. per train-mile).
New type (wool- and hair-lubricated) 1·71 pints per 1 000 train-miles (or 0·0032d. per train-mile).

Mr. C. Rettie: On page 748 the author refers to inductive interference with communication circuits caused by high-tension alternating current. In a Report * of the Californian Railway Commission recently published it was pointed out that the main trouble was due to the higher harmonics caused by the operating machinery and that with proper design a good deal of the trouble could be avoided; also that as the telephonic frequency was anything from 200 to 2 000 periods per second, 60 periods or less would have no effect. The Report winds up by stating that "practically all inductive interference to telephone circuits is due to the harmonic currents and voltages, and this renders it important that an effort be made to obtain rotating machinery for use in power systems which produces, as near as is reasonably possible, pure sine-waves of fundamental frequency, and also that an effort be made to obtain transformers and to arrange connections of the same in such a manner as to reduce as far as practicable the distortion of wave-form." With reference to comparative costs, Mr. Thompson of the Westinghouse Co. gives details † of the electric locomotives in use in big stations in New York. The locomotives have two motors each of 2 000 h.p. and the total mileage run per annum is 4 961 628. The cost per locomotive-mile, on a basis of 36 000 miles per annum, is only 3·51 cents, including all charges, the saving in expense in maintenance being equal to about 11 per cent on the cost of the service.

[The author's reply to this discussion will be found on page 774.]

NORTH-WESTERN CENTRE, AT MANCHESTER, 18 MARCH, 1924.

Mr. T. Ferguson: I have always been under the impression that the maximum draw-bar pull allowable on British railways is of the order of 13 tons, and I notice that Sir Vincent Raven in a recent paper read before the Institution of Mechanical Engineers in Paris stated that on British railways it is not feasible to go beyond 30 000 lb., and therefore he states that an adhesive weight of from 60 to 65 tons is all that is necessary for an electric locomotive. Presumably this weight is on the basis of an adhesive value of about 500 lb. per ton. The author evidently contemplates much greater draw-bar pulls than this, and makes reference in his tables to a 10-coupled freight engine having 53 000 lb. draw-bar pull, and on page 739 he refers to the combined draw-bar pull of two engines as being between 20 and 25 tons, and states that there is no objection to a single locomotive having a draw-bar pull of this magnitude. There is, of course, comparatively little difficulty in making an electric locomotive either as a single or a coupled unit to produce a draw-bar pull of this magnitude, but evidently some difference of opinion exists as to the desirability of adopting such high draw-bar pulls on British railways, presumably owing to the relatively light draw-bars in use on wagon and passenger stock. Another point in connection with the diagrams of steam and electric locomotives (Fig. 1) is the long, rigid wheel-base proposed for many of these designs. I should be glad if the author would state what he considers to be the limit as regards the rigid wheel-base that will be applicable to main-line railways in this country. The type of locomotive shown as No. 7 in Fig. 1, in which articulated trucks are used, would appear to be the best way of reducing the rigid wheel-base. The author showed on a lantern slide some

details of the side-gear drive, as made by Messrs. Brown, Boveri and Co. In this case the gear wheel lies wholly outside the driving wheels, and the clearance between rail-level and the underside of the gear case is somewhat limited. Will this type of gearing pass through English railway load gauges? The author also refers to the limitation in gear ratio which can be obtained with this type of drive, the limit being imposed by the fact that the motor shaft has to pass over the top of the running-wheel flange with sufficient clearance to admit of the rise and fall of the locomotive frame in the axle-box guides, and at the same time sufficient clearance between the bottom of the gear case and the rail level has to be obtained. The gear ratio is, therefore, obviously limited by the above, as is also the amount of permanent eccentricity, or displacement between the centre line of the gear wheel and the centre line of the running axle, and it is questionable how far this permanent eccentricity can be extended in a new design. The author states that the watt-hours per ton-mile for the various types of trains is not easily determined, and he deduces a figure for this from a series of draw-bar tests made over long runs. It is clear that the area under the curve of draw-bar pull represents the actual work to be done on the trailing load, but how far is the locomotive head-resistance plus its own resistance allowed for? The average value obtained from tests depends partly upon the work done in braking, as well as on the total train resistance, but the latter in a long-distance run is clearly of the most importance and would vary considerably with the speed and also the conditions of wind, dryness or wetness of the rail, etc. If only sufficiently representative train-resistance curves could be obtained from data, then further investigation would be a matter of easy calculation. The question is, whether it is any easier to obtain the watt-hours directly from the draw-bar tests over a given run than to deduce general train-resistance curves from these tests, and I should like to ask the author whether, in his opinion, the train-resistance curves given in Fig. 5 are sufficiently representative to use for future calculations. With reference to the method which he uses for calculating load factor, I note that he adopts as his basis the average power during the hour of maximum demand, and not the maximum power during a much shorter interval, say of 1 or 2 minutes. It is interesting to find how high the load factor is found to be for main-line electric working, and if we compare this with the obviously poor load factors which are obtained on suburban electrifications, where the traffic is largely rush-hour traffic, it would appear to indicate a still further advantage in favour of main-line electrification.

Mr. S. E. Povey: The electrification of main lines on British railways, and in fact the general electrification of railways, is gradually being narrowed down by the several recent investigations which have been carried out by engineers. One main step was made when the Advisory Committee to the Ministry of Transport made a definite recommendation that the standard voltage for the whole of the country should be 1 500 volts d.c. or multiples thereof. Another item is the provision of large power stations in accordance with the 1922 Electricity (Supply) Act. Under this Act the dividing of the country into areas of supply by the various public-supply authorities has practically eliminated the possibility of the railway companies acting as public-supply authorities. It is recognized that the combination of the industrial loads and railway loads is advisable, in order to provide cheap sources of supplies of electrical energy in general. These items may be taken as foundation stones, but I suggest that the author provides limiting values to what might be termed four boundary stones on the question of main-line electrification, the four items being: (1) The necessity of a cheap supply of electricity, (2) cost of electric locomotives and train equipments, (3) costs of operation and repairs, and (4) loading of the sections of a railway. Taking (1), it is of interest to note that although the loads are very peaked and intermittent the plant load-factor of a railway power station can be as high as 95 per cent. The trains work to a definite time-table even when running empty or balancing trips, and no additional trains are run unless definite traffic arrangements are made, and this usually gives ample time to increase the capacity of the plant on load if necessary. Therefore marginal running is not necessary and full advantage can be taken of the overload rating of the plant. The morning and evening rush-hour periods provide the peak loads and are each of about 2 hours' duration. A cheap bulk supply will provide cheap power for the handling of goods traffic in goods yards and therefore enable work in general to be speeded up. As regards (2), it is necessary, as the author points out, to standardize designs of electrical equipments and control equipments to enable them to be manufactured in bulk. It should be possible to standardize the control equipments for both locomotive and motor-car work. The provision of electric locomotives and train equipments from the renewal funds appears to bring the problem of electrification within practical politics, but it must be recognized that the costs of locomotives and train equipments must balance the steam-locomotive costs. It is true that an electric locomotive is capable of working at least double the mileage per day that a steam locomotive can do, but even by reorganizing the working of a railway it is not possible to take full advantage of this. The possibility of electrical equipments operating 23 hours out of 24 can be taken as established. There are cases of electrical equipments on suburban services operating 10 to 20 days in traffic and running 260 miles in a 19-hour day making one stop per mile without interim examination. These suburban services are much more severe than anything one can expect on main lines. Therefore, for express running with stations 20 miles apart and workings covering 24 hours per day, mileages of 500 to 750 are, as far as the equipments are concerned, easily attainable. As regards (3), it is only by standard and tried-out equipments that the above mileages and the necessarily low costs of maintenance can be obtained. Very small details and innumerable designs of contacts and screws should be eliminated. The density of traffic on the whole railway under consideration is shown to be higher than on the present successful suburban electrifications, and the development of Table 10 showing the economy of electrical operation over steam operation is very valuable.

The author somewhat minimizes his method of investigating the question, but by taking the statistics published by the Ministry of Transport he has included the costs of running-shed charges, preparing of locomotives, standing time, etc., which it is otherwise impossible to evaluate. Electrification will provide other large sources of revenue in addition to those indicated by the author. The elimination of smoke and noise makes it possible for the whole of the sites, including the lines approaching the terminal stations and stations in large cities, to be covered by buildings used for hotels, offices and other purposes. Again, goods yards and sidings form a big item as far as land is concerned in the middle of most large cities, and electrification makes it possible to cover the whole of these sidings and goods yards with warehouses and offices. In addition, property in the neighbourhood of the railways will increase in value.

Major P. B. Coulston : The author says, at the top of page 730 : " The decision whether or not to electrify portions of the British main lines will rest with financiers rather than with technical experts." With that view, I think, we shall all heartily concur, because the paper makes it perfectly clear that there is no proposition of any nature whatsoever from the engineering standpoint which the engineers of this country will not be glad to undertake. Finance is, however, a question which engineers will have to consider very seriously. The author does not say how the money is going to be raised, but some figures which I have taken from the *Investors' Chronicle* of 5 January, 1924, are significant. In 1913 the total issues were £196 537 000, of which £52 436 000 represented Government borrowings and the remainder private enterprise. For the year 1923 the total was £271 392 500, of which £173 407 000 was on the Government account and the remainder for private enterprise. That shows that there is plenty of money in this country. We may certainly take it that that 100 millions was invested with the laudable desire that it should be returned with interest, and I think that few prospectuses issued in recent years would show the same safe security with prospects of a reasonable dividend as the proposition put before us in the paper. Roughly 20 years ago a paper was given by Sir John Aspinall, then the chief engineer of the Lancashire and Yorkshire Railway Co., on the electrification of the Liverpool and Southport line, in which he stated the hopes of himself and those associated with him—amongst them the author of the present paper—as to what might be anticipated as the results of electrification. Reading that early paper in conjunction with the present one, I was much impressed with the fact that those intelligent anticipations have been realized. One point which struck me very forcibly was that electrification might have a very important bearing upon the housing of the population. Nowadays high-class residential property is being built as close to electric railways as possible, as they cause none of the inconveniences which are inseparable from steam railways. With the advent of main-line electrification the building of private houses in the immediate vicinity of the railway may be carried out to a large extent.

Mr. J. R. Billington : I can vouch for the accuracy of the dynamometer-car figures which the author has so ingeniously used, together with other railway statistics, to prove his contentions.

Mr. W. J. Medlyn : It is necessary that we should bear in mind that the primary function of a railway is transport, and, quite rightly, the author has given first consideration to the important question of transport economics in dealing with the alternatives of steam and electric haulage respectively. It must not be overlooked, however, that the telegraph and telephone services also play an important part in the organization and control of the transport operations, and, whatever system of electric supply is adopted, it will always be necessary to take reasonable precautions to ensure the continuity and reliability of these communication services. The author recognizes the importance of this aspect in his brief reference to the subject on page 748. The Post Office is also directly concerned in this question of interference from power-supply circuits. Many thousands of pounds have been sunk by the Post Office in the provision of telegraph and telephone circuits carried on the railway undertakings, and in many cases maintained by the railway companies themselves; therefore, in dealing with the economics of railway electrification, it is necessary to keep in mind the effect which the methods adopted may have on the efficient working of the telegraph and telephone plant, whether it belongs to the railway company or to other administrations. In the abstract sense, of course, it does not much matter whether the losses due to depreciation of the communication services are borne by the railway companies or by the telegraph and telephone administrations, because in the long run the cost of wastage has to be borne by the community, but in the particular sense it is only a matter of equity that the party deriving economic advantage from the change of system should also bear the cost of the consequent losses to other parties. In the early days of development, railway engineers appear to have shown a preference for the single-phase system of electrification. The disastrous effect of this system on neighbouring telegraph and telephone wires was fully emphasized in the recent discussion on " The Electrification of the French Midi Railway." * The system has the further defect that high voltages are induced in adjacent telegraph and telephone wires, thus introducing a risk to life and a liability to other damage. It is interesting to note, therefore, that modern practice tends towards the adoption of a less dangerous system. On page 739 the calculations are based upon a three-phase supply converted to 1 500 volts (d.c.). Presumably the adoption of this standard would involve considerable scrapping or modification of the plant now in use on sections of railway which have already been electrified, such as, for example, the Manchester–Bury line which is operated at 1 200 volts (d.c.). On page 748 it is mentioned that the use of cables for the distribution of current would render the cost prohibitive. I understand that on the Liverpool–Southport line an armoured cable was used for supply purposes, but that it rapidly deteriorated owing to the electrolytic effect of the direct current which reached it from the operation of the service; and, as a result, the power-supply wires were diverted to the

* *Journal I.E.E.*, 1924, vol. 62, p. 213.

overhead system. It would, I think, be useful if the author would give us some information on this point, because if supply cables are liable to rapid electrolytic action there is not only the higher capital cost to be provided for but also the extra cost of maintenance and renewals. This question of electrolytic trouble arising from the d.c. system was mentioned by Dr. Parker Smith in his recent lecture on "Railway Electrification in Foreign Countries." * I mention the point because I think it is a matter of very great interest in connection with the economics of electrification. As an illustration of the penetrating inductive effect of this power-supply system, it may be of interest to mention that the Post Office has a lead-covered telephone cable in an iron pipe laid alongside the Liverpool–Southport railway, between the outskirts of Liverpool and Formby. One might naturally expect that the iron pipe and lead sheath would form an effective screen against the inductive effects from the overhead power system, but a very distinct hum is noticeable when one is listening on the telephone line, although in practice this does not generally cause appreciable interference with the transmission of speech. On page 748 the author suggests that the transmission line should not be taken along the railway but should approach the substation by an independent route. From one point of view this idea is attractive, but difficulties are likely to arise in practice in securing such routes, especially where main lines passing through long stretches of open country are involved. In this connection Post Office engineers are liable to feel rather apprehensive regarding the safety of the existing extensive network of Post Office lines generally. At one time it was the practice in America to intermingle telephone wires and power wires on the same poles, including routes along the public thoroughfares. I have recently heard that this practice has now been altered, the power wires being placed on the top arms and the telephone wires below. Before this change was made, on an average every year 24 telephone linemen were killed, whereas at the present time the fatal cases amounted to only six a year. One would naturally expect trouble if we had so many as six cases a year in this country, and the fact that such cases are rare with us is a good tribute to the efficiency with which the electric supply undertakings are constructed and maintained.

Mr. R. Brooks: I do not propose to deal with the broader financial aspects of the paper, but there are one or two control points mentioned by the author which I think are worthy of some discussion. On page 748, in discussing the track equipment and speaking about the necessity for both third-rail and overhead collectors, he says: "As the overhead collector must be clear above the structure gauge, the bow in its 'up' position fouls the structure gauge, and means will therefore have to be provided whereby the bow automatically rises to meet any stretch of overhead trolley and automatically falls when it leaves it, or, alternatively, every over-bridge and tunnel will have to be equipped with a dummy trolley." I take it that he is putting that forward as a problem for design engineers. Dealing with the first alternative, I am in general agreement with the author's statement of the case, except that I do not see the necessity for the automatic raising of the trolley as it approaches an overhead section, if means are provided whereby the collector can be safely raised at any reasonable distance in advance and maintained in that position until it comes on to the contact wire, without doing away with the automatic lowering feature when it leaves the wire. The problem has indeed been studied along those lines, and a gear has been devised, manufactured and put into use, which accomplishes these requirements. The central feature of the equipment is a special control valve which is used for operating a pantograph, or other type of collector, which is air-operated. This valve is of the piston type; that is to say, the valves are actually operated by a piston which is controlled in its movements by two small electrically-operated needle valves, one of which controls the upward movement of the pantograph and the other the downward movement. They are of a type which only requires excitation momentarily. That is a very important point because it very considerably simplifies the problem of automatic lowering. Once the valve is in either the upward or downward position it remains there independent of the continuance or otherwise of the excitation. With regard to automatic lowering, there are probably several ways in which that can be done, but in this particular case it has been effected by attaching special contacts to the pantograph so that when it exceeds its maximum operating height by a very short distance, say 2 or 3 inches, it excites the lowering mechanism of the pantograph, the valve brings the pantograph down, and it stays down until such time as it is raised by deliberate action of the motorman. The approach to any section of overhead wire will have a long, easy ramp, and with this type of control the man can, by holding the control switch over in the "upward" position, raise the pantograph before it reaches the overhead wire, and maintain it in that position until he is under the wire, when he can let the switch go. The pantograph will then remain in contact until on running off at the end of the section it automatically lowers itself. The second alternative mentioned in the paper, namely the dummy trolley, certainly seems to me to have serious disadvantages. In the first place it will be very expensive, especially in congested areas; secondly, a normal type of collector, which is necessarily a very lightly-built structure, is subject to rather severe strain when running for long periods at high speeds without being in contact with the wire. I think that trouble would be developed there. There is also a point to which the author has made a passing reference, namely that there would be considerable insulation trouble with a dummy trolley under bridges and in tunnels. On page 749 the problem of one-man operation is mentioned. No one will deny the accuracy of the statement that it is an extremely difficult problem to attack. It is obvious that the normal type of "dead man's handle" which is used on suburban trains will be entirely unsuited for main-line traffic where long stretches of line are travelled without a stop. No man can be asked to exert a continuous muscular effort, however slight, over extended periods, especially where, as in the gear now in use, the release of the mechanism is instantaneous and there is no time-

* *Journal I.E.E.*, 1924, vol. 62, p. 317.

lag in the operation. It may be of interest to many to know that a type has been introduced which will probably go some way towards the solution of the problem, and is used on one of the Swiss railways. On certain one-man trains the " dead man's handle " equipment is operated by the driving wheels and operates on a distance basis, so that it acts more quickly at high than at low speeds. Moreover, in order to enable the man to leave the driver's position to take off side signals, there is a second button on the other side of the cab to which the man has ample time to go before the gear will operate. He can put his hand on that, and lean out of the window to take any observation he may require. Now although that goes some way it is by no means a solution of the problem; I merely put it forward as a suggestion of the lines on which investigation may be carried out. It seems to me that the author is correct in suggesting that the force of public opinion will for a long time militate against the adoption of a one-man system, however complete or perfect the mechanical safeguards may be. In conclusion I should like to stress the necessity for adhering as far as possible to the simplest form of equipment that will attain the object aimed at. It is extremely easy with electrical equipment to provide all sorts of unusual devices, so that there is a temptation, which it is hard to resist, to demand these things. When mechanical engineers characterize the electric (in contrast with the steam) locomotive as an " appalling box of tricks " they are comparing things with totally different characteristics. On the American lines where a considerable amount of heavy electrification has been carried out, experience has very definitely shown the desirability of eliminating as far as possible every complex piece of apparatus which can be done without, and of adhering entirely to apparatus which is robust and simple in its characteristics and functions. This ideal of simplicity seems to me to be a perfectly attainable objective and I feel certain that the day is not very far distant when the electric locomotives which will be available for all purposes will leave nothing to be desired, in regard to both simplicity and reliability.

Mr. T. E. Herbert: It is rather regrettable that the paper is a reasoned statement of the case for the electrification of main lines instead of an account of a *fait accompli* such as that relating to the French Midi Railway. It is indeed unfortunate that so few engineers attain positions of supreme importance on the directorate, since their experience and training would be of inestimable value in assisting to arrive at a correct economic decision.

Mr. H. Allcock: I agree with a previous speaker in the discussion that the author's most significant sentence is that in which he states: " The essence of the problem is financial, and the decision whether or not to electrify portions of the British main lines will rest with financiers rather than with technical experts." The real difficulty appears to be that the capital cost of the new electrical equipment must be added to the capital cost at which the existing steam equipment already stands in the company's books, so that, until the latter could be written off, the undertaking would be, in effect, saddled with the burden of double capital charges. Ways and means of reducing this burden must therefore be found, and on these grounds, if on no other, I think that the electrical engineers of our railways must contemplate the purchase of current from outside sources, wherever it is available at reasonable prices, instead of building their own generating stations. The case in favour of suburban electrification seems to have been made good in spite of the capital charges, and there may even be special lengths of main line where the growing density of traffic would justify capital expenditure upon electrification as an alternative to incurring the cost of widening the existing road. I should expect that—for instance, on the main Manchester–London (Midland) route—the cost of widening the viaducts and tunnels in Derbyshire would be greater than that of the electrification of the existing track, in which case the electrification of this section of the main line will fall due when the point of steam-traffic saturation is reached. It would be interesting to know the percentage of extra traffic which these metals would carry if they were electrified. This capital question is so obviously the crux of the whole problem that I suggest that the Institution should take advantage of every legitimate opportunity to bring before the Government the justification for financial assistance by the State—under the Trades Facilities Act—for a term of these double-capital years until the financial burden of electrification could be shouldered, unaided, by the railway companies themselves. Not only would the national interests be served by the provision of improved transport facilities, but British technical men would thus be given opportunities of employment in their own industry instead of being forced, through unemployment, either to become unskilled roadmakers at home or to transfer their capital values to some other country offering more favourable opportunities for their advancement.

[The author's reply to this discussion will be found on page 774.]

South Midland Centre, at Birmingham, 2 April, 1924.

Mr. J. Dalziel: Previous speakers have rather reflected on the enterprise of British railways in respect to electrification, but I think that there is a great deal to be said on the railway side of the matter. I hope that the author will be able to drive home the conclusions at which he has arrived, equally effectively in the higher quarters where the future of electrification in this country will be decided. I think that it must be agreed that to have undertaken a very heavy expenditure on a more or less uncertain project such as main-line electrification must be (to the lay mind at least, whatever it is to our own), is not a procedure that in these days could commend itself to railway directors or, if to them, to the shareholders to whom they are responsible. Again, it is all very well to point out, as previous speakers have done, that Continental

and American progress in electrification is ahead of our own, and that the mileage of Continental railways under electrification exceeds the total mileage of British railways. That may be so, but it does not affect the matter. The conditions are different. Whereas our coal is still comparatively cheap, in the countries in which electrification is going on so extensively coal is dear and mainly purchased abroad, and water power is available. The price of coal in Italy, for example, rose at one time to as high as £5 per ton, or even more, with the result that the Italian railways are nearly all being electrified. The same applies to Switzerland, where the railways are undergoing wholesale conversion. In France the southern railways, which are in much the same position, are being electrified. It will be noticed, however, that the Nord railway is not being electrified, for the very good reason that it runs through a colliery area and its coal, like our own, is comparatively accessible and cheap. The matter of economy, in fact, largely turns on coal, and I hope that it is clear that the author's comparison of coal versus current is not a comparison of locomotive against power-station coal, but one of steam-locomotive coal as against all current costs. If we take a comparison of fuel against fuel alone, electric operation gains both because the quantity consumed is less and because a lower quality is used. At the end of the paper the author shows that the saving in fuel is about 50 per cent and, in addition, while locomotive coal must be of the highest grade (say 23s. per ton), electric power station coal may be of the lowest (say 4s. per ton). There is clearly a great economy in this direction, but up to the present it has not appeared to be sufficient to pay for the capital cost of electrification, especially when the other costs incidental to the generation of current are added. The paper shows, however, that the savings to be effected in other directions will compensate for these. There are three directions in which the case for electrification can be bettered, and in one of these, especially, members of this Institution can help materially. The first and most important is to reduce the cost of the apparatus required by the railways. It is for manufacturers to do their part, as well as for the railways to do theirs, and that is the direction in which they can best do it. Another direction is to raise the price of coal, but I hope that this will not be done. Nevertheless, the higher the price of coal the greater the saving and the better the case for electrification, especially as the price of the higher grades used on steam locomotives is liable to rise more than that of the lower grades used for electric generation. The other direction in which electrification may be hastened lies in the realization of its advantages by the traffic-operating officers. The gist of the whole matter in this direction lies in the fact that by the use of an electric engine of weight equal to that of the maximum steam locomotive permitted on the line the maximum train weight on, say, a 1 in 100 incline can be raised by 50 per cent and the speed to something like 3 times. This results, as the paper makes clear, from the fact of the electric locomotive having behind it the whole capacity of the power station, that is to say each electric locomotive can draw upon and use effectively a far greater reserve of power when it requires it to go up a gradient, or for other reasons, than can the steam locomotive which has only its own boiler to draw upon. Another advantage of the electric engine is that it is always ready for work and is not affected by weather variations to anything like the extent that the steam locomotive is. The steam locomotive, in fact, may be slow in responding if the particular quality of coal with which it is being fed does not suit it, while if the weather is cold and the axle boxes therefore stiff it runs more slowly, whereas the electric engine simply increases slightly its power input and output. I have a great deal of sympathy with the desire for a pressure of 3 000 volts. The major portion of my own experience with traction has been with a 6 600-volt single-phase system. There is one difficulty which affects both 1 500 and 3 000 volts, but the latter especially, and that is the drop in the track return. If this can be unlimited, substation distances can be increased as one would expect them to be, though this is not quite as the square of the voltage, but if the track-return drop is to be kept down to a low figure and an equal value throughout, the gain from 3 000 volts against 1 500 cannot be fully realized. The efficiency would rise, but capital expenditure would not be reduced nor would substation distances be proportionately increased. So far as the use of single-phase current is concerned, I should like to make the position clearer. Technically, I do not think that there is very much difference between a single-phase 25-period supply and a d.c. supply. Costs generally would probably show very little difference, though from my own experience I think that d.c. motors must always be somewhat more robust and must always have an appreciable advantage in regard to brush wear and similar details. But the whole question turns mainly on interference with communication circuits, and in this respect the railways in this country, and especially the northern railways, are in an entirely different position from any of the other railways which have used single-phase current for their electrification. The communication circuits on the northern lines are of the utmost importance and they carry, for example, the main Post Office trunk telephones between London and the large northern cities. I think that it is sufficiently clear that any interference with these must be avoided, and single-phase traction certainly does interfere with them to such an extent as to make them unworkable. It has been said that the Brighton line used single-phase current without trouble of this kind, but what the Brighton company did was to put underground all its message circuits within the influence of its single-phase current, and in other cases they have been removed to at least 200 yards from the traction lines. It is fairly obvious that the latter cannot be done in this country. There has been a great deal of rather ill-informed talk, especially at the time of the great storm in 1916, as to why the railways do not put message wires underground and so on. The fact is, of course, that a cabled telephone line, owing to its high capacity, will not work if it is of considerable length, and has to be loaded with inductance coils to counterbalance its capacity at short intervals to enable it to be used at all. I do not say there are no workable underground tele-

phone lines, but they are only workable because they are loaded with inductance. Not only are they very expensive, but I do not believe that even so loaded they give as good speaking-service as is obtainable from overhead lines. I do not say that it is not possible to make message wires workable in the vicinity of a single-phase traction system; for example, the return current can be brought back overhead as close as possible to the outgoing current, so partly balancing its electromagnetic induction, and earthed screening wires can be put between the traction and the message wires to check electrostatic induction, and there are many other devices. All these remedies add to the cost of the single-phase system, however, and if this system makes itself uncommercial because of the cost of remedying the interference with message wires, then there can be no justifiable case for it. Interference with message circuits by three-phase overhead lines is, of course, an entirely different matter. I do not mean to say that there is no risk of inductive effects with three-phase current, but in the single-phase traction system the overhead conductor is in the air in a position fixed by that of the rails; the return current flows along the rail and may in fact take through the earth a different route altogether, so that there is no counter-balance to the inductive effect of the overhead current and the conditions are as bad as they can be. With three-phase power lines the position of the wires is much less inflexible and if they are placed in correct relation to each other and revolved as they should be, and if the message circuits are also revolved, an inductive electromagnetic and electrostatic balance is more or less obtained. The risk of inductive trouble will chiefly arise with unbalanced phases, and this trouble is always liable to occur when lighting or other single-phase supplies are given.

Mr. A. M. Taylor: I wish to dissociate myself from any suspicion of having an undue bias for single-phase work, and although I believe that the adoption of high voltages for single-phase work would carry very distinct financial advantages with it, yet I realize the importance of electrical engineers in this country being practically of one mind on the advantages of electrification, and I shall therefore not discuss single-phase electrification. I have, however, a very strong misgiving as to the advisability of using 1 500 volts as the distribution voltage for d.c. main-line electrification. In order to deal with the question independently, I have worked out the question of traffic service between London and Birmingham, a distance of 108 miles, and have taken a service of 30 passenger trains each way per day of 12 hours—twice the frequency now obtaining—and a service by night of 15 goods trains each way for 12 hours. I am aware that in taking these figures I have neglected the goods service during the daytime, but it somewhat simplifies the case, and, moreover, the passenger service is probably over-estimated, so that this will compensate for the other. On this basis I make the figures to be 2 800 000 train-miles per annum with 12 trains on the line at any period of the day and with a headway of 18 miles between each pair of trains. I have assumed each train to absorb 1 500 kW, i.e. 3 000 kW per pair of trains. I have also assumed a 9-mile spacing of the substations and a distributing copper cross-section of 1 sq. in. on each pole (equivalent to 6 sq. in. if of iron), which allows a current density of 1 000 amperes per sq. in., and I have worked out under these conditions what happens during the cycle while two pairs of trains are changing place on the line. I found that, roughly, the average drop in the d.c. distribution amounted to 16 per cent. If the author had taken a 12-mile spacing the drop would have been of the order of 20 per cent. I note, however, that in Table 6 the author has only taken a 10 per cent drop in the distributing system, and I therefore conclude that in order to bolster up his case he has been forced to use a double copper section, at a cost of another £170 000 or so. This, therefore, is debitable to the use of 1 500 volts. Again, the use of 1 500 volts limits the spacing of the substations to 12 miles, but the proper spacing should evidently be 18 miles. Now it is clear that each substation must be able to deal for a time with two trains simultaneously passing it and hence must have a capacity of 3 000 kW. Nine stations, each of 3 000 kW, gives a total of 27 000 kW, whereas the ideal way would be to use six substations, each of 3 000 kW, giving a total of 18 000 kW, which might be obtained if 3 000 volts instead of 1 500 volts were employed for local distribution, and in addition the 2 sq. in. of copper already alluded to could probably be saved. The author has apparently taken £10 per kW of maximum demand at each substation and so obtained £270 000 as the outlay on the substations. I would suggest, however, that unless he contemplates using rectifiers it would be likely to take more nearly £15 per kW, which, of course, brings his figure up to £405 000 and would make his estimate appear to be £135 000 too low. If, on the other hand, his substations were spaced 18 miles apart the total cost would be £180 000 if taken at £10 per kW, or £270 000 if taken at £15 per kW, so that in the latter case he is spending unnecessarily £135 000 on the substations, plus £170 000 on distributing copper, a total of £305 000. This could largely be avoided by using 3 000 volts as the distributing pressure. In addition to this the wages for, and cost of running, the additional substations would have to be considered. There is, therefore, in my opinion, a clear case for the employment of 3 000 volts. As regards the question of transmission of the power from the generating station, I have looked into this question and, assuming power to be fed from each end of the line, as, for example, from London and Birmingham, I find that the section of the overhead conductors put forward by the author would be only just sufficient if the two parallel lines were both employed, and if one broke down the drop would be serious. Now I believe that 40 000–60 000 volts is altogether too small a pressure to be employed for such a purpose and that the overhead system is not one that should be adopted. On the question of pressure, it was an argument used by some of the advocates of d.c. equipment (see *Engineer*, 1924, vol. 137, p. 342) that three-phase current at 50 periods could be supplied for general purposes from the various substations to smaller towns on the route. If, however, this is to be done, a power factor of the order

of 0·8 will have to be faced instead of a unity power factor, which has been taken in the present case; in fact the present case is unworkable unless a power factor of unity is assumed, and even then the drop is normally of the order of 10 per cent. If, however, the power factor of 0·8 had been assumed, the drop would immediately be doubled and under breakdown conditions would be 40 per cent. Now the regulation obtainable at the substations under such conditions will be totally impracticable for the public supply of electricity and I feel very strongly that the right thing to do is to put in a transmission with underground cables at the highest possible voltage; and I am in the position to prove that assuming, for example, that the "hexaphase" system, which I have advocated, were put down of a capacity several times that necessary for the railway, power could be fed from either end of the line for general distribution purposes on a large scale to towns en route, or right through from London to Birmingham, or vice versa. The interest and depreciation on such a line would be very much less than on the overhead system at an equal voltage; in fact it will only be of the order of 0·001d. per unit with a 20 per cent load factor. The transmission loss from, say, London to Birmingham, or vice versa, will have to be added to this, but it need not be of the order of more than 0·02d. per unit for the same outlay, and this can in fact be reduced to 0·01d. by increasing the copper section at an extra capital charge of only 0·001d. per unit. The result will be a means for linking up large power stations with a north-and-south trunk line, capable of giving power at cheap rates along the route and developing the resources of the country. For example, if power in London were to cost 0·45d. per unit and in Birmingham were to cost 0·42d. per unit, there will be a clear gain, with a liberal margin in hand, in transmitting power from Birmingham to London. In fact a difference of only 0·02d. per unit in the price as between Birmingham and London will amply warrant the free interchange of current from one to the other. It is worth mentioning that the interest and depreciation charges on the line for the amount of power mentioned above will alone be of the order of £113 000 per annum, but this will be paid by the companies or municipalities utilizing the line. It is true that these figures are based on my "hexaphase" system, but even supposing that nothing better than single-phase cables were available and that the limits which are now in serious contemplation in America in connection with single-phase cables were found to be satisfactory, the results will only be reduced by some 30–40 per cent and will still be well worth considering. As regards the use of overhead lines, I feel certain that, if reasonably suitable voltages were to be employed, the distance apart of the conductors will cause serious danger of interference with the Post Office telephone system; and, moreover, there is always the danger of total interruption of both lines (which, I understand, are to be run on one set of poles only) by a stroke of lightning or by collision with an aeroplane. The difficulty with overhead lines on a length of system such as is being considered is that if we confine ourselves to comparatively low pressures of 40 000 or 60 000 volts, the line is inadequate for transmission at anything but unity power factor, and that only in small amounts of power. If, on the other hand, we adopt higher voltages and larger powers (still with overhead transmission) there are the increased inductive effects on telephone circuits, due to the wider spacing of the conductors, and the impracticability of running these overhead systems through many densely-populated parts. There is also the very serious question of accumulation of sleet on the lines and insulators—particularly in the North of England. Speaking generally, I think that the overhead system is unsuitable for such service in this country, except in the sense of a pioneer line to demonstrate the other advantages of electric traction, and even in this case it should be superseded at the earliest possible moment by underground cables. If it should be pleaded that the difficulties of induction and accommodation for the overhead system could be avoided by running the overhead system on a route separate from that of the railway, I can only say that the cost of obtaining wayleaves would be very serious indeed. Moreover, there would be no ready access to the overhead line for the purpose of repair and renewal of insulators, such as there would be if it were situated along the route of the railway.

Dr. C. C. Garrard: It seems to me that the question of the electrification of main-line railways in this country has got beyond the technical stage and now requires more of a political treatment. The author has shown, once more, the great advantages which will accrue from the electrification of our railways, but we have known this all the time; the trouble is to get the railway companies to take action. It is necessary to point out that railway electrification is making rapid strides on the Continent. This is the case not only where water power is available, as in mountainous districts, but also in industrial and agricultural countries like our own, with power derived from steam power stations. Statistics are now available from such electrifications, carried out since the war, showing that the savings effected by electrification have been equal to a return of 15 per cent on the capital involved in the electrification. When considering electrification the auxiliary advantages must not be lost sight of. Take, for example, the city of Birmingham. The centre of Birmingham is most congested, there being no land available for necessary new buildings. Nevertheless, the land occupied by New-street Station represents many acres. If the railway were electrified, the whole of this area could be covered in, and the new hotels and other buildings which Birmingham so urgently needs could be built. The capital value thus created would be extremely large, and would be a set-off against the cost of electrification. It is also useless to wait, before electrifying, to decide upon the best system. We have the single-phase a.c. system and the d.c. system. Both these have been thoroughly proved and, as far as we can tell at present, their relative advantages are approximately equal. The slight advantage which one might have over the other could only be determined after, perhaps, 20 years of trial. We in this country should go ahead with both of these systems. For example, there is the London, Brighton and South

Coast Railway which it was proposed to electrify completely on the single-phase system before the war; this should go ahead. Then at the other end of the country we have the Newcastle–York line of the North-Eastern Railway. The electrification of this on the d.c. system should also go ahead. If these two schemes were to be set going forthwith, as they could be, they would bring most valuable experience which would help in the further electrification of railways. The general public must be made to understand the great advantages that they can get in better service, quicker journeys, and improved amenities generally. They must then bring pressure to bear upon Parliament. It was hoped that the recent railway amalgamations would have helped to bring forward electrification, but at present they seem to have had the opposite effect and the inertia seems to be greater than ever. The electrical profession and industry must, therefore, turn their attention to the general public and secure their co-operation and agitation until the Government forces the hands of the railway companies and makes them go forward without further delay.

Mr. J. D. Carlmark: The estimate of a 33⅓ per cent reduction in favour of electric traction under the item of "Engine-men's wages" in Table 3 appears to be too low; a much larger reduction ought to be possible under electrification. A very important point arising out of railway electrification is the possible supply of current to districts not yet in possession of electric power and the means of lessening the cost where supply already exists. Apart from this it would also increase the demand for motors and domestic apparatus, and this would help the industry to reduce the cost of their goods. The cost of shunting work in connection with sidings, goods yards, sheds, etc., seems to constitute a comparatively large proportion of steam railway expenses. With electricity for disposal along the line, a large amount of this could be saved by the installation of electric capstans where a locomotive is required perhaps only occasionally. Here the power would be at hand when it was required, the cost of overhead conductors or third rail would be avoided, and the expensive locomotive with its attendant motor men would be released for other work. That no armature or field coil has had to be rewound during 7 years' service on two lines speaks very well for the sound construction of the present-day traction motor.

Mr. E. Blakemore (*communicated*): The first page of the paper explains the great difficulty of obtaining a reasonable basis for argument, and lays the blame on the English method of recording railway statistics. The author quotes four bases, viz. number of locomotives per mile of track, coal consumption per mile of track, ton-miles and engine-miles, and rightly states that the last "though a concrete fact, has a somewhat indefinite meaning." It would seem almost impossible to set out a really logical and convincing argument even if statistics were compiled in such a manner as to provide a more satisfactory unit, as main-line electric service and main-line steam service are so totally different in character. In other words, generalization must form the greater part of the argument and the two services cannot properly be compared, because although one starts with the same time-table it would change rapidly due to increased speed on up grades and the decreased gross weight of the train, or, on the other hand, slightly increased trailing weight, and many other advantages now candidly admitted by engineers who have hitherto been sceptical. Despite the difficulties, the paper shows: (i) The feasibility of main-line electrification; (ii) the vital considerations; and (iii) the possibility of many traffic economies. An important point arising from the paper is the effect upon the economic density of an alteration in the cost of coal. Assuming that at 0·4d. per kWh the coal costs 0·15d., then at the tread of the electric locomotive the coal will cost 0·225d. per kWh, i.e. $(0 \cdot 6/0 \cdot 4) \times 0 \cdot 15 = 0 \cdot 225$. Thus coal will cost 2·16d.

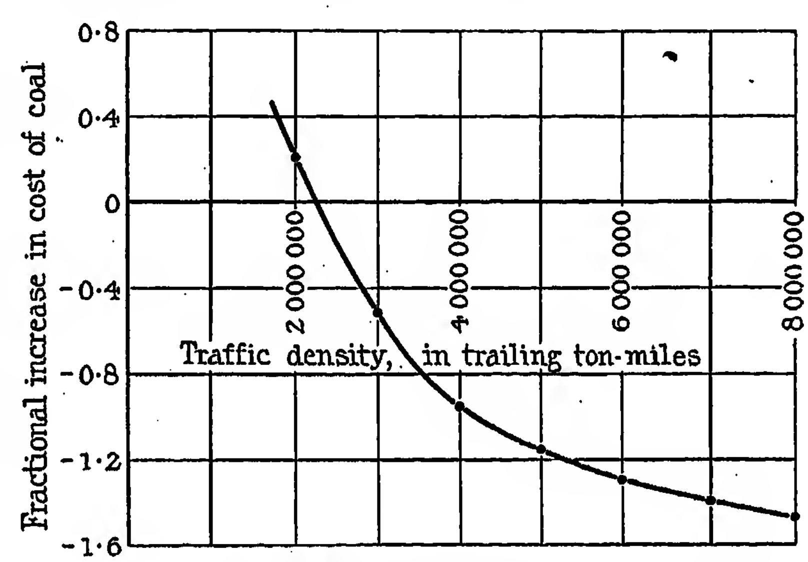

FIG. A.—Curve showing effect of alteration in cost of coal on the economic traffic density.

per electric engine-mile, while it will cost 7·4d. per steam engine-mile. We may therefore write:—

$$\text{Total cost per steam engine-mile} = F + 7 \cdot 4K$$

where K is the fractional increase in the cost of coal.

$$\text{Total cost per electric engine-mile} = E + 2 \cdot 16K$$

$$\text{These costs will be equal when } K = \frac{E - F}{5 \cdot 24}$$

Values of F are given in column 6 (Table 10), and values of E in column 5. Obtaining values of K from this formula and plotting we get the curve shown in Fig. A which indicates that, assuming all other factors to remain constant, if the cost of coal is increased it will pay to electrify most of the lines given in Table 2, but if the cost is decreased there is a greater likelihood of loss unless the traffic density increases. With regard to Table 1, I find it difficult to agree on the method of allocating the charges given as repairs, but I nevertheless regard it as being a very fair comparison.

Mr. R. H. Rawll (*communicated*): The author states that the cost of replacement of steam locomotives by electric locomotives should be chargeable to revenue, on the grounds that railway companies set aside a fixed sum annually for locomotive renewals. Now it appears fairly evident that if it were decided to electrify a particular section of a given line, such a section would,

of necessity, be of considerable length, since, as the author points out, main-line electrification has either to be done on a large scale or not at all. This being so, it is conceivable that the initial cost of a sufficient number of electric locomotives to operate in the new electrified section might be vastly in excess of the normal expenditure on steam-locomotive renewals in this particular district, and thus might easily become a capital charge. It might, of course, be argued that the steam locomotives would still continue in service on the electrified section and that, as their turn came to be replaced, they would be superseded by electric locomotives. This would take a fairly long time to accomplish, however, and considerable loss would be involved in working the two systems of locomotives at the same time over the same section of line, besides delaying unnecessarily the decided advantages which electrification claims. I should therefore be glad if the author could throw some light on this aspect of the question. In ascertaining the probable load factor to be expected, reference is made in the paper to the suburban electrifications of the London, Midland and Scottish Railway, where tests were made with the batteries eliminated at the substations, in order to see what effect this had upon the load factor. A few years ago I was present at one of the above company's power houses while such a test was being carried out. The coal consumption was practically the same as when the batteries were in commission and, as the author has stated, the load factor was slightly reduced. The one outstanding effect was, however, the very increased instantaneous load-kicks on the generating units. The real value of a battery for main-line railway work appears to be in its function of smoothing-out the heavy demands for energy on the e.h.t. system, when, for example, two trains simultaneously start in close proximity to a substation. It has been thought by some that the battery is employed solely to act as a stand-by in the case of an interruption of the supply system. How remote this contingency is to-day is shown by the fact that the substations feeding the underground railways of London do not include a battery in their equipment. But the above smoothing-out action of a battery would not have a marked effect in this case, since the traffic is very much denser than that which would be obtained on a main line, and, consequently, there is more of a constant load on the system.

Lieut.-Colonel H. E. O'Brien (*in reply*) : I was for many years a sceptic as to both the desirability and the possibilities of financial success of main-line electrification; my conversion to other views has been brought about entirely by the new facts which have emerged during the last five years. The extraordinary progress made in electric locomotive design, as witnessed by locomotives recently constructed by British, American and Swiss manufacturers; the data showing the reduction in the cost of repairs and shed maintenance when compared with steam locomotives as communicated by Sir Vincent Raven and others and confirmed by the results obtained on suburban railways; the multiplication of highly economical power stations in the congested areas most suitable for electrification; and the definite indication of very high traffic densities on main-line routes given by British railway statistics, are all factors which have only recently become applicable on a sound basis to the solution of the problem. If one-man operation of locomotives and the cheap electrification of sidings can be put, in the next few years, on an equally sound basis, the case for the electrification of a considerable proportion of the main lines of this country will be irresistible. It is scarcely to be expected that these new data, which have as yet but lightly impressed themselves on the minds of the technical staffs of the railways, will have penetrated to the traffic officers, accountants and directorates, but, fortunately, there will be in Europe within a year or less, and within easy reach of this country, working examples of the new conditions produced by electrification on railways more analogous to British railways than the electrified railways of the United States have been. It is to be hoped, therefore, that both directors and operating officers will be tempted to visit the French, Swiss and Dutch electrifications in the near future and thus obtain first-hand evidence of the improvement that can be effected by the introduction of electric traction on main lines.

Mr. Gill has misapprehended the nature of the change brought about by main-line electrification. If 100 electric locomotives were required to take the place of 100 steam locomotives his calculations would be correct, but in fact only 50, and possibly fewer, electric locomotives are required to replace the 100 steam locomotives. The railway company must maintain their assets—in this case haulage power—intact; this they do by the provision of 50 electric locomotives with the same haulage power in ton-miles per annum as the 100 steam locomotives displaced. Further, the 100 steam locomotives selected for displacement will not be 15 years old but 40 years old, so that their whole value is available in the depreciation fund for the purchase of the 50 or 40 electric locomotives which displace them. In effect, the renewal fund is merely diverted from the purchase of steam locomotives to the purchase of electric locomotives of equal haulage power in ton-miles per day.

It is very pleasant to receive from such an authority as Mr. Welbourn so many figures confirming the conclusions in the paper. The Chicago, Milwaukee and St. Paul Railway is, of course, a special case, but though the cost of haulage on its heavy gradients was favourable to electrification, its low density of traffic was equally unfavourable.

In further support of the claims of economy put forward for electric traction, the following comparison between the cost of electric locomotive operation per train-mile on the recently electrified section of the Paulista Railway and the cost of steam-locomotive operation per train-mile on the same section of line immediately prior to electrification, shown in Table B, is interesting.

It is based substantially on figures published by Dr. F. de Monlwade, General Inspector of the Company,* the figures being reproduced here without alteration except those representing the cost of coal and current, which have been adjusted, as described below, to make them applicable to the conditions obtaining in this country. Owing to the high cost of coal in Brazil the actual saving effected by electrification has been very great indeed, the cost per train-mile before and after the change-over being 69·92 cents (coal 51·14 cents) and 22·97 cents (current 11·97 cents) respectively. In order to make these figures representative of conditions in Britain the author has adjusted the cost of coal to bear the same ratio to the remaining steam-locomotive operation costs that it bears in British practice. The cost of current has been based on the density of traffic which, from the published figures, the author estimates at 3 770 000 trailing ton-miles per track-mile per annum.

TABLE B.

Total	26·16 c.	23·51 c.	26·24d.	22·00d.

SUMMARY.

Actual saving on Paulista Railway on cost of locomotive operation, using regeneration .. 67·2 per cent
Estimated saving on locomotive operation with coal and current adjusted to British conditions without regeneration .. .. 10·1 per cent

At this density the cost per engine-mile from Table 9 is 13·1 pence in Britain, the ratio between this and the remaining costs being 13·1 : 8·9, which has been used to determine a comparative cost in cents per engine-mile in Brazil. The adjustment in this case is one of increase in cost. In the above alterations to figures the cost per engine-mile and per train-mile are assumed to bear the same ratio to each other in the two countries.

Mr. Taylor emphasizes an objection, raised also by several other speakers, to the proposal to use low-tension distribution at 1 500 volts rather than at 3 000 volts, and, whilst I appreciate the superiority of the latter system in some respects, I do not wish to enter into the arguments for and against the various systems of electrification but rather to demonstrate the advantages of electric traction over steam traction. With this idea in view the system adopted for the purposes of the paper was that which was unanimously recommended by the Electric Railway Advisory Committee as being the most suitable for this country.

Mr. Taylor's further remarks are based on a misapprehension both as to the probable industrial demand on an electrified route and as to the probable length of transmissions required. In the first place, 90 per cent of the industrial load is already concentrated in the near vicinity of the large power stations already in being or under construction; secondly, at least on the West Coast and in the Midlands large and economical power stations are so plentiful in the vicinity of the main lines of railway that practically no transmission line for railway purposes would exceed 30 miles in length. With 12 miles between substations and such short transmission lines the distance between main generating stations will be 72 miles. From London to Crewe is 159 miles, to Birmingham 113, to Preston 209, to Carlisle 300, so that a comparatively small number of power stations would serve the whole London, Midland and Scottish Railway south of Carlisle if electrified. In this connection it may be pointed out that the transmission voltage would not exceed 33 000, and that, as experience has already proved, no difficulty would be experienced in finding routes across country for such transmissions which would avoid all interference with Post Office communication circuits. Central Scotland, the North-East Coast and Lancashire are already covered with such lines. Notwithstanding their greater cost, such independent routes, readily approachable by road, are certainly preferable to those following the railways themselves, the difficulties attending the use of which, viz. liability to interference with communication circuits and difficulty of access

in the case of a breakdown, are much more serious than Mr. Taylor appears to believe.

Mr. Livingstone doubts whether a modern steam locomotive could be sold by a trading concern at £50 to £70 per ton. The figure of £50 per ton refers to the weight in working order, and £70 per ton to the weight empty, i.e. without coal and water; these are to-day's market prices for two-cylinder non-superheater engines; the cost of three- or four-cylinder engines with superheaters would be somewhat higher. In giving the cost of electric locomotives in Appendix 2 the cost per ton of the locomotive structure is rather too high and that for the control rather too low. He is correct in assuming that the maximum draw-bar pull of an electric locomotive may be taken as one-third of the adhesive weight. The further particulars he gives of typical electric locomotives are interesting, but it must be realized that to make these figures intelligible to the non-technical railwayman, or to the railway mechanical engineer, it is necessary to state the loads that can be dealt with on various gradients and on the level, at various speeds. He refers to certain advantages of electric traction such as reduced fire insurance, reduced accommodation for rolling stock, etc., not mentioned by the author. I desired, however, to make a most conservative statement of the advantages of main-line electrification that would bear the closest scrutiny, and therefore confined myself strictly to those items of locomotive operation which could be evaluated in cash.

Mr. Dalziel's remarks are so much to the point and so valuable that they require no further emphasis by me. As regards the comparative merits of collection from third rail and from an overhead conductor, the outstanding merits of the third rail are the ease with which it can be maintained by the platelaying staff and the ease with which it can be laid without interference with traffic. These, and these only, are the reasons which influenced me in recommending it for the bulk of main-line electrification. There must, however, be no prejudice in the matter, and detailed examination of a particular problem may lead to a decision to use overhead collection exclusively. There is one other point that Mr. Dalziel raises which requires some comment, namely, the permissible drop in the return. It is important to distinguish between maximum momentary drop and the average drop. With 1 500-volt substations 12 miles apart and the worst probable conditions on a double-track main line, the momentary drop in the positive conductor would be 185 volts and in the return 235 volts with third rails of 105 lb. per yard, and the average drop would be much less, probably about 10 per cent.

The use of regenerative braking mentioned by Prof. Marchant is, as he surmises, not of any great importance in this country on account of the absence of steep grades of considerable length.

Mr. Morton questions the figure of 15s. per ton for coal used at generating stations, but this is very representative of the price paid by many large undertakings in this country.* The costs of steam-locomotive coal quoted in Table 4 are, of course, for a quality of coal much superior to that used in most power stations. With regard to the figure of 0·6d. per unit used, stated as the cost of equivalent electrical energy at the wheel of the locomotive, this depends solely upon the cost of generation and the average overall efficiency of transmission given in Table 6, the load factors of the power station and the losses having no bearing on the question except in so far as the cost of generation and the overall efficiency are themselves dependent on them. In using a 44 000-volt system as the basis in calculating transmission costs in Table 9 I have in mind the fact that the power delivered by any one power station to a main-line route will not in general be sufficiently great to justify the use of much higher voltages.

I cannot contribute to Mr. Highfield's belief that electrification will not be adopted solely because it will reduce working expenses. This fact is, indeed, the most important argument in its favour, and if electrification is not done primarily with a view to increasing net profits it will never be done. Two at least of the other factors which in Mr. Highfield's opinion offer more decisive arguments for electrification,

TABLE D.

Typical Costs of Coal Delivered to Generating Stations, for Year 1923.

The average calorific value of the coal is 10 900 B.Th.U. per lb.

Distance from London	Pit-head price per ton	Miles hauled from colliery	Carriage on railway at ½d. per ton-mile	Handling and trimmers' wages at generating station	Total cost
Miles	s. d.	Miles	s. d.	s. d.	s. d.

187	11 4	11	5½	2 4	14 1½
211	11 5	26	1 1	1 7	14 1
Averages	11 3	43	1 9½	1 8	14 8

* See Table D.

viz. the possibility of increasing train loads and speeds, and in other countries the desire to make use of water-power resources, are ultimately reducible to statements of diminished working expenses.

In reply to Mr. Jackson's inquiry concerning the engine-mile basis used in Tables 1 and 3, for the steam railways in all cases the gross engine-mileage has been used which, as he suggests, is a basis favourable to steam traction in the comparisons.

The choice of route for transmission lines mentioned by Mr. Carter has been considered in the reply to Mr. Taylor's remarks on the same subject. The figure used in the paper for the cost of track equipment, viz. £2 500 per track-mile, does not include an allowance for the removal of signal rods, etc. The last column in Table 5 is an estimate based upon an actual case. With regard to my estimate of 92 per cent for the average efficiency of transformation, this figure may be anticipated with substations equipped with mercury-arc rectifiers. The average for a typical suburban system having rotary converters has been found to be 90 per cent, which agrees well with the figure given by Mr. Carter.

In reply to Sir Philip Dawson, whose communication is a valuable contribution to the history of railway electrification, I realize that the presentation of a special case of main-line electrification would have been more convincing. The investigation of a specific case of electrification on a large scale—for to give the most fully successful results such an operation must be on a large scale—is, as Sir Philip Dawson shows, a lengthy business demanding not only the co-operation but also the interest of all the departments on a railway. I felt that under these circumstances a more convincing case could be made by using the average figures for train-miles, traffic densities, costs, etc., and by showing first that electrification would give a moderate net return on the capital expended for the whole of a large railway system, from which it follows that there must be some portions of that system where the traffic density is higher than the average and where the cost of certain services must also be higher than the average, the electrification of which would result in a saving greater than that actually calculated. The trains hauled on such routes are likely to be of the heaviest class, drawn by the largest and most expensive types of steam locomotives, and the cost of repairs and fuel will therefore be higher, probably 25 per cent greater than the average for the whole system. It is interesting to me to find that my estimate of the gross freight and coaching ton-miles of the London, Brighton and South Coast Railway, as deduced from the locomotive coal-consumption per ton-mile, is 2 699 million ton-miles per annum, as compared with Sir Philip Dawson's figure of 2 616 million ton-miles per annum. The cost which he gives of electrifying 500 miles of single track seems to be very high, even allowing for the prices prevailing in 1921, but no doubt a large proportion of the cost was for the additional track facilities required to handle the expected increased traffic, and the whole of the new electric stock has also been included. I am glad to feel that such an authority as Sir Philip Dawson supports me in the view that main-line electrification is a revenue-earning proposition and that it would prove of great value to railways, the engineering industry and the public alike.

The information given by Dr. Garrard as to the return obtained on the capital expended on electrification abroad is most valuable; I only regret that it is not published in full. It seems to be the general experience that at least 15 per cent return on capital may be expected from any electrification where the traffic conditions are favourable. It is regrettable that both Dr. Garrard and Sir Philip Dawson should have revived the old alternating current versus direct current controversy. I feel that the prolonged discussion of their respective merits reveals the fact that the choice of system will have but little effect on the financial success of a main-line electrification. The choice of system to be adopted is rather governed by the *status quo*, the large mileage of existing electrified lines at 600 and 1 200 volts on the direct-current system, the greater suitability of that system for suburban work, and the existence of a very large mileage of suburban railways whose electrification could, and should, be dealt with at the same time as that of the first main lines to be electrified. If current is purchased, the electrification of 100 miles of four-track route would not cost more than £5 000 per track-mile, or a total of £2 000 000 exclusive of locomotives, which would be the only charge debitable to capital account in carrying out the electrification. Interest and depreciation charges on this sum would not exceed £160 000 per annum, equivalent to about 5d. per engine-mile on a basis of 8 000 000 engine-miles per annum. Such a large-scale experiment could not possibly result in any loss to the company carrying it out, the capital expended would represent about 0·15 per cent of the total capital of the British railways, and the experiment would result in the whole controversy as to whether main-line electrification would be profitable or not in this country being concluded for ever, one way or the other.

Mr. Carlmark touches on a subject which would require a paper to itself when he raises the question of the most economical method of carrying out shunting work on an electrified main line. The relative merits of electrifying the sidings and of using accumulator locomotives, and the extent to which capstans could be used, would require the most careful investigation—and the case of each station would have to be decided on its merits. He is on less-debatable ground when he refers to the low cost of maintenance of the modern traction motor. The advances made in the design of traction motors and of electric locomotives in recent years form the basis of the arguments presented in the present paper and cannot be over-emphasized, as a large part of the economy to be effected by electrification arises from the reduction in maintenance costs both in the works and at the locomotive sheds.

Mr. Blakemore also makes an important point when he draws attention to the effect of the rising cost of coal. Nobody doubts that coal costs will tend to rise rather than fall, and that the least improvement in the internal trade of this country would result in a substantial rise in coal prices.

Mr. Rawll's point about the replacement of the

steam locomotives is akin to that made by Mr. Gill, but his supposition that the capital cost of the electric locomotives required to operate some portion of a system might be greater than the normal expenditure on steam-locomotive renewals for that section is least likely to apply to those sections electrified which would be chosen, as has been stated elsewhere, for their high traffic density, and on which the steam locomotive renewals-cost would be above the average and the possibilities of continuous service of the electric locomotives more nearly realizable. The estimates in Table 9, showing the relation of cost of current per engine-mile to traffic density per track-mile, allowed the very large sum of £12 per kilowatt of substation plant, the cost of a 6 000 kW substation being taken at £72 000, including a large battery. I do not consider that batteries would actually be required for main-line work, but I included them in order to make the estimates conservative and unassailable; with modern plant the contingency of appreciable interruptions to supply is extremely remote.

Mr. Lydall is correct in his assumptions with regard to curves 1 and 3 in Fig. 5. Curve 1 includes machinery resistances, that is the frictional resistance offered by the engine mechanism, in addition to the resistance of the locomotive as a vehicle; it has been derived by Mr. L. H. Fry from the results of a large number of tests on various locomotives but applies only to engines with six wheels coupled.* The machinery resistance of the locomotive at any speed may be taken to be 9 per cent of the tractive effort at the tread of the wheels at that speed. Curve 3 represents only the vehicular resistance of the electric locomotive (see Appendix 4 to paper) and is typical of locomotives having individual drives running on level straight track; it does not apply to locomotives having coupling rods. Very little is known about the average resistance of freight trains and I do not wish to suggest that curve 2 in Fig. 5 is applicable to freight trains in general. The curve has been derived by Mr. Fry from the results of tests made by Sir John Aspinall on four-wheel fully-loaded 10-ton goods wagons having an average tare weight of 6 tons, and it agrees well with some tests recently made by the London, Midland and Scottish Railway. In these latter tests, five in number, freight trains of weights between 800 and 1 250 tons trailing and made up of fully-loaded four-wheel wagons having an average gross weight of 16 tons were hauled a distance of 24½ miles at an average speed of 16 miles per hour.† The average resistance, after making allowance for change in level, was found to be 8 lb. per ton. If allowance is made for the fact that the average maximum speed reached in the tests was 26 m.p.h. it will be found that the agreement with curve 2 is very good. The resistance of freight trains as ordinarily built up, that is composed of mixed four-wheel and bogie wagons often only partly loaded, together with covered vans, must, in thea bsence of better experimental data, be estimated from results such as the above. With regard to the remark that curve 4 in Fig. 5 representing the resistance offered by L.M. and S. Railway passenger stock gives figures which are high in comparison with those obtained in tests on the New York Central Railway, this difference may well be accounted for by differences of weight, type of bogie, etc., between the types of coach experimented with, and I believe that this curve, which has been derived from the results of recent experiments, is fairly representative of modern passenger stock as used in this country. However, in calculating the energy consumption for an electrified main line I purposely used a fairly high figure for the watt-hours per ton-mile in order to ensure that my estimates of saving should be conservative.

In connection with the very interesting figures given by Mr. Lydall in regard to the mileage performed by electric locomotives, I believe that electric freight locomotives on the Midi Railway of France are doing 1 000 miles weekly.

In answer to Mr. Ferguson, it can only be repeated that it is the usual practice on British railways to double-head many trains, the two locomotives then used having usually a combined draw-bar pull of at least 60 000 lb. at starting, and 16 000 to 20 000 lb. when running. The rigid wheel-base of locomotives having driving wheels coupled by side rods should in general not exceed 17 feet, but with electric locomotives having individual axle drivers of the Brown Boveri type, in which side play of the axles may easily be provided for, this restriction does not apply and wheel-bases of 18 to 19 feet may be safely employed if desired. Messrs. Brown, Boveri's side-gear drive will pass through most of the English main-line gauges, and can easily be modified to pass any English main-line gauge. By the courtesy of the Swiss Federal Railways I recently inspected one of these locomotives after over 80 000 miles' running on work quite equal to heavy main-line duty in England; everything about the locomotive, including not only the gears but also the tyres, was in such perfect condition that the most sceptical steam-locomotive engineer or traffic officer would have been convinced that the claim that locomotive repair-costs would be reduced to between one-third and one-fifth those of steam locomotives was justified. With regard to the work done on the train as recorded by the dynamometer chart, this, of course, does not include the work required to propel the locomotive itself, which should be obtained by using curve 1. Further details in connection with this and the other resistance curves have been given in the reply to Mr. Lydall's remarks.

Mr. Povey, Major Coulston and Dr. Garrard all draw attention to the increased use of station sites which could be made on an electrified line owing to the absence of steam and smoke, but it should also be pointed out that in the neighbourhood of London especially and other large towns the reduced accommodation required for locomotive stock would free an appreciable acreage of valuable sites for other purposes. In this connection I again wish to repeat that the case I have endeavoured to make for main-line electrification is based solely on the economies to be effected in connection with locomotive operation and repairs. If the other and consequential advantages are included the case is unanswerable.

Mr. Medlyn need not fear interference with Post

* For this and formulæ for engines with four and eight wheels coupled, see *Engineer*, 1909, vol. 107, p. 310.

* With Brown Boveri individual drive this figure may readily be reduced by extending the wheel-base. † Based on grate area. ‡ For short period only at starting.

Office circuits by power lines; the principles to be observed to avoid such interference are well known. It is undesirable to put lead-covered cables in the near vicinity of electric railways worked on the direct-current system, but jute-served cables, even if laid in the ground, have proved immune.

Mr. Brooks's solution of the problem of raising and lowering the pantograph is very neat; it will, however, be necessary to provide means for preventing the motorman from raising the pantograph until he is actually under the section equipped with the overhead collector wire, otherwise the pantograph might be raised prematurely and come in contact with some structure. For passenger work the provision of any overhead collector would probably be as unnecessary as it is for suburban electrifications. Its necessity arises in connection with freight-train operation and busy sidings where there is much movement of staff. As to one-man operation of main-line locomotives, there is little doubt that when the demand actually arises the technical skill of British engineers is quite capable of providing a control which will satisfy both the Ministry of Transport and the public as to its safety in operation. Every operating engineer will agree with his remarks as to the desirability of robustness and simplicity of design in electrical apparatus for railway work. The electric locomotive is, in fact, a simple piece of apparatus compared with a steam locomotive, owing to the fact that all moving parts have purely rotary motion, that no portion is exposed to high temperatures or large differences of temperature, and that the complicated portion, i.e. the electrical connections, are all permanent and stationary and require practically no maintenance or inspection.

Mr. Allcock should realize that the electrification of even 5 000 track-miles of main line, or about 15 per cent of the total running track-mileage of Great Britain, would only increase the total capital of the railways by about 3 per cent. As he suggests, an extensive electrification scheme of much less magnitude than the above would have a marked effect on the unemployment problem.

Mr. Roger Smith suggests as a basis unit to be adopted for comparison purposes, ton-miles per engine-hour. Some such unit would be more satisfactory than that used in the paper, but its use would have involved a more elaborate statistical research than the time available permitted. I am in complete agreement with Mr. Roger Smith's other remarks and also with Mr. Lydall's. It is improbable, however, that the weight of British trains will tend to increase very much; the weight of the freight trains is limited by their length, which, in turn, is limited by siding accommodation, and in passenger work the tendency is rather towards more frequent trains of less weight.

In conclusion, I venture to add three more tables. Table C gives the principal locomotive operating statistics for 1923 for the four principal companies, as taken from their published accounts. Table D gives the prices of fuel suitable for power-station purposes to compare with that given for locomotive purposes in Table 4 of the paper. Table E is a most striking comparison between recently-built electric locomotives and the nearest comparable steam-locomotive combinations.

SELECTION OF BALL AND ROLLER BEARINGS FOR ELECTRICAL MACHINES.*

By T. D. TREES, Associate Member.

(*Paper first received* 31*st October*, 1923, *and in final form* 3*rd May*, 1924.)

SUMMARY.

The paper has been prepared to indicate the lines on which the selection of bearings should proceed in cases where it has been decided to employ ball or roller bearings for electrical machines.

In order that due allowance may be made for bearings under different conditions of loading, it is suggested that some method should be adopted that would employ definite factors graded according to the service required, by means of which the capacity of bearings could be properly checked when necessary.

It is not sufficient simply to use the makers' tables of safe loads for all purposes, and certain "load factors" are put forward in order to furnish a rational basis of comparison.

In conclusion, observations of a general character are made with regard to capacities, costs, types, etc.

A list of previous papers on the subject is given for reference.

INTRODUCTION.

The use of ball and roller bearings in nearly all classes of machinery has grown considerably in recent years, particularly since the war, and although comparatively few electrical manufacturers used them in standard practice in pre-war days, various firms have now adopted them in their standard machines.

It is not desired to discuss the relative merits of the different types which may be used or the advantages and disadvantages of ball and roller bearings in general, although widely different ideas appear to be held by engineers with regard to their use in electrical machines. There is no doubt that ball and roller bearings offer certain advantages, but there is equally no doubt that their importance is sometimes rather exaggerated, and it is quite an open question whether it is worth while for the manufacturer to embody them as standard in preference to the ordinary ring-lubricated bearings. Some firms compromise by supplying their standard frame sizes with either type, according to the requirements of the customer.

Papers dealing with the design and manufacture of ball and roller bearings have been read by various authorities, but mainly from considerations of interest to the bearing manufacturer or the automobile engineer, and articles of either a theoretical or descriptive nature have appeared in the technical Press from time to time.

The present paper is presented as an attempt to amplify the work above referred to, since it is thought that the mathematical papers and articles on ball bearings published hitherto have been of only a limited value to the machine designer or operating engineer.

The design and manufacture of ball bearings is quite a special subject, and formulæ which may be accepted as being theoretically correct offer little assistance to the practical engineer or the user of these bearings, because such formulæ should only be used in combination with certain constants or allowances which have been derived from the results of tests and experience in actual manufacture. Thus it may be easily understood that the quality of the materials used, the relative proportions of the balls, races and grooves, and the accuracy of workmanship, etc., are all vital factors to be considered. These factors are fully known by the bearing maker only and in practice may differ appreciably as between one firm and another.

It is therefore not proposed to deal with the theoretical side of the subject which has been so ably expounded, but it is felt that some notes on the selection of bearings may prove interesting and helpful.

Although the engineer is not called upon to design the actual bearings it is essential that he should be able to determine whether or not his bearings are capable of sustaining the load imposed. It frequently happens in practice that a motor of standard frame size may be suitable electrically for a certain duty, but would not be reliable if fitted with bearings of the standard size. In such cases it too often occurs that the bearings are taken for granted or are passed as correct by simply checking the catalogue load tables without making any allowance for the nature of the load to be sustained.

GENERAL.

Supposing that it has been decided to use ball or roller bearings, how shall the size or type be determined? The electrical manufacturer, in general, takes the path of least resistance, or, in other words, hands the job over to the bearing maker whose name happens to be best known to him, or the one who is most favoured at the time for some reason or other. This practice has been adhered to, partly because it is so simple, but principally because the bearing makers recommend and encourage it. In some catalogues the load-carrying capacity of the bearings is not stated at all; in others we are told that they are merely comparative figures, so that lack of confidence in the load tables published leads most engineers into accepting the makers' offer to determine the size and type of bearing necessary. Although much may be said for this method of dealing with the question,

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

it is not considered to be sound engineering practice, for reasons which will be given later.

Another method that is sometimes used is to fit bearings of the same diameter as the standard ring-lubricated bearings employed on similar machines, without reference to the maker or checking the load capacity in detail. This is not to be recommended; it may be satisfactory in the case of machines which have necessarily very stiff shafts, but the engineer is really working in the dark, and the bearing maker cannot be expected to accept any responsibility if the size thus chosen is not correct.

The chief reason given for adopting the first of these methods is that the ball-bearing maker is a specialist and also one who has acquired much experience in the pursuit of his profession, but it should be realized that this experience has been obtained simply because he has tackled problems of all kinds that have been passed to him from many directions in response to his insistent invitations.

Let us consider for a moment other details of a machine—insulation, for example. The maker of the material gives test figures regarding electric strengths, tensile strengths, etc., but the designer determines the electrical or mechanical loading. Similarly for steels the maker will give the magnetic or mechanical properties, but the engineer decides for himself with what flux density or stress he shall work the material under certain conditions. In the author's opinion it is no more rational to place the bearings out to be designed by another firm than it would be to request the steel maker to design the shaft.

There is no obvious reason why basic load values and allowances should not be assigned to ball and roller bearings of all sizes according to their type and make, by the aid of which the engineer could himself determine the size and type of bearings to employ on the machine, even though his factors of safety or allowances were not similar to those used by the bearing maker. After some experience he would have the great advantage of knowing fairly well what results to expect under almost every condition, and with this end in view the author is putting forward definite recommendations which are based on personal experience and may or may not agree with the practice followed by any bearing maker.

Little or nothing has been published by British bearing makers regarding the allowances that should be made when selecting bearings to meet various requirements, and the engineer is assured that it is not possible to publish tables or charts to indicate the capacity of the bearings under varying conditions. Tables are published giving the maximum steady load which the bearings will stand under continuous running for certain types and sizes. They do not state, however, what life may be expected for a bearing under the load and conditions quoted, nor are the load values guaranteed. This absence of definite information is regrettable, although there are very good reasons from the makers' point of view why all bearing problems should be referred to them. It should not be expected that a motor manufacturer who is making standard machines in large quantities can afford the time and trouble to submit each individual case for the bearing maker to consider, especially as in many instances stock machines are sold and guaranteed without the manufacturer knowing what is the exact nature of the drive and the resultant loads that will be imposed on the bearings. In special cases where a non-standard machine is being designed, suitable bearings can be chosen for the particular duty required, but when considering the selection of bearings for a standard line of motors it is essential to ensure that the shafts and bearings are large enough to withstand the maximum loads which are likely to be imposed upon them under any conditions for which the motors may be designed.

For simplicity of production when manufacturing machines for general purposes it is not desirable or customary to design the bearings for each individual service, and therefore it will frequently happen that the machine is employed for a duty which does not by any means load the bearings to their maximum capacity. For example, there may be steady loads such as are experienced in direct-coupled motor-generator sets in which the drive subjects the shafts to torsion only and the sole function of the bearings is to support the weight of the rotors. On the other hand, a machine may have to withstand severe shocks such as are experienced when driving rolls or crushers through gearing. In each of these cases machines having the same size of frame may be capable of giving the output required, but obviously if the bearings fitted are capable of withstanding the latter duty much lighter bearings could be employed if desired on the machine which is not subjected, by the nature of the drive, to additional external load.

Due to the increased output developed in the case of intermittently rated motors such as those used for crane duty, the bearings are subjected to still heavier loads for machines having the same size of frame. Therefore, if the standard motors are to be suitable for intermittent ratings, it is necessary to provide stiff shafts and bearings of ample capacity when the mechanical design is standardized for each machine. In general, standard motors only have one size of shaft per motor, but it is a matter of policy rather than of design to settle in the first case the purposes for which the machines shall be manufactured. With some firms it is the practice to make a standard line of machines for general duties, but to supply similar machines with stiffer shafts and larger bearings for crane ratings.

Selection.

Assuming that the above general questions have been reviewed and settled, it is now proposed to examine various types of drives which may be used and to suggest comparative methods of determining the load-carrying capacity of the bearings under these conditions.

It is not sufficient simply to calculate the theoretical load and choose a bearing suitable for this capacity from the load tables, without making certain allowances according to the type of drive employed. The theoretical bearing load should be multiplied by some value (which is here called the "load factor") before the bearing size is selected. Although in certain cases it may happen that values given in manufacturers' load tables are far too high, in using the load factors given later

In the paper it is assumed that the load tables published are not too optimistic and that with ordinary good fitting the bearings may be expected to have a reasonable life when running under conditions similar to those on which the tables are based.

Belt drives.—It is considered desirable to draw attention to a few important points regarding the calculations of the belt pull. Although these may appear obvious, it is found that they are frequently overlooked in practice. It should always be borne in mind that the standard formula for the ratio between the tensions on the tight and slack sides respectively is correct only when the belt is on the point of slipping. Sufficient initial tension must be applied in order to ensure that the belt will not slip at the maximum overload of the machine, and this initial tension is usually much greater than that theoretically required to transmit the normal full-load output. At any load less than the maximum overload that the belt will transmit, the tensions on the tight and slack sides will automatically adjust themselves so that the difference in belt tension is equal to the effort required to transmit the lower power, and the total belt pull on the bearing will be the same at all loads if the motor is running at constant speed. In the case of machines which run at variable speeds,

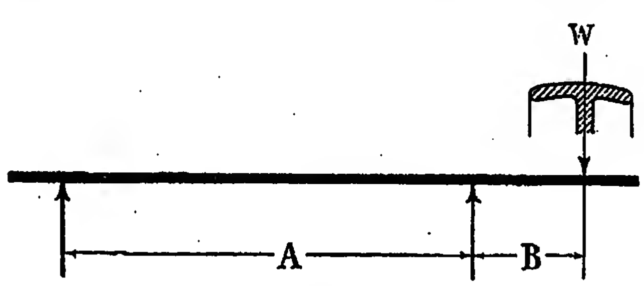

FIG. 1.

however, the bearing load will be rather greater at the low speeds than at the high speeds, because the centrifugal force acting on the belt is less at those speeds, and therefore the belt pressure on the pulley is not relieved to the same extent.

It is interesting to note that if a heavier belt than necessary be fitted a greater centrifugal force has to be counterbalanced at full speed, and consequently a greater initial belt tension is required than would be the case with a lighter belt. Due to the absence of the centrifugal effect at starting, the bearing loads are higher than when running, but it is not considered necessary to make allowance for this fact, as this increased load occurs for a brief period only. In this connection it may be observed that a belt drive is able to transmit a certain amount of torque over and above its full-load torque. This amount depends on the initial belt tension and the final running speed of the machine.

The chief point that it is desired to emphasize is that the pull on the bearing will be practically the same at all outputs of the machine and that it depends primarily on the initial belt tension.

Another fundamental rule is frequently overlooked in practice when the effect of the "leverage" of the shaft when calculating the belt pull on the bearing is neglected. This may mean that the figure thus arrived at may be anything from 10 to 25 per cent too low. For example, in the case shown in Fig. 1, where W = belt pull, A = bearing centres, and B = pulley centre, the actual load on the driving-end bearing due to belt pull is

$$W\left(\frac{A+B}{A}\right)$$

For normal leather-belt drives and for cases in which the angle of drive and the arc of contact, etc., are not known, it may be assumed that the ratio of the belt tensions is $2\cdot5:1$, i.e. the total belt pull is $2\cdot33$ times the effective belt pull.* In addition, as the motor is frequently guaranteed to withstand an overload of 50 per cent momentarily, allowance must be made for this fact in order to ensure that the belt will not slip at the maximum overload, and the initial belt tension should allow, say, a 10 per cent margin.

Taking into account these various factors the total belt pull becomes

$$W = \frac{2\cdot33 \times 1\cdot5 \times 1\cdot1 \times \text{horse-power} \times 33\,000}{V}$$

$$= \frac{3\cdot85 \times \text{horse-power} \times 33\,000}{V}$$

where V = velocity of belt in ft. per min.

For general purposes and for convenience it is proposed to use a round figure and make the "load factor" = 4. Thus

$$\text{Belt pull} = \frac{4 \times \text{horse-power} \times 33\,000}{V}.$$

Gear drives.—In contrast to the load imposed on the bearings by belt drives, the bearing load for a geared drive varies directly with the output of the machine, and in the case of a motor for a varying load the bearing is consequently not always working under the maximum conditions of loading. Although the bearing must be large enough to withstand peak loads, its life should be considerably longer than that of the bearing running continuously under such peak-load conditions as those customary for belt drives. On the other hand, however, some allowance must be made for inaccurate machining of the gear teeth, as although a high standard of precision has been attained in gear-cutting practice one cannot expect to obtain absolutely perfect meshing of the teeth. It is well known that exceedingly high loads may be impressed on the teeth if the gears do not mesh accurately, and it has been stated by one authority† that these impressed loads increase in direct proportion to the square of the tooth velocity.

When designing gearing it is customary to increase the factor of safety by working the teeth at lower stresses at the higher tooth velocities. The arbitrary values of the permissible stresses at various velocities given by Wilfred Lewis‡ have long been adopted as standard and proved satisfactory in practice. Allowance should be made in a somewhat similar manner for the

* In cases where the coefficient of friction and the arc of contact are such that a different value is obtained for this ratio, the load factor should be modified accordingly.

† O. LASCHE: *Zeitschrift des Vereines Deutscher Ingenieure*, 1899, vol. 43, p. 1417. See also DANIEL ADAMSON: "Spur Gearing," *Proceedings of the Institution of Mechanical Engineers*, 1916, Jan.–May, p. 353.

‡ *Proceedings of the Engineers' Club of Philadelphia*, 1893, vol. 10, p. 16. See also DANIEL ADAMSON, *loc. cit.*

probable increase of load imposed on the bearing by tooth pressure as the pitch-line velocity increases.

The curves in Fig. 2 have been drawn to illustrate the author's suggested load factors. For ordinary non-reversing metal spur-gearing, the load factors given by curve A may generally be recommended.

In motors which may be continually reversing, the bearings will probably be subjected to additional shock loads due to "backlash," and it is considered that some higher load factors (as given in curve B) should be assumed when selecting the bearings.

Where the motors are fitted with non-metallic pinions such as paper, raw hide or fabric, it is expected that the shocks will not be so severe, consequently slightly lower load factors may be used, such as those shown in curve C, whilst for double helical gearing a still lower factor may be employed, as much smoother running is obtained, the values suggested in this case being shown by curve D.

In order to avoid confusion, no curves have been shown for reversing-gears of the raw hide or double helical types; but an increased load factor should certainly be allowed for reversing-gear drives similar to that shown by the two curves for spur gears.

For machines which are guaranteed to withstand such an overload as 25 per cent for half an hour, it is of course essential that the gear thrust should be calculated at this overload. For momentary overloads, however, it is not thought necessary to base the capacity of the bearing on the maximum overload, but a somewhat lower factor should be used which may be taken from Fig. 3. The equivalent gear thrust then becomes

$$\frac{k \times l \times P \times 33\,000}{V \times \cos\theta}$$

where P = maximum power (expressed in horse-power) other than momentary overload,
V = tooth velocity at pitch circle in ft. per min.,
θ = pressure angle of gear,
k = load factor from Fig. 2,
l = overload factor from Fig. 3.

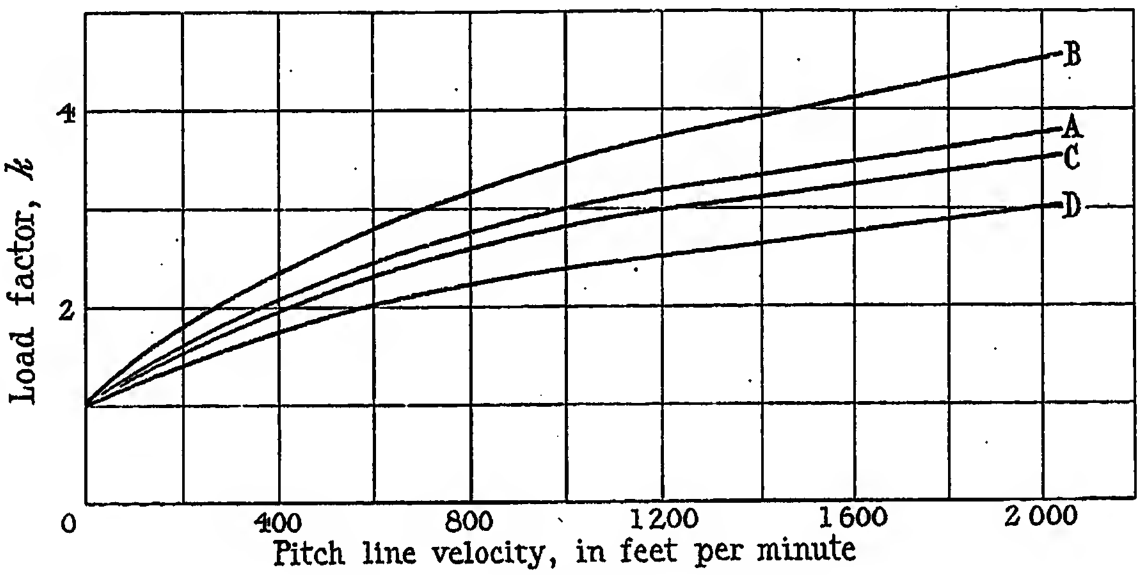

Fig. 2.—Bearing load factors for machine-cut gearing.

In order to make the meaning of this overload factor clear, let us assume two cases :—

(a) 20-h.p. motor capable of developing 100 per cent overload momentarily.

(b) 20-h.p. motor capable of developing 25 per cent overload for ½ hour and capable of developing 100 per cent overload momentarily.

For case (a).—The equivalent bearing load should be taken as that due to 20 × 1·5 (from Fig. 3) = 30 h.p.

For case (b).—The 100 per cent momentary overload is equal to a 60 per cent increase on the maximum half-hour output of 125 per cent.

The constant l, therefore, is now 1·3 (from Fig. 3) and the maximum sustained load of 1·25 should be multiplied by this factor. The equivalent bearing load is thus due to 1·25 × 1·3 × 20 = 32·5 h.p.

Rope drives.—It will generally be found that rope drives are not employed on motors of the smaller outputs such as those in a standard range of sizes fitted with ball or roller bearings, but are more commonly used on the larger machines in which the standard practice is to use lubricated bearings. Although for this reason it may not be necessary for some manufacturers to concern themselves with the loads to be expected, yet other firms will find it desirable to make provision for rope drives in special cases if not in their standard lines.

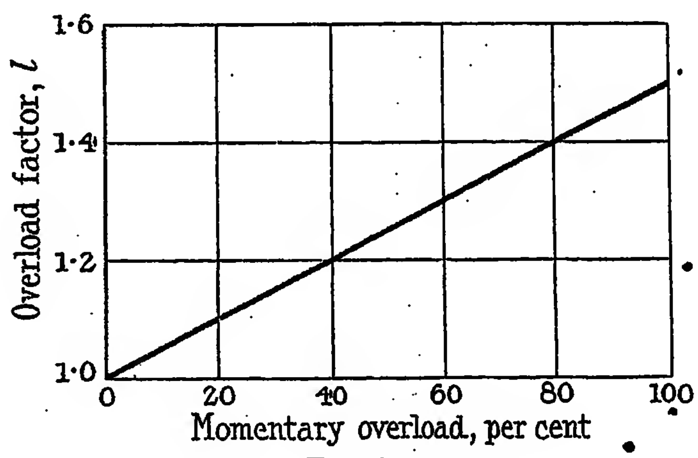

Fig. 3.

Where this type of drive is used, it is to be noted that the conditions regarding initial tension and load being continually on the bearings, etc., are similar to those discussed for machines with belt drives.

The use of grooved pulleys is customary, and by a wedging effect the grooves of standard shape considerably increase the effective value of the coefficient of friction between the ropes and the pulleys. In consequence the tension on the slack side is very much lower than that required for an ordinary belt drive transmitting the same output, the ratio of the tensions being approximately 4 : 1. The corresponding expression for the rope pull then becomes

$$\frac{1{\cdot}66 \times 1{\cdot}5 \times 1{\cdot}1 \times \text{horse-power} \times 33\,000}{V}$$

which simplifies to

$$\frac{2{\cdot}75 \times \text{horse-power} \times 33\,000}{V}$$

Link belts with grooved pulleys.—It is occasionally necessary for machines of moderate output to use leather link belts of tapered width running in grooved pulleys. In such cases, as in ordinary rope drives, the wedging action increases the effective coefficient of friction. Therefore the tension on the slack side and consequently the total load on the bearing is lower than that necessary for belt drives with flat pulleys, and the formula for the belt pull may be taken as

$$\frac{2 \times \text{horse-power} \times 33\,000}{V}$$

the load on the bearing at all outputs being practically equal to the initial tension, as in the usual belt drive.

Chain drives.—Where chain drives are employed for transmitting the power developed, the conditions are more like those obtaining for gears, since no tension is necessary on the slack side of the chain, and the load on the bearing is directly proportional to the output of the machine. However, although there is no slip such as is experienced with belts, and the drive is positive, a considerable amount of flexibility is gained from the working clearances between the links and pins, as a result of which the bearing should not have to withstand anything like the same amount of incremental load due to inequalities of pitch and vibration as a bearing for a gear drive. For these reasons the load factor can be omitted and the load on the sprocket within the usual range of chain speeds (from 500 to 1 300 ft. per min.) may be taken as

$$\frac{P \times 33\,000 \times l}{V} \quad (l \text{ from Fig. 3})$$

In some instances the weight of the chain may appreciably affect the bearing load; this naturally depends on the position of the motor relative to the drive. For the roller chain such as may be used for low speeds up to 50 h.p., the total weight of the chain for average conditions may be approximately equivalent to 10 per cent of the effective chain pull. For the silent chain type generally used for higher speeds the chain weight will vary from about 5 per cent to 20 per cent of the effective chain pull for average drives from 3 to 200 h.p. It will be necessary to make allowances in this respect to meet individual conditions, in the same way that one should include the weight of belt or rope pulleys, flywheels, clutches or gearing, etc., when considering the total bearing load.

Direct coupling.—For direct-coupled machines not subject to such external loads as are described above, it is considered that the bearing should be capable of withstanding under steady running conditions the amounts stated in the makers' load tables. At the same time, however, it is pointed out that considerable loads may be impressed on the bearings unless direct-coupled sets are properly lined up on the same bed-plate. In cases where there is a possibility of the machines getting out of line, flexible couplings should be used, but in this connection it is important to observe that the fitting of a flexible coupling does not obviate the necessity for careful lining up when erecting.

When a unit having several bearings is required, such as a motor-generator set in which two or more machines are connected by solid couplings, it is preferable to have only one thrust bearing fitted for the complete set, as if a thrust bearing is fitted to each machine an initial load may be imposed on these bearings when the couplings are being bolted together. Similarly, if the thrust is to be taken by journal or location bearings, only one bearing in the complete set should be fixed, the remainder being given sufficient end-play in the housings to enable them to take up their correct running position without restraint.

Loads due to miscellaneous causes.—In addition to the specific cases mentioned above, the bearings have to withstand loads due to causes which are frequently lost sight of, and, although it is not proposed to go into details as to what allowance should be made for all cases, it is considered desirable to draw attention to some of these points. For example, when bevel or single helical gears are fitted on the motor shaft a certain axial thrust from the gears has to be sustained by the motor bearings, whilst, when double helical gears are employed, provision should be made for a small end-play, either on the armature shaft or the gear-wheel shaft, in order that the pinion may centre itself with the gear wheel. If this is not done, end thrust will be set up in one or other of the bearings.

The unbalanced magnetic pull due to shaft deflection and bearing wear, which may be present in certain machines, can be determined by well-known methods, but is often neglected when calculating bearing loads. Although it has not the same importance as when ring-lubricated bearings are employed, it should not be ignored.

Some trouble was experienced with certain vertical motor-generators fitted with ball bearings; this was simply due to the fact that the necessity of having shafts just as stiff for vertical as for horizontal machines was not properly understood. Because there was no external drive and the load due to gravity was not acting on the shaft and journal bearings as in horizontal machines, it was apparently assumed that small shafts and bearings could be employed. Such reasoning is unsound, because for high-speed machinery, such as

electric motors, it is necessary to consider the whirling action of the rotor, and in order that the critical speed of the shaft shall not be near to the normal running speed it is essential to provide a shaft of exactly the same stiffness, whether the motor be horizontal or vertical. If the shaft is not stiff enough, vibrations will be set up and, as a result, severe loads may be imposed on the bearings, thus causing trouble for which the bearings are often unjustly blamed.

Another important question is that of the machine fitted with a third bearing. It is a very common practice in these cases to assume that the load from the drive is shared equally between the outer bearing and the bearing at the driving end of the motor, and that the weight of the motor is shared proportionally between the two motor bearings. This method of calculating the bearing loads is quite wrong and may lead to bearing trouble. There are various methods of arriving at the actual load on each bearing, but these need not be discussed here. Generally speaking, the middle bearing may be expected to carry about 70 per cent of the total load due to both the weight of the rotor and the load imposed by the drive. Usually, most of the remainder is carried by the outer bearing because the driving load is much greater than the weight of the rotor, whilst the motor bearing remote from the drive may only be called upon to carry about 3 or 5 per cent of the total load, dependent on the direction in which the driving load is acting in relation to the downward weight of the rotor and the distance between bearing centres. Similarly in the case of direct-coupled motor-generator sets with three bearings, the middle bearing should be capable of supporting probably about five-eighths of the total weight of both rotors, and, unless correct methods be employed for calculating the bearing loads, it is probable that smaller bearings than are necessary may be selected for the centre bearings of both three- and four-bearing sets.

The above remarks are made on the assumption that the shafts are horizontal, but again one must not overlook the effect of incorrect alignment. In practice it is difficult to obtain perfect alignment, and if the outer bearings are higher than the centre bearings the load will be more evenly distributed. Therefore, while it is necessary to make the centre bearings large enough to carry safely the maximum theoretical load (assuming that the bearings are all horizontal) it is also desirable to put in larger outer bearings than appears to be necessary, due to the fact that the bearings will seldom be perfectly in line.

For machines which are intended to operate in tropical climates or in situations where high temperatures are experienced, it may be necessary to reduce the permissible bearing loads. The bearings may be expected to operate satisfactorily, for the loads given in the makers' tables, with suitable load factors such as have been suggested, at temperatures up to about 60° C. In many situations such as engine rooms in India and on board ship in the tropics, the temperature of the bearings may exceed this figure and it is desirable to specify a lubricating grease of a high melting point and also to reduce the permissible loads to, say, 80 per cent of the normal values.

While various questions have now been dealt with in order to provide for the different types of loads which may be imposed, no mention has been made of any factor connected with the duration of service. Obviously, one may expect the bearings of a motor which is run at only infrequent intervals and for short periods to have a much longer life than the bearings of a machine which is running for 24 hours per day and 7 days per week, and in consequence one may say that the bearings in the first case could be run at a much lower margin of safety.

It has been stated that the life of ball bearings varies approximately inversely as the cube of the load carried. Thus, on this basis, the bearings of a machine which is running for only 1 hour per day could carry twice as much load as those of a machine running 8 hours per day, given the same size and life of the bearings. Although this may be usefully considered in special cases, it is not proposed to introduce a "life factor" for general use when selecting bearings for a standard line of machines. It may be said that this point is taken account of more or less automatically by the well-known fact that electrical machines, when running at intermittent or short-time ratings, will give a much higher output for the same temperature-rise than when running continuously, and as the manufacturer naturally wishes to use the same size of bearings whatever the duty, the result generally will be that the intermittently rated machine with heavier loads will have approximately the same bearing life as the continuously running machine with lighter loads. However, for a standard line it is not desirable to assume that for short-time ratings the bearings can safely be expected to carry heavier loads than those suggested by the foregoing load factors. It is not fair to choose small sizes on the assumption that all machines under these conditions have only a very small working life. It is obvious that a motor may be intermittently rated and may still have to run continuously, being on light load most of the time. The bearings, therefore, are not necessarily to be under the same rating conditions as the motor in which they are fitted, and they may also be operating under the same load whether the motor is developing its full output or running light.

General Considerations.

There are many considerations which may influence the choice of bearings, and various observations which may be of interest may now be made. For example, as already stated, although bearings of the same type, size and price, may be purchased from different firms, the loads which may be safely carried by these bearings, according to the makers' tables, vary considerably. This is illustrated by the curves in Fig. 4 plotted from the loads quoted by different British manufacturers. It is interesting to note also that according to general practice the quoted safe load is directly proportional to the square of the shaft diameter. It is rather a striking fact that, taking bearings of, say, 3 inches diameter, the safe load which may be carried varies from 2 000 to 7 700 lb. even from these curves, which do not include heavy-type bearings. The curves have been plotted from the makers' safe loads at 1 000 r.p.m.,

this speed being chosen for the purpose of illustration since it is a common motor speed. For journal bearings it appears to be the general practice among bearing makers to quote such values that the load varies inversely as the cube root of the speed (r.p.m.).

Several formulæ have been published from time to time to give the load capacity of ball and roller bearings, but it is not desirable to take a general formula and apply it to any particular make in the absence of definite information, unless it is recognized that only an approximate result can be obtained. Even when the diameter and number of balls or rollers and the diameter of the ball track are known, there are unknown differences in design and manufacture, clearance and materials, which reduce the value of the average formula. However, if one is dealing regularly with one particular largely by factors apart from the output and speed, and depends on the rotor weight, distance between bearing centres, whether the core is built on a sleeve or not, size of air-gap, etc. It therefore follows that one firm may have shafts of a larger diameter than another for the same outputs, and in cases where the shafts are comparatively large it may not pay to fit medium-type bearings, but for smaller shafts the medium type becomes necessary. If the bearing cost is not important, then for the average machine it is better to fit medium-type bearings, the increase in cost being a smaller percentage than the increase in load capacity obtained, and a reserve capacity is obtained which gives improved reliability for normal drives and entails less departure from standard construction for higher-load conditions in special cases.

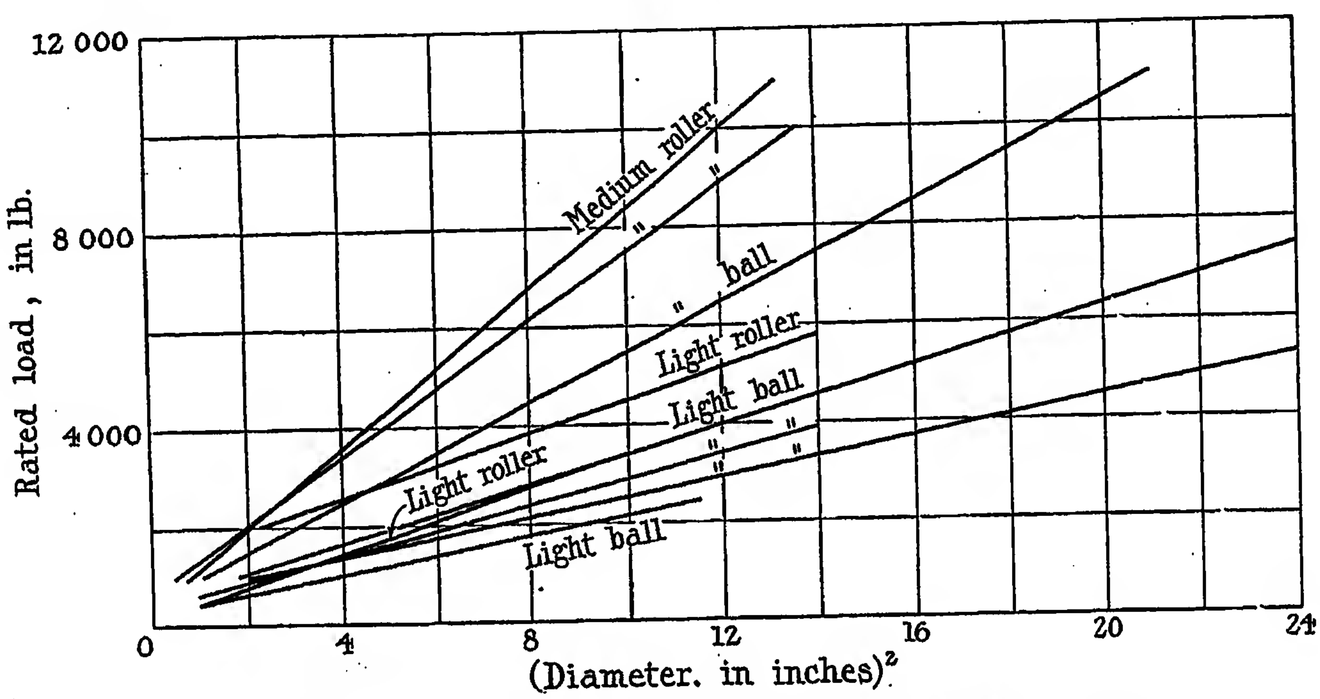

FIG. 4.—Relation between safe load (lb.) and (bearing diameter)^2 at 1 000 r.p.m.

make and type of bearing, and prefers to have a formula, it is easy to see that:—

$$\text{Safe load at 1 000 r.p.m.} = aD^2 + b$$

and $$\text{Safe load at any speed } v = (aD^2 + b)\sqrt[3]{(1\,000/v)}$$

where a and b are constants, D = diameter of bearing, and v is expressed in r.p.m.

This can readily be solved for a and b by plotting from the makers' load table.

It is not proposed to dicuss the heavy types or metric sizes as this would unnecessarily lengthen the paper. The bearings usually employed in electrical machines are the light and medium types which are generally capable of carrying the loads normally experienced.

In the determination of the most suitable journal bearing for a standard line, it is natural that cost should be a deciding factor if reliability and capacity are not thereby affected. It will be found that, load for load, the medium-type bearing is cheaper than the light type in most British makes. The question of type is not, however, merely a question of load and cost; it may probably be determined automatically by the size of shafts required for the construction of the particular machines under review. The shaft size is governed

The diameter of the bearing for the light type is from 1·3 to 1·5 times the diameter necessary for a medium-type bearing of the same capacity, and in some cases where the former has been preferred the bearings are mounted on sleeves or hubs to avoid increasing the shaft diameter. This practice can often be adopted with advantage in vertical machines having a direct-coupled drive.

It may be of interest to compare the capacity and cost of average bearings of given diameters, although, as already pointed out, these are not necessarily the deciding factors. In the curves shown in Fig. 5 the medium-type ball-bearing cost and load have both been taken as unity. It is then clear (if we accept the general statement from the makers that a roller bearing will safely carry 50 per cent more load than the single-row ball bearing of the same make) that the roller bearing is a really good investment for the heavier loads. Naturally, this does not mean that one should fit roller bearings whether there is sufficient work for them to do or not; in cases where they are not necessary it is hardly good business to increase the cost of the machines by fitting roller bearings throughout.

The external dimensions of the roller and ball bearings

of similar types are identical and the methods of mounting are similar except that the outer race of the roller bearing should be clamped stationary. Therefore with very little modification to the bearing housings or caps either type can be fitted, and it is suggested that it may be worth while to consider the fitting of both in a standard line. Provision may be made by suitable machining, so that for light and medium duties ball bearings are used, and for heavy duties roller bearings. Generalizations have been made by one firm regarding the fitting of ball bearings in motors up to a certain horse-power, and roller bearings in motors above this horse-power. It will, however, be apparent from the paper that the selection of the bearing is not merely a question of the horse-power transmitted, and consequently it is not correct to lay down definite rules that are only arbitrary and in practice tend to hamper clear

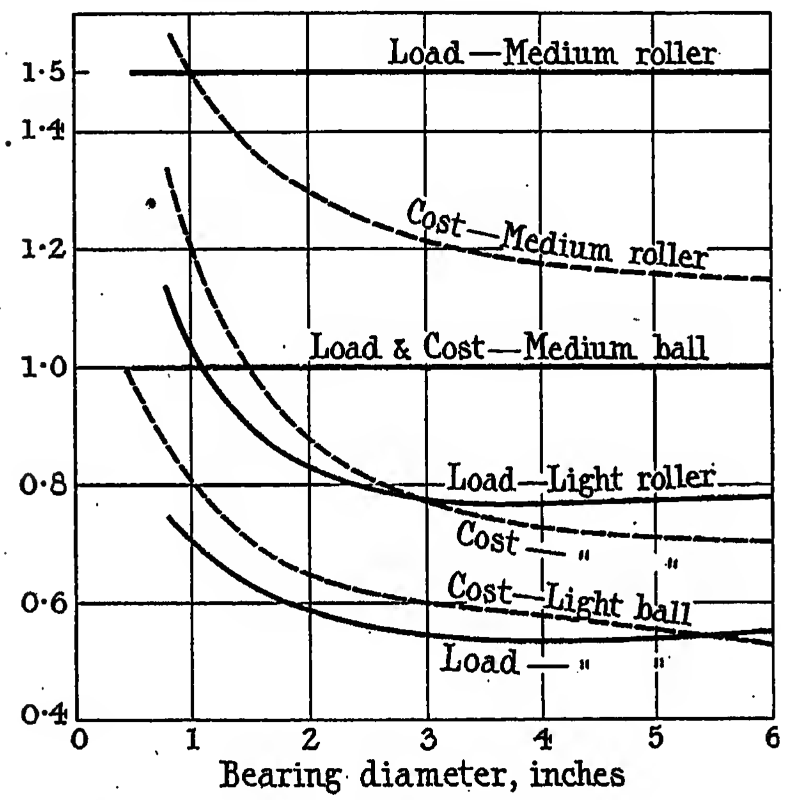

FIG. 5.—Comparative load capacity and cost of average bearings.

thinking. Sweeping statements, such as the above, are apt to be accepted by some engineers without consideration if put forward in an attractive manner, and although it may be safe to follow such rough-and-ready rules it may not be economical or necessary.

With the roller bearing of the short, parallel type which is referred to above, and is in most common use, it is necessary to make provision for supporting the end thrust on the shaft. This may be accomplished by using a radial ball bearing at the commutator or slip-ring end to carry the combined radial and thrust load, or by fitting a separate location bearing, or by means of a thrust bearing in addition to the journals. The last two methods entail an additional cost which need not be incurred in the majority of cases. The bearing remote from the driving end is usually lightly loaded, and a ball bearing can easily be arranged to take the end thrust. In this case it is preferable to use a bearing of the non-filling slot type; although those with filling slots in the ball races may be suitable in general, it is considered that filling slots introduce a weak point into the bearing and render it more liable to failure when running under maximum load conditions.

The following formulæ have been given by various firms for determining the permissible combined radial and thrust load:—

$$W = 3T + R$$
$$W = 4T + R$$
$$W = 6T + R$$
$$W = 7T + R$$
$$W = R + \frac{T}{2 \sin \alpha}$$

(For self-aligning bearings)

$$W = R + (0\cdot0004\,v + 0\cdot8)T$$

(For single-row bearings without filling slot)

$$W = R + (0\cdot0004\,v + 1\cdot4)T$$

(For single-row bearings with filling slot)

where W = equivalent radial load,
R = radial load,
T = thrust load,
α = pressure angle,
v = speed (r.p.m.).

It is considered that general requirements will be met by the use of the expression $W = 3T + R$, but the value of R must include the load factors previously suggested.

In the author's opinion an excellent combination for motors subject to heavy duties is to fit a medium-type parallel roller bearing at the driving end, and a medium-type double-row self-aligning bearing of the same diameter at the other end to support both the radial and thrust loads. If it is desired to fit separate location bearings it may be assumed that the capacity for axial loads is equal to 25 per cent of the rated radial loads. A thrust bearing is very commonly fitted not only for roller bearings but also when ball journals are employed, and it will be found that where these are required it is preferable to purchase them with sleeves ready for mounting direct on the shaft, thus eliminating a possibility of careless adjustment during assembly. Suitable sizes are put forward for both medium- and light-type thrust bearings in Fig. 6.

Taking the medium-type location bearing with an end-thrust capacity assumed equivalent to 25 per cent of the radial load, it is found that the light-type thrust washer of the sizes suggested is cheaper and of equal or greater capacity. Except in extreme cases, however, the author considers that the combined duty of journal and thrust bearing can be sustained successfully by the self-aligning type fitted remote from the driving end in motors up to about 200 h.p.

The leading bearing manufacturers issue publications containing a great deal of information in regard to the applications of their respective products, and it is not desired to include such matter in this paper. No comments will therefore be made on methods of mounting, machining allowances, etc., except to remark that the makers' instructions regarding fitting should be carefully carried out.

It is well known that ball and roller bearings are

splendid examples of the high standard of precision which can be obtained in everyday engineering practice, and it should be noted that this feature is absolutely essential to their proper functioning. It cannot be too strongly emphasized that articles which are made to such fine limits and which receive so much care at every stage of their construction should be accorded a corresponding amount of care from the time of their purchase until they are in actual operation. It is most probable that incorrect machining and fitting has been responsible for many of the troubles experienced, especially with those firms who have not manufactured standard machines with these bearings and in consequence may

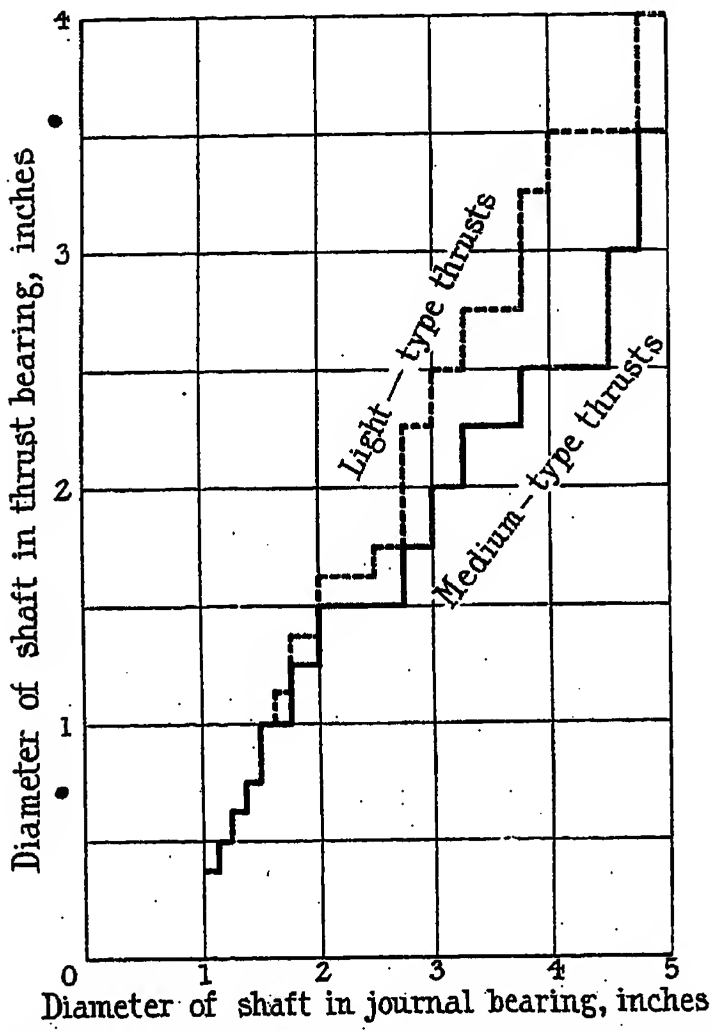

FIG. 6.—Sizes of thrust bearings (with sleeves) for use with medium-type ball or roller bearings.

lack experience in this direction. From such instances mistaken prejudice may easily have arisen against ball bearings in general or against a certain type in particular.

Care should be taken to state definitely that the bearings are intended for use in electrical machinery, in order that the makers may supply bearings of the "slack" type to allow for expansion. The bearings should be inspected on receipt in order to ensure that the correct type has been sent, and then repacked in the makers' wrapping with the original protective grease covering on them. The bearings should on no account be permitted to lie about the stores or on the fitting benches unpacked. It is important that they should be properly protected from picking up dirt or iron filings, etc.

The practice of repairing bearings or building up "new" bearings from old sets is not recommended. The manufacturers have most elaborate systems of gauging and selecting balls, rollers and races in order to obtain the high degree of accuracy necessary. When it is considered that a manufacturer will produce balls which differ by only 0·0001 inch between maximum and minimum, and then will sort these into five different lots for the purpose of assembling all balls in one bearing to within 0·00002 inch of the same size, it may be realized how inefficient the ordinary engineering shop is for this class of work. The amount of clearance, end-play, alignment and eccentricity are all important factors, and attempts to patch up old bearings for use in high-speed machinery should not be entertained.

It has been suggested on various occasions that the sizes of bearings for electrical machines should be standardized according to the output and speed. The operating engineer does not always realize the difficulties of the designer, but there are many good reasons (which may be apparent from the points discussed in the paper) why the designer should be left free to determine his own size and type. The wide differences between the safe loads of various makes and types is one drawback to the standardization of bearing diameters, and the different types and proportions of machine construction for similar outputs is another difficulty.

In the author's opinion it is most undesirable that design details should be taken out of the responsible engineer's control by a standardization committee, and the arbitrary methods usual to standardization should not be recommended in this connection.

Many questions have not been touched upon, such as those affecting the theory and manufacture of the bearings; it was felt that these were rather outside the purpose of the present paper, which has been prepared from the engineer user's point of view as an attempt to put forward helpful information for those interested in the application of these bearings.

FAITHFUL REPRODUCTION IN RADIO-TELEPHONY.

By L. C. Pocock, B.Sc., Associate Member.

(*Paper first received 8th March, and in final form 5th April; read before the* Wireless Section *7th May,* 1924.)

Summary.

On account of the great number of processes and transformations that energy undergoes between its acoustical source and the ear of a listener when wireless telephony is the means of transmission, it is not possible in a single paper to explore in detail all the avoidable and unavoidable possibilities of distortion. The proper understanding and application of certain general principles enable individual circumstances to be examined and indicate the path to be taken in the pursuit of high-quality transmission.

In this paper, therefore, an attempt has been made first to define terms suitable to the scientific study of faithful reproduction, second to analyse into separate constituents the types of distortion occurring, and third to lay down the general principles above referred to and give them as far as possible a mathematical form. This has been done not only for the purpose of ensuring precision and definiteness of statement, but also to enable quantitative application to be made and to prepare a foundation on which to build as knowledge of the subject progresses.

Special consideration has been given to transient phenomena because in much of the apparatus used for radio-telephony the ordinary forms of steady-state distortion can be reduced to a negligible amount. The consideration given to transients is, however, of a preliminary nature only; it is not possible to develop the study of transients in this paper beyond the simple cases of "ironless" circuits. An interesting and difficult field left open for investigation by mathematical and experimental means is the exploration of transient phenomena in circuits having impedance operators that are not single-valued functions.

In Part II, the principal types of apparatus employed in radio-telephony have been considered in as general a way as possible.

A bibliography has been attached, where detailed investigations will be found of many matters touched upon but lightly in this paper, because the presentation of matter covering so wide a field seemed to exclude extended investigations that had already received very full treatment as self-contained publications.

Introduction.

It may probably be claimed justly that the art of reproducing the human voice or instrumental music has reached higher perfection in the direction of electrical loud-speaking apparatus than in the gramophone. It is not unlikely that the cause of this is directly traceable to the fact that the electrical transmission of speech has important commercial application in the telephone and that very extensive research has been possible and necessary with the funds available to the large public-utility companies which have to do with the telephone.

Whether or no these hypotheses be accepted, there is no question at all that almost the only available information on the nature of speech and the effect of distortion is the result of research carried out for the purpose of telephony. It is probably not generally appreciated how far research has gone in the matter of improving and standardizing the quality of speech transmitted by telephone lines and cables.

In the early days of telephony the economic factors were such that the principal problem was that of securing sufficient speech volume at the receiving end; almost from the first it was realized that the instruments and lines distorted the speech and lowered the intelligibility, but it was possible to erect lines in which the speech volume fell below a commercial value long before the line attained such length as would cause serious distortion. The advent of loading coils increased very considerably the distance over which telephonic communication was possible, but loading also brought with it on cables an improvement in the quality of the received speech. Finally, the invention of the thermionic valve, to which radio-telephony owes its development, made possible the only really successful telephone repeater by means of which it is possible to transmit speech unlimited distances over land.

The telephone repeater brought with it a host of new problems, to most of which intensive research gained a speedy solution; above all, however, it reversed the order of relative importance of speech loudness and speech intelligibility; it became economically possible to obtain sufficient speech volume at the end of the longest line, but no improvement in intelligibility attended the increased range. Further, the results hitherto considered to be commercial left much to be desired; even at the present time telephonic communication is carried on with only about 50 per cent of the syllables correctly heard, the remainder being guessed by the context. When, however, unfamiliar names, isolated letters or figures are to be transmitted, the context is of no assistance and it is a matter of common experience that very great difficulties are encountered.

Definitions.

The subject of faithfulness of reproduction in radio transmission requires a basis of definitions and it is a matter of some care to select suitable definitions and to avoid confusing terms. The science of radio-telephony has developed rapidly, and has specialized for various obvious reasons along its own lines without much regard to the sister science of line telephony. This has led to some confusion; such terms as transmitter, receiver, high frequency, etc., mean one thing to a telephone engineer and another to a radio engineer. As this paper will deal with ground common to both sciences, and it is hardly possible to alter the accepted

significance of telephone terms, the following definitions will be adopted :—

The terms "high frequency" and "low frequency" will not be used, but instead the terms "radio or carrier frequency" and "speech frequency or audio frequency."

"Transmitter" and "receiver" will be used to designate the corresponding telephone instruments known in the radio art as microphones and headphones.

The complete sending or receiving apparatus will be called a transmitting set or receiving set respectively.

Turning now to the definitions with which reproduction is to be studied :—

The *Articulation* of a reproducing system is the average percentage of monosyllables correctly received when conveyed by the system without context of any kind. Articulation measured in this way is a function of the ability of the observer as well as of the reproducing system.

The *Intelligibility* of a reproducing system is the percentage of ideas correctly received when conveyed by the system and expressed in the form of short sentences. Intelligibility is a function of articulation.

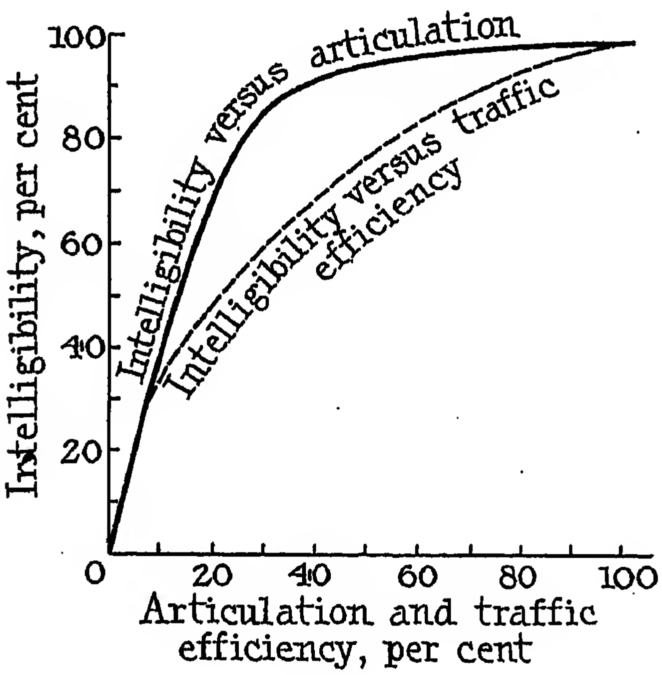

Fig. 1.

The *Traffic Efficiency* of a reproducing system is inversely proportional to the time taken to convey a single simple idea over the system.

Fig. 1 shows the relationship that has been experimentally established between articulation, intelligibility and traffic efficiency.

The foregoing definitions have to do with the capability of a system for transmitting ideas by means of speech. The coming of broadcasting calls for far more than the reproduction even of perfectly intelligible speech. Natural reproduction of the human voice and of music is required, and it is quite possible to obtain a high degree of speech quality as defined above without the reproduced voice sounding at all natural.

It is not at present possible to specify degrees of naturalness or degrees of perfection in reproducing music, though it is obviously possible to lay down the theoretical conditions for the exact reproduction of speech or music. For the present the following semi-defined quantities must be recognized :—

Naturalness is the similarity of reproduced speech or music to the original, apart from such properties as can be specifically defined under speech intelligibility.

Perfection of Reproduction is the total degree of similarity of reproduced speech or music to the original, taking into consideration naturalness and those factors which affect intelligibility.

In these two definitions it has been assumed that the intelligibility of a reproducing system which, as defined, refers to speech only is of some significance when the system reproduces music. This assumption is a very doubtful one, and it is probable that "Perfection of Reproduction" is the only heading under which the reproduction of music can be properly considered. For example, it has probably been observed by all who have had occasion to use a number of different loud-speakers that some types are better than others for speech, while some of those that are worse for speech are better for music; sometimes, even a receiver is found which reproduces a particular type of musical instrument very well indeed but is poor for other music or speech. In many ways, however, the perfection of reproduction for speech is a good all-round test of the characteristics of the system, and when speech is well reproduced music also will generally be well reproduced.

Part I.

Defects of Reproduced Speech.

Reproduced speech may suffer from several distinct kinds of distortion, all of which are generally present to some extent.

It is necessary to consider speech or music as capable of being expressed as a Fourier series. Strictly speaking, only vowel-like sounds or musical tones, i.e. sounds which can be indefinitely sustained, can be expressed as a Fourier series, but by a well-known extension a wave-form which is not repeated can be expressed in a similar form, and it is commonly accepted that problems in telephonic transmission may be regarded as steady-state problems; that is to say, all transients are neglected. This mode of regarding transmission tacitly neglects one form of distortion and will have to be revised. The consonant sounds are in general transients, and all the reproducing apparatus should be capable of reproducing these transients faithfully; more will be said on this at a later stage.

In so far as steady-state conditions may be assumed, the distortion that may occur is due either to the ratio of reproduction being different for different single frequencies (frequency distortion), or to the reproduction of different amplitudes at any given frequency in different ratios (amplitude distortion). In the latter case the distortion produced is two-fold; first, the intensities of the sounds are not heard in their proper ratio, crescendo passages, for example, perhaps failing to show any appreciable crescendo effect; and second, a number of frequency components are introduced which were not in the original sound.

It is apparent that another variable, namely "phase,"

may be distorted, but it has been well established * that the relative phase of the reproduced frequencies makes no appreciable difference to the sound heard, although the shape of the wave-form may be very greatly changed by alterations of phase.

There is yet another kind of distortion which is of a somewhat different character and is caused by the non-linear relation between the response of the ear and the energy intensity of the sound heard.

It is evident that if two sounds, one of which has twice the energy intensity of the other, are produced by a system which is capable of giving out these two sounds always with the same ratio of intensity but at different levels of absolute intensity, then because of the non-linear characteristics of the ear as regards both frequency and amplitude † they will only be interpreted in their correct ratio if the ear hears them at the same level of intensity as the original sounds would have been heard. Receiving apparatus ought therefore to be adjusted to give about the same volume of sound as is being used in the broadcasting studio, and if it is incapable of giving the necessary output without introducing other kinds of distortion, ideal results cannot be obtained.

Frequency Distortion.

Reference has been made to the distortion arising from amplification of various frequencies to unequal degrees: this is called "frequency distortion" and is at the same time both the simplest kind of distortion and the most difficult to eliminate from some of the apparatus used.

The effect of frequency distortion on music can be easily conceived; certain notes will ring out loudly while others will be lost; again, the higher harmonics which give timbre to the notes will perhaps be lost, making it hard to identify the instrument that is being played. As regards speech, the very low audio frequencies up to, say, 500, and to a less extent the high audio frequencies, are responsible for naturalness and those characteristics which enable one to distinguish one voice from another. The range from 500 to 1 500 carries most of the loudness and a considerable amount of the intelligibility. The range from 1 500 upwards is concerned less in the loudness of the sounds heard but is of supreme importance in securing high intelligibility, that is in enabling every sound to be correctly heard and interpreted without mental effort.

It has been established ‡ that higher audio frequencies can be masked, according to their intensity, by tones of lower pitch, so that if some of the higher audio frequencies required in speech are reproduced in less than a certain ratio to the lower audio frequencies they might as well be absent altogether for all the effect they are capable of producing in ameliorating the quality.

The circumstances that give rise to frequency distortion have in general an effect upon the transmission of transients. For example, suppose there is an electrical or mechanical resonance in the apparatus with a single free period. The equation of a series resonant system may be written

$$m\frac{d^2y}{dt^2} + r\frac{dy}{dt} + ky = \frac{d}{dt}F(t) = F'(t) \quad . \quad . \quad (1)$$

where $F(t)$ is the applied force expressed as a function of the time; m, r and k are the inductance, resistance and capacity or equivalent mechanical quantities of the system; then y represents current or velocity.

In (1) substitute $\frac{r}{m} = 2\beta$; $\frac{k}{m} = \omega_0^2$; $\frac{d}{dt} = D$; the equation becomes

$$\frac{1}{D}(D^2 + 2\beta D + k)y = \frac{1}{m}F(t) \quad . \quad . \quad . \quad (2)$$

Then the steady-state solution when $F(t)$ is a periodic force with angular velocity ω is

$$y = \frac{F'(t)}{m\{(\omega_0^2 - \omega^2)^2 + 4\beta^2\omega^2\}^{1/2}} \quad . \quad . \quad (3)$$

a formula sufficiently well-known to require no comment, since it represents the current taken by a series resonant circuit in terms of the inductance, natural frequency, applied frequency and damping. It may perhaps be worth while pointing out that if in (3) m alone varies, ω_0 and r being held constant, the tuning becomes sharper as m increases, for the maximum amplitude of y is unchanged while all other values of y are reduced when m increases. Thus lightness of the moving parts of mechanism in the reproducing system is essential.

Now examine the capabilities of the series resonant system represented by (1) for responding to transient forces.

Suppose that a unit steady continuous force is suddenly applied so that the right-hand side of (2) becomes $(1/m)(1)$ where (1) signifies that the force is zero before time $t = 0$ and unity when t is positive.

The well-known solution of the equation is now

$$y = \frac{e^{-\beta t}}{m\gamma}\sinh \gamma t \quad . \quad . \quad . \quad . \quad . \quad (4)$$

in which $\gamma^2 = \beta^2 - \omega_0^2$. Expression (4) applies when the system is heavily damped and γ is real. With less damping γ is imaginary, and the solution is written as in (5) if γ is still treated as real, while if γ is zero the system is critically damped and the solution is as given in (6), thus:—

$$y = \frac{e^{-\beta t}}{m\gamma}\sin \gamma t \quad . \quad . \quad . \quad . \quad . \quad (5)$$

$$y = \frac{te^{-\beta t}}{m} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

From these three solutions it is seen that if free oscillations depending only on the structure of the system are to be avoided, the damping must be at least critical.

The further application of these formulæ depends upon the circumstances of each case; the system may be a circuit coupled to the grid of a valve, and the formula must be developed according to the coupling adopted. Thus if it is the voltage due to the current y through a resistance r in a series resonant circuit that operates on the grid, (4), (5) or (6) applies, after multiplying by r; but if it is the voltage across the

* See Bibliography (1). † *Ibid.*, (5). ‡ *Ibid.*, (2 and 9).

inductive element of the circuit that is effective, the formulæ have to be operated on by $m(d/dt)$; and if it is the voltage across the condenser that is effective, (4), (5) or (6) must be integrated with respect to time and multiplied by $m\omega_0^2$. In the last case only will the steady applied force ultimately produce a steady corresponding effect.

The response to a transient force of the type considered has been calculated for three cases, and is shown by the curves of Figs. 2 and 3. Fig. 2 shows the value of y (current or velocity) and Fig. 3 the integral of y proportional to displacement or electric charge.

By differentiation of (4), (5) and (6) it is found that the initial slope (at $t = 0$) of the response curves in Fig. 2 is equal to $1/m$, indicating again the importance of small moving mass in any mechanical system. Figs. 2 and 3 show that increased damping retards the response after the first moment.

To obtain a good approximation of the value of the displacement to the value of the applied force, it is essential that m should be small and the initial slope of the y curve correspondingly steep. The damping should be at least critical in order to prevent oscillations,

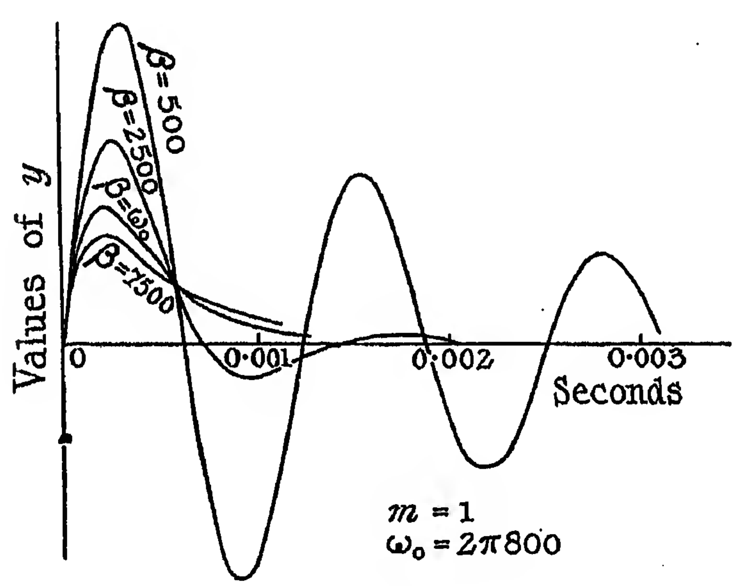

FIG. 2.

and the natural frequency should be high so as to limit the time over which the disturbance lasts.

Examination of Equation (3) shows that high natural frequency and small mass are also the requisites for good reproduction under steady-state conditions, while high damping must also be added if the natural frequency is not well outside the frequency region to be reproduced.

The case of a series resonant system has been given fairly fully because of its inherently great importance; e.g. in the simple radio receiving circuit (Fig. 4) the aerial is a series resonant circuit, and the important quantity is the voltage across the inductance. Similarly (2) is a series resonant circuit provided that the grid conductivity can be neglected. Again, if the grid side of an intervalve transformer has high capacity and the grid filament circuit has negligible conductance, a series resonant circuit similar to (2) is formed. Lastly, the mechanism of a telephone receiver or loud-speaker is a resonant system of the same type expressible by Equation (1).

Parallel resonance circuits are met with in tuned anode circuits, in the plate circuit side of intervalve transformers having high capacity, and so on.

There is no reason to suppose that a reproducing system will be called upon to respond faithfully to a transient of the kind discussed in Equations (4), (5) and (6), but the results have been given in some detail because the response of the system to any non-periodic

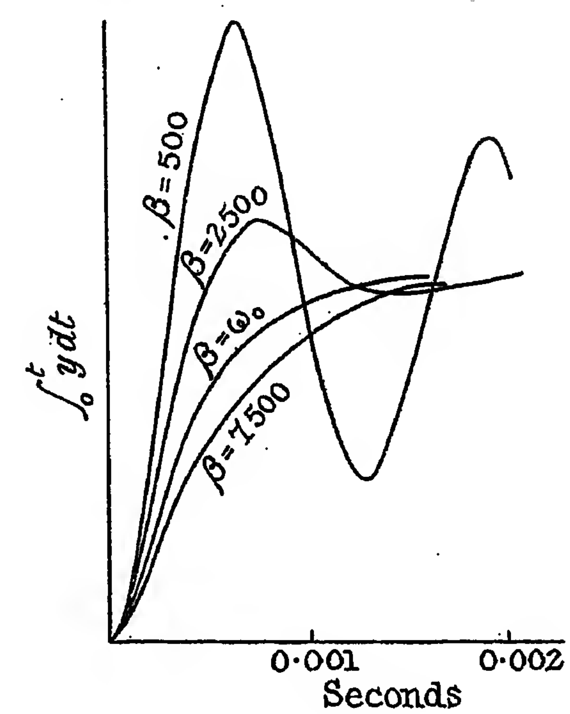

FIG. 3.

applied force, or to any change of amplitude or frequency of a periodic force, can be obtained from its response to a suddenly applied steady force. It therefore seems reasonable to regard the response of a system to a suddenly applied steady force as a good indication of its behaviour towards the transients that will actually occur in speech and music.

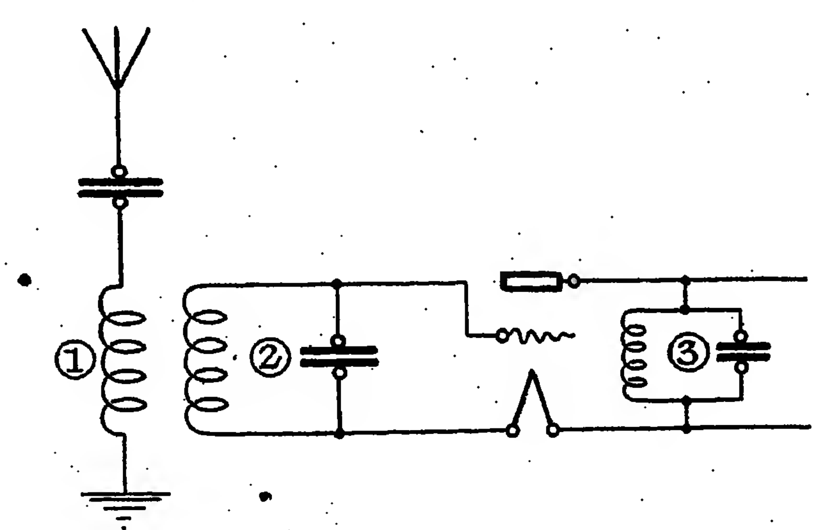

FIG. 4.

It is not proposed to examine in detail the many different types of elementary circuits and mechanisms involved in telephonic transmission; the methods of doing so have been developed elsewhere, and the possible combinations are very numerous. For example, the total damping of the system can always be divided into two components, one useful, the other wastefully dissipative; in the case of an electrical circuit element

there may be series or parallel resonance, and the total effective resistance, or either of its two components, may be in series or in parallel with either the inductive or capacitive element. It may, however, be noted that since parallel circuits contain elements similar to the elements of series resonance circuits, the potential, kinetic and dissipative energies of a parallel system enter into Lagrangian dynamical equations of the same form as series systems but with different co-ordinates; the conditions for most faithful response can be derived by superposition of variables effective in series circuits, and will therefore be the same in parallel combinations as in series combinations. When we are concerned with the shunting effect of a parallel resonance circuit, so that attention is not directed to the response in the resonance circuit (e.g. in a tuned anode circuit), the same conditions apply, for it is only by the quick and faithful response of the bridging resonance circuit that the back E.M.F. necessary to maintain the form of the impressed voltage can be secured.

Different Distorting Elements, Additive or Otherwise.

The next inquiry while general principles are under study is the consideration of the effect, cumulative or otherwise, of two unilaterally coupled series resonant elements in the transmission chain. There may be two parts of the transmission system which are resonant in character but so situated that they do not react on each other, and their natural frequencies are independent. So far as frequency distortion goes, it is evident that if the two resonances have approximately the same damped frequency the distortion will be intensified, whereas if they have suitably different frequencies the overall response characteristic may be levelled up and, to a certain extent, improved.

Again, it is evident that the steady-state frequency-distortion characteristic can be levelled up by the application of networks having suitable characteristics; as a simple example, the peaked form of the current/frequency curve in a series resonant system can be reduced to a less peaked form by the addition of a suitable parallel resonance circuit, which may be separated from the series circuit by a vacuum tube to prevent interaction of the impedance of the two elements.

It is shown in the next section that the effect of successive distortions on the transient phenomena may be judged by its effect upon the steady-state frequency distortion.

The Response-frequency Characteristic as a Criterion of Quality.

The frequency distortion of any element of a reproducing system is shown by plotting the output or response against the frequency for an input voltage or force of constant amplitude. An element of the system is here taken to mean one complete closed circuit, or its mechanical equivalent.

It is seen from Equations (3) and (4) that in the specific instance examined the reproduction of a transient depends upon β and ω_0, as also does the steady state, and the amplitude of reproduction is in both cases inversely proportional to m.

It is shown in an Appendix that this relation is general and that the response-frequency characteristic is related to the response for transients as well as for the steady state as far as analytical methods are applicable.

In order to obtain a more general conception of the performance of a system in respect of transients, suppose that the force acting is $E(t)$, and the response is given by $Y(t)$, both being functions of the time. Then these two functions are related (in an invariable system) by a third function, which depends upon the constants of the system only and may be thought of for the moment as a mutual admittance, as it actually is in the electrical case; it can therefore be expressed in a generalized way as a function of the circuit constants, and the operator d/dt which will be denoted by q. Thus $E(t)$ and $Y(t)$ are related by an expression of the form

$$Y(t) = f(q)\, E(t)$$

Now in solving such an equation for the steady state when $E(t)$ is a sinusoidal force, the usual procedure is to substitute (jn) for q. Following the methods of Heaviside we may regard $f(jn)$ as the generalized mutual admittance effective with its proper value of n for every real frequency in the Fourier integral expressing a transient applied: thus, as is shown by T. C. Fry,* we write the applied force

$$E(t) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} dn \times e^{jnt} \int_{-\infty}^{+\infty} d\lambda E(\lambda) e^{-jn\lambda} \quad . \quad . \quad (7)$$

and
$$Y(t) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} dn \times f(jn) e^{jnt} \int_{-\infty}^{+\infty} d\lambda E(\lambda) e^{-jn\lambda} \quad . \quad (8)$$

Here the response to the transient applied force is seen to depend on the mutual admittance expressed in complex form, that is, as a modulus with an angle. The relation of response to input, which ordinarily forms the frequency-distortion characteristic, is determined as the modulus only of the mutual admittance without regard to angle. In the steady state this is justified, since it is experimentally well established that the alterations of wave-form resulting from alterations of phase do not appreciably affect the sound heard. Under transient conditions, however, the infinite series of frequencies summed in the Fourier integral occur as single waves only, and the shape of the response may be very considerably altered by phase distortion. It cannot be claimed that there is definite experimental evidence that the change in the shape of a transient resulting from changes in phase of its component frequencies can be appreciated by the ear, but it is difficult to see how one transient is to be distinguished from another if this kind of distortion does not matter. It is not difficult to suppose that an harmonic analysis of sustained sounds is made by the ear, and that the phase elements are discarded. It is more difficult to see how the ear could carry out such an artificial process as the reconstruction and identification of a Fourier integral from a received pulse that differed materially in character from the original force. The problem of reconstructing the original transient force from its

* See Bibliography (45).

distorted reproduction is obviously incapable even of being uniquely mathematically solved in the absence of data regarding the law of distortion.

As a commentary on the foregoing remarks we may note that the most difficult sounds to reproduce with sufficient accuracy to make them easily identified are p, b, t, d, k and g, the stop consonants which are truly transient in character. Other difficult consonants are f, v, th and s, but these owe their difficulty to the relatively high audio-frequency region involved in their formation.

If the English consonant sounds are examined, it will be found that many of them, like the last group mentioned, are capable of being sustained and are therefore vowel-like in character. W in "away" is clearly a transitional sound, practically composed of a series of vowels in such quick succession that the steady state can scarcely be established. It is probable that the vowel-like consonants are to be regarded in the same way as W, since they frequently seem to be merely a way of beginning a true vowel and are therefore transient in character.

Amplitude Distortion.

The response-frequency characteristic of any element of a system has already been defined from the point of view of frequency distortion. If the ratio of output to input is a function of the amplitude, the definition must be extended to a more generalized form.

If there is no amplitude distortion the ratio of output to input, voltage or force, for any element defines the frequency distortion, thus

$$V_2 = G(n)\,V_1 \quad . \quad . \quad . \quad . \quad . \quad (9)$$

where G is the frequency distortion, a function of frequency only.

If amplitude distortion is present, V_2 will vary non-linearly with V_1 at a given frequency, and the relation may be written

$$V_2 = G(n)H(V_1) \quad . \quad . \quad . \quad . \quad (10)$$

Frequently $H(V_1)$ may be expressed in the form

$$H(V_1) \propto V_1^a \quad . \quad . \quad . \quad . \quad . \quad (11)$$

This kind of distortion is found in iron-core coils, on account of the non-linearity of the BH curve of the iron, and also in valve circuits on account of the curvature of the valve characteristic. In the same two cases hysteresis may be present, in which case the distortion will be represented approximately by

$$H(V_1) = \hat{\mu} V_1^a \quad . \quad . \quad . \quad . \quad . \quad (12)$$

where $\hat{\mu}$ is a complex operator.*

In all these cases a single-frequency impressed force V_1 produces a response in which the fundamental is not proportional to the force, and in which there are a large number of different frequency components having precisely the same effect as a variable superposed noise.

It should be noted that there are four kinds of amplitude distortion, according to whether the function H is single-valued or double-valued, and whether it is symmetrical or asymmetrical about the point at which the system is in equilibrium with no impressed forces.

* See Bibliography (46 and 47).

The Measurement of Intelligibility.

In telephone work it has been found necessary to have some means not only of testing apparatus for the speech articulation it is capable of transmitting, but also of specifying the result of such tests, in terms of some characteristic that will measure all possible kinds of distortion in apparatus of different nature.

For many years it has been customary to recite lists of meaningless monosyllables over a telephone system to be examined, and to determine the proportion of syllables accurately recorded. For this purpose a large number of lists (over 150) of syllables have been compiled, each list being arranged to give equal weighting to the different elemental speech sounds.

The technique of these tests has been developed to the point where definite and significant results can be obtained. These "articulation percentages" depend, however, upon the acuteness or alertness of hearing of the observer, and also upon the amount of practice obtained. Reference has already been made to Fig. 1, in which is exhibited the correlation between intelligibility and the articulation percentages obtained with a particular set of lists.

Some idea of the importance of the various speech-frequency regions in giving faithful reproduction will be seen by examining the curves shown in Fig. 1 of Mr. Sandeman's introductory paper to a recent discussion on loud-speakers.* These curves show the effect upon articulation of transmitting, without distortion, the frequencies from zero to n only, or from n upwards only for different values of n.

Naturalness and Intelligibility.

Intelligibility has been defined as the inherent ability of a reproducing system to convey the elements of speech that are important from the telephonic point of view for conveying ideas; it is, as has been shown, a function of articulation. By "naturalness" we understand all the other properties of reproduction, additional to those which have been found to have a measurable effect on the observed articulation. For example, the insertion of a small condenser in a telephone system may have very little effect on the articulation or intelligibility of a system, but may make a great difference to the character of the sounds heard.

It seems probable that naturalness in speech is to be associated with the vibrations of the vocal chords, for Sir Richard Paget has shown † that the essential qualities of each vowel are inherent in two or more reinforced frequencies, and that vowels and unvoiced consonants of perfect intelligibility may be sounded without the assistance of the vocal chords, that is by whispering.

If, then, naturalness of speech is concerned in just these low audio frequencies which do not greatly affect

* *Journal I.E.E.*, 1924, vol. 62, p. 275.
† See Bibliography (20).

the observed articulation, it may be expected that a good idea of the behaviour of a reproducing system for general purposes is gained by observing the capability of articulately reproducing speech, together with the degree of tone resemblance between the original speech and the reproduced speech.

Modulation and Demodulation.

By modulation we understand the distortion of a carrier current in some arbitrary manner by speech-frequency currents, so that the modulated carrier contains the speech-frequency elements. The carrier may be modulated in various ways, the essential requirement being only that the modulating current shall definitely change the carrier in some reversible manner, and not be merely superposed upon it. The distorted or modulated carrier can then be demodulated by the receiving apparatus; demodulation—a better word for telephony than detection—is the converse of modulation, and is the process of disentangling or recovering the original speech-frequency currents from the modulated carrier.

Without going into the details of the different methods used to procure modulation, let it be assumed that the modulated carrier of angular frequency c is represented by

$$B(1 + A \sin pt) \sin ct \quad . \quad . \quad . \quad (13)$$

when a single speech frequency of angular frequency p is operating and B is the amplitude of the unmodulated carrier. Then, when a number of different speech frequencies are present, the form of the modulated carrier will be

$$B(1 + \sum_{0}^{P} A_p \sin pt) \sin ct \quad . \quad . \quad . \quad (14)$$

where the upper frequency-limit P may be taken as equivalent to 6 000 periods per second for speech, and some higher value for music.

Let A be the maximum instantaneous value of modulating voltage; it is clear that this must be less than unity or overmodulation will take place, a phenomenon associated, as will presently be shown, with distortion in the demodulator. Thus, for all possible frequencies and for all possible intensities to be transmitted, A must be less than unity.

The process of demodulation depends upon the proper use of an asymmetrically distorting circuit, the particular form of distortion being approximately represented by saying that the amplitude of the demodulated signal varies in most cases as the square of the modulated carrier amplitude.

The demodulated voltage will therefore be proportional to

$$B^2 \sin^2 ct(1 + \Sigma A_p^2 \sin^2 pt + 2\Sigma A_p A_q \sin pt \sin qt + 2\Sigma A_p \sin pt) \quad . \quad . \quad (15)$$

With these assumptions, and since the maximum value of A must be less than unity, the average value of A will be considerably less than unity, in practice certainly not more than about 0·6 for speech (the usual percentage modulation), and lower still for music. The terms of second degree in A then tend to disappear as the percentage modulation is lowered, and the signal becomes proportional to $2B^2 \sin^2 ct \Sigma A_p \sin pt$, that is, it is proportional to the original signal and to the square of the carrier.

We see then that with these (the ordinary) assumptions there is distortion in the process of modulation and demodulation, viz. the two terms of second degree, and that the importance of these terms increases as the percentage modulation is raised; in fact, the maximum value of A should not be allowed to approach unity, since all such amplitudes will appear in the demodulated current accompanied by large parasitic or unwanted components.

Our next inquiry will be into the nature of the distortion due to the parasitic frequencies represented by the quadratic terms.

Consider first a term in the demodulated current of the form

$$2(A_p A_q \sin pt \sin qt) \sin^2 ct \quad . \quad . \quad . \quad (16)$$

The two frequencies p and q modulate each other, or in the language of speech-frequency currents they produce beats, or sum-and-difference tones; the preceding expression may be written

$$A_p A_q \sin^2 ct \{\cos (p - q)t - \cos (p + q)t\} \quad . \quad (17)$$

so that the unwanted terms in the received signal consist of tones of frequency $(p + q)$ and $(p - q)$, one or both of which may be in the frequency zone transmitted and may cause beats or interference with tones of the same or near frequency which are legitimately received as part of the desired signal. Similarly, the symmetrical terms of second degree are equivalent to a single double-frequency parasitic tone.

The question will now naturally be raised as to whether, and under what conditions, it is possible to secure distortionless modulation and demodulation. It is readily seen that if linear modulation as in (14) is used, and demodulation is also linear, the required result will be secured. Linear demodulation, however, requires the demodulator to have a linear characteristic, and at the same time be a rectifier; that is, in the case of a valve using plate-current demodulation the plate-current/grid-voltage characteristic would have to be linear up to some point, and also beyond that point, but with a different slope. It is well known that the effect of space charge and varying voltage along the filament prevent the realization of this ideal demodulation.

It has also been suggested * that distortionless reception can be secured when demodulation follows a square law if

$$I^2 - I_0^2 = KE$$

where I is the amplitude of the modulated carrier,
I_0 is the amplitude of the unmodulated carrier,
K is a constant, and
E is the signal to be sent.

If $\Sigma A_p \sin pt$ is the signal the law of modulation is then

$$I = (K\Sigma A_p \sin pt + I_0^2)^{1/2} \quad . \quad . \quad . \quad (18)$$

If the received signal is proportional to I^2 it is received without distortion.

* See Bibliography (44).

Such a law of modulation gives, however, very much larger changes in the amplitude of the modulated carrier for relatively small modulating voltage than for voltages sufficient to give complete modulation. The result is that when demodulation fails to approximate to the square law, and especially if it approaches a linear law, there is serious distortion. It has been shown by Moullin and Turner that for strong signals the demodulation is likely to follow a linear law.

Another point in connection with modulation of this kind is that the law is difficult to realize in practice. In general, modulation will not exactly follow a linear law, and demodulation will not exactly follow a square law; in either case amplitude distortion will be introduced, and it is therefore generally accepted that moderate linear modulation is best.

In the sending aerial circuit, and in the receiving circuits, the modulated carrier undergoes distortion in proportion to the sharpness of tuning. If the expression for modulated carrier is expanded in the form

$$\sin ct + \tfrac{1}{2}\Sigma A_p \{\cos (c - p)t - \cos (c + p)t\} \quad . \quad (14a)$$

it is seen to consist of terms which are sum-and-difference frequencies of carrier and audio frequencies, forming, as is well-known, the two side bands. As the response of the resonant tuned circuits is a function of frequency, the higher audio frequencies in the received signal will be reproduced in smaller proportion than the lower audio frequencies. In the absence of reaction and at the shorter wave-lengths this distortion is, however, not serious, even when there are three or four such tuned circuits involved in the transmission.

A complete study of modulation and demodulation would take up too much space, especially if the different methods employed were discussed. The principles involved have therefore been given in their most general form, and further information to which the principles here given may be applied can be obtained from many excellent investigations that have been published—a few of these are given in the bibliography at the end of this paper.

Part II.

The foregoing discussion has described the broader principles concerned in the avoidance of distortion. Where possible these principles have been expressed in precise mathematical forms for the purposes of concise definition and in order that they may be used as the basis of calculation and analytical study, as knowledge of the subject progresses. We shall now turn our attention in greater detail to some of the elements commonly used in radio-telephony.

It is natural that the first element studied should be the transmitter, and here at the beginning of the radio-telephone system is a problem of no mean proportions. The transmitter must fulfil the following conditions:—

Its electrical voltage output at all frequencies from 20 per second up to some undetermined high audio frequency—say about 10 000 per second—must be a faithful reproduction of the pressure in the air due to the sound to be transmitted.

This condition, of course, implies absence of frequency distortion and amplitude distortion both symmetrical and asymmetrical.

The carbon transmitter used in ordinary telephony depends for its efficiency upon the judicious use of a certain amount of resonance, permitting unavoidably a definite and known amount of frequency distortion; it is, moreover, guilty of amplitude distortion, as any instrument must be which operates by the variation of resistance unless the resistance variation is very small. Asymmetrical distortion is also present, due to the non-linear variation of carbon resistance with pressure (unless it is specially compensated as in what is known as a "push-pull" arrangement). It is evident, in view of the enormous amount of study that has brought the carbon telephone transmitter to its present state of commercial efficiency and quality, that no high-quality transmitter can at present be made with anything like the same transmitting efficiency. This is, however, not serious. Thanks to the high degree of distortionless amplification obtainable by valves, the lower limit of permissible efficiency is only controlled by the degree of electrical disturbance picked up by the transmitter leads, and the amount of noise inherent in the early stages of the amplifying system.

Excellent transmitters can be made by securing very high natural frequencies with high damping in the mechanical system, and there is then not much difficulty in avoiding amplitude distortion. Alternatively, arc and flame transmitters have been made in which there is no mechanical system; both mass and stiffness are negligible, but amplitude distortion has to be considered. The author has no information on this aspect of the case, but it does not seem likely to introduce any serious difficulties.

It is hardly necessary to add that electrical and acoustical resonances, as much as mechanical resonances, must be avoided in connection with the transmitter as elsewhere.

So far as is known, only five types of high-quality transmitter are in use at present. In the condenser transmitter a light and tightly stretched diaphragm, heavily damped, forms a small condenser which varies in capacity with the pressure of the air. If a steady voltage E is applied through a resistance across which connection is made to the amplifier, the alternating voltage across the resistance will be proportional to the current flowing when the condenser capacity varies.* For the minute alterations of capacity resulting from the varying pressure of sound incident on the diaphragm the amplitude distortion is quite negligible, and the combination of damping and high natural frequency (about 16 000 p.p.s.) gives an almost flat frequency characteristic.

In the "push-pull" carbon transmitter a similar highly-damped stretched diaphragm operates on two carbon buttons, one on each side and so connected as to compensate mutually for the non-linear carbon distortion.* The variations of resistance are so small that the amplitude distortion arising from the reciprocal relation between carbon pressure and current is quite negligible.

In the electromagnetic transmitter a light coil with

* See Bibliography (35 and 48).

very little stiffness is made to vibrate in a magnetic field by the sound waves; the damping is partly mechanical and partly electrical. The output voltage varies directly as the frequency. The natural frequency is probably low, so that the variation of output with frequency partly compensates for the falling amplitude/frequency characteristic of the vibration, and the frequency distortion can be corrected by suitable inductance.

A fourth type of transmitter operates by the direct action of sound waves on a silent glow discharge provided with a third intermediate electrode. It has been found possible * to control the frequency distortion of this transmitter and to procure a practically flat characteristic by suitable adjustment.

In a fifth type † developed in Germany, sound waves influence the current flowing across an ionized air space between a Nernst glower and a cold electrode.

Amplifiers.

The transmitter will, in general, be connected to an amplifier or series of amplifiers, and it is proposed to

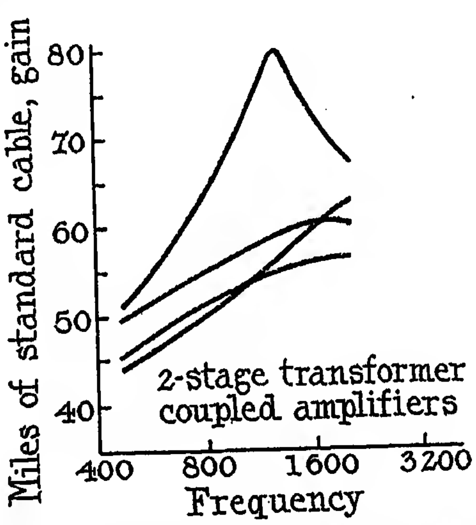

Fig. 5.—Frequency-distortion curves of speech-frequency amplifiers for radio receiving sets tested by the American Bureau of Standards.

consider next the problems of amplification, but it should be understood that the remarks about to be made apply equally to audio-frequency amplifiers used in the receiving apparatus.

It has been pointed out to the author that at a recent discussion on loud-speakers at this Institution, two telephone engineers (of whom the author was one) both assumed without comment that undistorted speech currents at any required level of volume could be delivered to a receiver, while other speakers spoke of the difficulty or impossibility of securing undistorted amplification. It is also noticeable that the technical Press has published several articles recently on high-quality resistance-coupled amplifiers. This criticism of speech amplifiers, in general, appears to have some foundation, as is shown by Fig. 5,‡ which is a reproduction of the frequency-distortion curves of four representative makes of speech-frequency amplifiers for radio work. These curves were published by the American Bureau of Standards. Fig. 6 is the frequency-distortion curve of another well-known make of loud-speaker amplifier.

To a telephone engineer these response characteristics are an amazing revelation; for several years telephone repeaters have been regularly manufactured to requirements holding the variation of gain over the

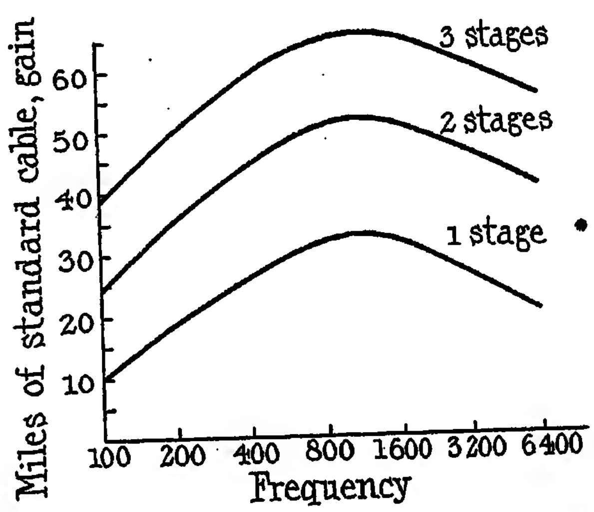

Fig. 6.—Frequency-distortion curves of a loud-speaker amplifier.

range 200 to 2 600 p.p.s. within a range of $1\frac{1}{2}$ miles of 800-cycle-mile standard cable. Figs. 7 and 8 show characteristics of good amplifiers for radio-telephony employing either inductance and condenser or transformer coupling, and should settle definitely the question of whether or not amplification without distortion is possible, at least as far as frequency distortion is concerned. It will presently appear that amplitude distortion can readily be reduced to an almost negligible amount.

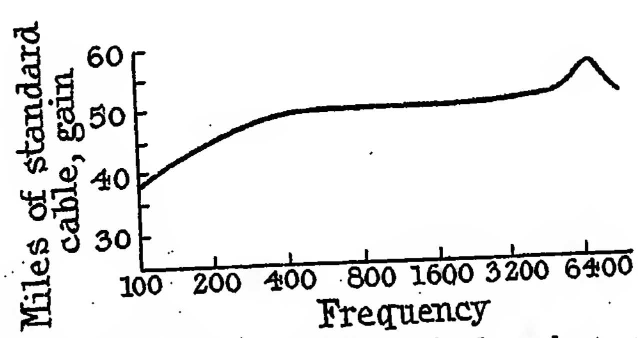

Fig. 7.—Characteristic of a two-stage loud-speaker amplifier of good quality with transformer coupling.

We shall investigate the conditions for avoiding distortion under three headings :—

(a) The valves.
(b) The coupling.
(c) The combination of valve and coupling.

(a) In order that an amplifying valve may operate without distortion, the grid-voltage/plate-current characteristic under the working conditions must be linear over a certain range, and the instantaneous voltage applied to the grid circuit must always lie

* See Bibliography (34).
† *Ibid.*, (43c).
‡ The ordinates are plotted as the number of miles of standard cable having an attenuation loss at 800 p.p.s. equal to the gain of the amplifier at each frequency. Standard cable at 800 p.p.s. has an attenuation constant of 0·109 per mile. The amplification has been plotted in miles of standard cable, that is logarithmically, because it is known that the apparent loudness of two sounds is more nearly proportional to the logarithm of their energy intensities than to the intensities themselves. In this respect the sensation of hearing appears to follow a law similar to the Weber-Fechner law for optical sensation.

between the values of abscissæ which correspond to the limits of linearity. These conditions will be approximately fulfilled when the valve has suitable capacity for the work it has to do if the grid voltage and plate voltage are correctly chosen. A rough guide in choosing these relations is that the maximum alternating voltage applied to the grid should not exceed the amount of the grid bias (including any grid bias that may be due to a high-resistance leak in series with the biasing potential); the actual values should, however, be chosen after a study of the dynamic characteristic has been made, or at least after the dynamic characteristic has been calculated from the static characteristics and the circuit constants. The effect of using a valve over too large a range of its characteristic has been discussed theoretically and experimentally by J. G. Frayne,* where also it is shown how negligibly small the distortion of wave-form becomes as the alternating voltage applied to the grid is reduced to a value commensurate with the steady grid-bias voltage.

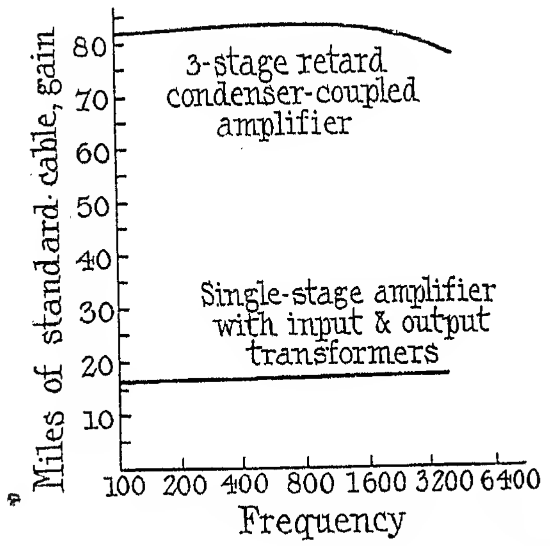

FIG. 8.—Characteristics of good-quality amplifiers for speech-input equipments.

(*b*) The forms of coupling in common use are impedance and condenser (the impedance being either a high resistance or a large inductance) and transformer coupling.

Resistance coupling naturally gives very good quality, and freedom from frequency distortion is easily secured, but it requires a plate battery of higher voltage, and a large part of the effective alternating E.M.F. in the plate circuit is lost unless an extremely high-voltage plate battery is used.

Inductance and capacity coupling has been very successfully used. The points requiring attention are that the inductance must be large enough to offer an impedance high in comparison with the tube impedance at the lowest frequencies to be transmitted, and at the same time the winding must be so arranged that the self-capacity of the coil does not approach the resonance condition at a frequency within the range to be amplified. The core must be sufficiently generously designed to prevent saturation by the plate current flowing in the windings.

Transformer coupling has the greatest overall efficiency and presents the greatest difficulty in avoiding distortion. The advantage of transformer coupling is that the voltage can be stepped up between valves, thus reducing the number of valves required for a given amount of amplification. The difficulty lies in the fact that the primary of the transformer must meet the conditions specified for inductance coupling, while the secondary, in order to get a voltage transformation of four or five, must have an impedance 16 to 25 times as high as the primary. Under these conditions the capacity of the secondary winding is only to be prevented from having serious resonance effects by extremely careful design. The hysteresis effect must also be kept low to avoid asymmetrical distortion. In spite of these difficulties, however, transformer coupling has been successfully employed in high-quality amplifiers, as has already been shown.

Another distortion, somewhat more common than it should be in audio-frequency amplifiers, is due to the curvature of the *BH* characteristic of iron, which causes a certain amount of amplitude distortion. So long as a transformer is sufficiently generously designed, it is possible to keep the variation of flux density so low that the amplitude distortion is negligible on account of the small part of the *BH* curve concerned; but many transformers are made for audio-frequency or loud-speaker amplifiers with very much smaller cores than have ever been used in ordinary telephony, although in the case of loud-speaker amplifiers the speech power applied to the transformer is much greater than that concerned in telephony.

The use of small iron cores reacts also on the frequency distortion of the circuit, because high-impedance windings must be obtained to secure high efficiency at low frequencies. Now the requisite high impedance can be secured by increasing the number of turns or by enlarging the core, but a limit to the increase in the number of turns is in practice soon reached on account of the self-capacity of the coil; thus from the point of view of frequency distortion as well as amplitude distortion a generously designed iron circuit is necessary.

(*c*) It is necessary to study the combination of vacuum tube and coupling because thermionic tubes are not, and cannot be, perfectly unilateral in their behaviour. It comes about, therefore, that the input grid-filament impedance of a tube is a function of the impedance in the plate circuit. In order to investigate this relation rigorously, it would be necessary to think of a vacuum tube as a variable electrical system; that is, the plate-filament impedance should be treated as a function of the instantaneous plate current, a class of problem which has been examined by H. W. Nichols and J. R. Carson.* For most practical purposes, however, it is satisfactory to regard the plate-filament impedance as constant, and as containing a voltage equal to μ times the voltage impressed on the grid, according to the method described by H. W. Nichols.† The various kinds of distortion that may be encountered when the grid voltages are small have been described by the present author elsewhere,‡ where it is shown that the input impedance of the tube is a function of

* See Bibliography (32).

* See Bibliography (48). † *Ibid.*, (26*a*). ‡ *Ibid.*, (25).

the impedance in the plate circuit, and consequently distortion may result if the input impedance varies greatly with the frequency. It is also shown that distortion of wave-form is indicated by a change in the reading of an ammeter in the plate circuit of a valve, and that this kind of distortion is to be avoided by making the external plate-circuit impedance high.

Reference must also be made, on account of its probable effect upon transients, to the phase distortion arising from reactive impedance in the plate circuit. It has been shown by Van der Bijl * that with inductance in the plate circuit the dynamic characteristic is an approximate ellipse having an area proportional to the alternating energy contained in the inductance (see also J. G. Frayne) †; it follows that if the inductance is sufficiently large the alternating current flowing in it can be made so small that the energy $\frac{1}{2}Li^2$ is small and the phase distortion is negligible.

Fig. 9 shows oscillograms taken with a Western Electric cathode-ray oscillograph, illustrating the elliptical form of the dynamical characteristic when the plate circuit is inductive. In Fig. 9 (*a*) the load was an inductance of 0·4 henry and in Fig. 9 (*b*) an inductance

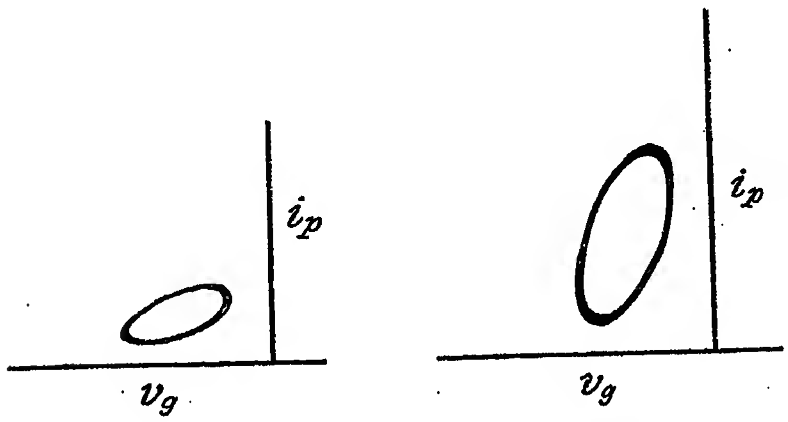

FIG. 9 (*a*). FIG. 9 (*b*).

FIG. 9.—Oscillograms taken with a cathode-ray oscillograph.

In Fig. 9 (*a*) the load was an inductance of 0·4 henry.
In Fig. 9 (*b*) the load was an inductance of 0·8 henry.

of 0·8 henry. The slope of the major axis of the ellipse is the average effective mutual admittance of the grid circuit to the plate circuit; and the ellipse itself, since the ratio of its axes depends upon frequency, indicates that the phase of the plate-circuit current will be a function of the frequency.

There is, however, an upper limit to the value of the inductance in the plate circuit, because the input impedance of the tube has an increasingly large negative resistance component for increasing plate-circuit inductances, and this tends towards oscillation; and even although actual oscillation does not occur, this condition must not be approached or excessive amplification of frequencies in the neighbourhood of the natural frequency of the system will result.

Fortunately, it is generally possible to find between the limits described a suitable value of inductance that will operate successfully over a wide range of frequencies, especially when inductance-condenser coupling is used, as the retard does not form the useful load but is only the high-tension feed; the effective plate-circuit impedance for large values of the inductance depends on the condenser coupling and grid leak of the succeeding valve which form a circuit in parallel with the inductance.

* See Bibliography (23). † *Loc. cit.*

REACTION.

Reaction is seen in its simplest form when it is applied to a radio-frequency amplifier; the output circuit is coupled back to the input circuit in any convenient manner so that the output produces an augmented input. In order to represent the arrangement in its simplest form we may ignore the inter-electrode capacities of the valve, and assume that we have a unilateral machine in which the output voltage is μ times the input voltage. We will suppose that a constant alternating voltage is applied to a series resonant circuit (the aerial), and that the voltage across the inductance is applied to the idealized voltage amplifier,

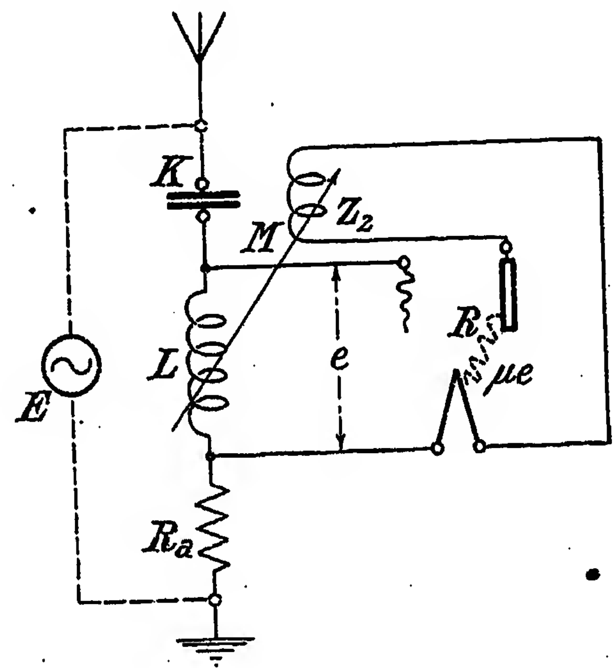

FIG. 10.

the output from which reacts on the aerial inductance (see Fig. 10).

The equations for this system at a frequency p, if Z_a is the aerial impedance without reaction, are

$$\left.\begin{aligned} x_1 Z_a + x_2 jMp &= E \\ x_1 jp(M - \mu L) + x_2(R + Z_2) &= 0 \end{aligned}\right\} \quad . \quad (19)$$

from which we derive the effective aerial impedance

$$\frac{E}{x_1} = Z_a - \frac{Mp^2(\mu L - M)}{R + Z_2} \quad . \quad . \quad . \quad (20)$$

Since M is related to Z_2 and L, it is convenient to substitute jpL_2 for Z_2 and $k\sqrt{(LL_2)}$ for M. We then get the following terms for the aerial impedance after rationalizing:—

Without reaction $\quad Z_a = R_a + jpX_a$

Real component due to reaction

$$= -\frac{p^2kLR(\sqrt{L_2})(\mu\sqrt{L} - k\sqrt{L_2})}{R^2 + p^2L_2^2} \quad (21)$$

Imaginary component due to reaction

$$= \frac{jp^3kLL_2(\sqrt{L_2})(\mu\sqrt{L} - k\sqrt{L_2})}{R^2 + p^2L_2^2} \quad . \quad . \quad (22)$$

From these expressions it is seen that as k or L_2 is increased the real component of aerial impedance due to reaction becomes at first increasingly negative, so that the effective aerial resistance is reduced and may reach the oscillation point; for still further increase in k or L_2 the real reaction component becomes positive and the reaction circuit forms a load on the aerial.

As L_2 changes, the reactive reaction component changes, at first increasing the effective aerial inductance and afterwards decreasing it.

In the practical application of reaction the effective aerial resistance is decreased, with consequent reduction of the aerial damping coefficient; at the same time the effective inductance is increased, so that if the aerial is tuned by condenser variation the damping is further decreased by the increase of inductance, but if the aerial is tuned by variometer the increased inductance due to reaction is neutralized in the tuning.

A moderate degree of reaction is legitimately and properly used to increase the sharpness of tuning when receiving faint or long-distance telephony; by sharper tuning the selectivity of the receiving set and the ratio of tuned signal to interfering noise, and signals on slightly different wave-lengths, is increased. If, however, the reaction is taken too far the curve of aerial current against frequency for constant applied voltage becomes sharply peaked, and the range of frequencies corresponding to the signal no longer lies on a sensibly flat part of the resonance curve, so that there is frequency distortion; this is exactly similar to the result obtained when sharply tuned radio-telegraph receivers are used for the reception of telephony on long wave-lengths. The general principles of oscillatory circuits examined in the first part of this paper also show that abrupt variations in the applied voltage will not be faithfully followed by the aerial current if the damping is made very low, but instead the aerial will set up a damped train of oscillations at its natural frequency at each transient change, and these when rectified appear as noise.

It is hardly necessary to comment on the excessive and incompetent use of reaction that is so common and causes so much interference; the resulting distortion of both kinds referred to above becomes very marked indeed and, in addition, the tuning is generally not exact as is shown by the heterodyne note, so that the upper and lower side bands are not symmetrically reproduced, with results that have been studied and described by R. V. L. Hartley.*

When reaction is applied to a single-valve demodulator, the results are substantially the same as in the case of the radio-frequency amplifier already described. The output from the valve consists of an audio-frequency component and a radio-frequency component; these are separated and the latter is fed to the reaction coil. In respect of the radio-frequency currents in the secondary circuit the valve operates in the same way as the amplifier previously described.

It is not possible to discuss here the many kinds of receiving circuit that are in use with and without reaction, but the application of the general principles given in this paper will generally be sufficient to reveal the conditions required for obtaining good quality in any circuit. There is, however, one type of circuit that uses a distinctive feature, on which a few words must be said. The type referred to is that originated by Armstrong, in which high reaction is used together with a quenching device that prevents continuous oscillation. Such a circuit is a valuable one for long-distance commercial communication, but cannot under any circumstances be considered as a high-quality receiving system, because the high reaction introduces the frequency distortion already described, and the periodic quenching of free oscillations introduces slight noise due to the audible components of the damped trains of waves.

Attempts are occasionally made to apply the principle of reaction to audio-frequency amplifiers. It may be said at once that no important developments are to be looked for along these lines.

It is shown in an Appendix that only a highly idealized resistance-coupled amplifier can have a truly flat frequency-distortion characteristic; in general, the characteristic of a speech amplifier falls away markedly at very low and very high audio frequencies, these frequencies in a good amplifier being outside the range to be transmitted. If reaction is applied, the departure of the characteristic from the ideal flat curve will become more marked, in just the same way as the tuning curve of an aerial becomes more peaked by the application of radio-frequency reaction. If, on the other hand, we suppose reaction applied to an ideal resistance-coupled amplifier, we have an amplifier inherently of rather low efficiency, and reaction will raise the efficiency. In practice, however, the capacity of the valve electrodes and the capacity and inductance of the apparatus prevent the realization of a flat characteristic, with the result that deterioration of the characteristic sets in directly reaction is applied to any useful extent; meanwhile the same improvement in efficiency can be secured with less harmful effect on the characteristic by the substitution of transformer coupling or inductance and condenser coupling. The practical application of reaction to audio-frequency amplifiers is beset with many other complications arising from the curvature of the grid-voltage/plate-current characteristic, which makes the amplifier unstable so that a strong signal may send it into an unresponsive condition.

Dual Amplification or Reflex Circuits.

Like reaction, a method of increasing the output of a single valve that is now coming into prominence is the use of dual amplification, that is the use of a single valve first for radio-frequency amplification and then for audio-frequency amplification. It is, in general, not satisfactory from the point of view of high quality to use a single valve for two different functions, because the circuit conditions that suit one condition of use

* See Bibliography (28).

are generally incorrect for another condition. In dual amplification the vacuum tube operates as an amplifier in both its functions, but the radio and audio frequencies have to be separated by condensers, which cause appreciable distortion in the audio-frequency circuit.

RECEIVERS.

Of the various types of apparatus that have been used for the final conversion of electric current to speech we shall confine our attention to electromagnetic devices, since these are by far the most commonly used.

Where crystal sets or amplifiers of low power having good characteristics are used with head receivers, it is commonly agreed that excellent quality can be obtained; the naturalness also is probably good, but the conditions of listening are such as to make the judgment of naturalness difficult. There are, however, differences observable in the naturalness of different head receivers, caused by differences in the natural frequency of the mechanism and, more particularly, differences in the degree of damping. Owing to the necessity of using mechanical resonance in order to secure an instrument of reasonable efficiency, receivers are less than critically damped; a good receiver, for example, may have a response to a suddenly-applied steady voltage similar to the curves $\beta = 500$ in Figs. 2 and 3, and the distortion inherent in resonant systems occurs.

In order to obtain a satisfactory compromise between efficiency and faithfulness, it has been necessary to make a careful study of the desirable vibration constants of a receiver, taking into consideration the increased damping of the receiver when it is held to the ear. The general theory by which the vibration constants are studied has been described by the author elsewhere.* For many years the design of receivers was based on experimental work with trial and error. The data accumulated by this method, together with Dr. Kennelly's methods of impedance analysis and modern research,† have placed receiver design on a sound scientific basis, to which strong testimony is borne by the fact that the first receiver designed by the new methods had an acoustic power output about $2\frac{1}{2}$ times greater than previous receivers for the same power input, although it was actually smaller and lighter. These improvements in design accompanied the study of telephone-speech quality, with the result that both frequency distortion and amplitude distortion were reduced.

LOUD-SPEAKING RECEIVERS.

Of all the transformations to which the speech or music is submitted in its passage from the source to the listener, the final transformation into acoustic waves by a loud-speaking receiver is the least satisfactory. No loud-speaker has yet been made that sounds perfectly natural, although by proper design and extreme care in manufacture it is possible to secure results that are highly satisfactory, and in fact the intelligibility may be made commensurate with the intelligibility of a head receiver; it is in speech naturalness and musical faithfulness that the principal improvements are to be looked for. Present achievements owe their success to the rather generous tolerance of the human ear* and cannot be said to mark the final development of loud-speaking apparatus.

* See Bibliography (38). † *Ibid.* (40, 42 and 43).

There are very many types of loud-speaking receivers on the market, and the diversities in their faithfulness of reproduction are about as numerous as their types. Some account of the difficulties of securing faithfulness and of the inherent disadvantages of certain types has been given by the author and others at a recent joint meeting of the Institution and the London Physical Society.†

It is not always realized that the receiver mechanism will not handle more than a certain amount of power without serious amplitude distortion; in this respect the receiver should handle as much electrical speech power without distortion as the valve which precedes it. Both valve and receiver must, however, be capable of dealing with the maximum peak voltages occurring, whether due to a peaky wave-form or to the varying intensity occurring pre-eminently in music. Measurements with the cathode-ray oscillograph have shown that the momentary ratio in a short time-interval of peak voltage to R.M.S. voltage for fairly rapid speech collected by a high-quality transmitter is about 6 or 7. A somewhat similar average figure was found for gramophone music, but the music varied in intensity up to a maximum of over 6 times the average intensity for the whole record. These figures are, of course, subject to variation and amendment, but they indicate that a given valve and loud-speaking receiver will only reproduce music without bad distortion on loud notes at an average intensity considerably lower than that at which they can reproduce speech satisfactorily. It is also apparent that in estimating the permissible variation of grid potential from any data obtained by measurement of the R.M.S. value of speech currents, an amplitude factor must be used to provide for the high peakiness of the wave-form.

As a very rough approximation, it may be stated that a good loud-speaking receiver may require from 0·0003 to 0·0005 apparent watt in order to give out speech at a convenient volume level in a moderate-size living room; the apparent watts are supposed measured by the product of mean-squared current and effective resistance (at 800 periods per second) of the receiver. Allowing that the peaks of the voltage wave are 7 times the R.M.S. value, it is easy to calculate that a valve of moderate power is required to give a good performance with speech, while a further margin is required to take care of the wide variation of intensity in music.

In regard to the receiver itself, the current through the receiver is very unlikely to respond well to the steep peaks in the voltage curve, on account of the inductance of the windings; this is, of course, the electrical equivalent of mass in a mechanical system, so that the inductance of the receiver circuit should be kept low relatively to the resistance as well as the mass of the moving parts. Naturally a receiver requires inductive windings, but the effective inductance under working conditions plays no useful part and is analogous

* See Bibliography (5 and 6). † See page 265.

to the leakage flux and magnetization inductance of a transformer; a 100 per cent efficient receiver need have no effective inductance.

The limited amount of power that some receivers are capable of handling is the cause of a certain amount of dissatisfaction, even though the reproduction may be faithful within the power limits of the receiver. The variation of intensity of music between the extreme of pianissimo and the extreme of forte with a full orchestra has been estimated to be an energy ratio of $1:10^7$. It is, therefore, easy to see that if a receiver is incapable of producing as much acoustical energy without distortion as the maximum music intensity to be transmitted, the performance must be heard at a subnormal volume level; under such conditions the pianissimo passages, only just audible in the original music, may be lost altogether in the reproduction, and the ear distortion caused by reproduction at the wrong loudness level will be present. Receivers can be made that will handle the requisite amount of energy to give normal volume reproduction of loud music, but the smaller and simpler types of instrument must not be expected to do it.

It may be assumed that a receiver can be designed to give a required output without amplitude distortion, and that it is used in conjunction with an amplifier of adequate capacity as judged by its freedom from amplitude distortion in handling the peaks of the alternating wave-form applied to the last grid. We then come face to face with the problem of frequency distortion, which in loud-speaking receivers is the most serious problem of high-quality radio-telephony. With ordinary care, and by comparatively easy means, the distortion of all the other apparatus used in radio-telephony can be brought down to reasonably small dimensions; in the loud-speaking receiver such an equally near approach to perfection is still possible, but not as yet at a commercial cost. As the author has pointed out elsewhere (*loc. cit.*) electromagnetic receivers can only be made of sufficiently high efficiency to enable them to be used with moderately-powered valves by employing mechanical resonance; it is by the sparing use of resonance, entailing perhaps the sacrifice of a certain amount of volume efficiency, that high quality has at present to be secured. It is therefore a corollary that the greater the amount of distortionless speech power that the loud-speaker amplifier can deliver, the less resonance need be used in the receiver and the better its quality can be. It is a further corollary that the receiver should be designed in conjunction with the amplifier in order that the combination may give the best results.

Some recent studies on four types of loud-speaking receiver brought into view some interesting facts bearing on the relation between speech quality and naturalness. It was found that the four receivers were approximately equal in speech quality, although they differed widely in naturalness, the same voice being produced with fair naturalness by two of the types, and with an unearthly hollowness and drumminess by the other two types. Investigation showed that the drummy effect was caused by the fact that the receivers in question had natural frequencies at about 650 periods per second, some 200 p.p.s. or more below the resonant frequencies of the more natural receivers. The low-pitched and relatively undamped resonances had little effect upon the intelligibility but had a great effect upon the naturalness.

Noise and Interference.

A consideration of quality would not be complete without some reference to noise and interference, although these factors fall somewhat outside considerations of distortion.

It has been ascertained, so far as speech goes, that the intelligibility of reception depends upon the ratio of noise intensity to speech intensity. The noise to be considered consists of atmospherics, interference from wireless stations or power circuits, valve and amplifier noises (sometimes caused by vibration) and also of the frequencies manufactured by amplitude distortion in the wireless apparatus.

At the present time very little can be done to reduce noise (other than distortion noise) in circumstances where it is serious. High selectivity of the receiving apparatus naturally tends to reduce the noise received when it is spread over a spectrum of wave-lengths; the use of a coil aerial may by its directional effect also enable the ratio of signal to noise to be raised. Other devices have been described from time to time, the object being often to eliminate one particular wireless signal on a wave-length near to that being received; such devices may consist of an auxiliary tuned aerial or various special circuit arrangements. Naturally these devices do not eliminate the extra frequencies due to amplitude distortion.

Conclusion.

In conclusion the author desires to express his indebtedness to his colleague, Mr. W. L. McPherson, for reading the manuscript and for much valuable advice.

Acknowledgments are also due to the Western Electric Company, Ltd., for permitting the results of work carried out in their laboratories to be published.

APPENDIX 1.

The Response-Frequency Characteristic as a Criterion of Quality in Respect of Transient Impressed Forces.

Of the two fundamental types of distortion under steady-state conditions, the frequency distortion is, in general, the more important and more difficult to avoid.

The quality of reproduction of an amplifier (or other piece of apparatus) is commonly examined by plotting the output (voltage or current) for constant input against frequency; such a curve is called the frequency-distortion, or response-frequency characteristic. The ordinates of this curve can be regarded as mutual admittances, or a similar quantity according to the definition of input and output adopted for the purpose of obtaining the characteristic. The phase of the

ordinates is not usually determined, so that it is the modulus of the admittance that is plotted.

In the light of the evidence that the ear will disregard phase differences in the steady state, and the suggestion that it cannot form an image of the original transient disturbance from a phase-distorted reproduction of it, the question arises whether the frequency-distortion characteristic should also show the phase distortion, in order to give a complete representation of the effect of the system on quality.

From the analytic point of view, we must confine our attention to "ironless mathematics," and suppose that our mutual factor relating input and output is formed by addition, multiplication and division of a number of simple factors of the form $\alpha + \beta d/dt$. For the steady state the mutual factor will then take the form $P + jQ$, where P and Q are rational real fractional functions of the frequency p. The modulus will be a polynomial fraction in integral powers of p with a finite number of terms.

The question is whether the modulus, i.e. $\sqrt{(P^2 + Q^2)}$, which forms the ordinary frequency-distortion characteristic, determines uniquely the phase distortion, or whether there can be a number of different functions of frequency having the same plot of modulus against frequency but different plots of phase angle against frequency, that is, different values of Q/P.

We may suppose that the full expression of the mutual factor is $(F_1 + jF_2)/F$, where F, F_1, F_2 are rational polynomials in powers of p. The modulus is $\sqrt{(F_1^2 + F_2^2)}/F$, but is only known as

$$\sqrt{(A + Bp^2 + Cp^4 \ldots p^{2n})}/F$$

The problem is therefore to determine whether $M = (A + Bp^2 + Cp^4 + \ldots p^{2n})$ can be expressed as the sum of the squares of two rational polynomials in more ways than one.

$$\left.\begin{array}{l}\text{Let } F_1 = a_0 + a_2p^2 + a_4p^4 \ldots a_np^n \\ F_2 = b_1 p + b_3p^3 + \ldots b_{n-1}p^{n-1}\end{array}\right\} \quad . \quad (1)$$

Then on squaring F_1 and F_2, adding them together and equating to M, an identity is obtained which furnishes $(n + 1)$ equations to determine the $(n + 1)$ coefficients $a_0 \ldots a_n$, $b_1 \ldots b_n$. Hence F_1 and F_2 can be uniquely determined and the phase angle is

$$\text{arc tan} = F_2/F_1 \quad . \quad . \quad . \quad . \quad . \quad (2)$$

It is seen, therefore, that the plot of the modulus of the mutual factor of any physical system defines also the phase angle of the mutual factor, provided the modulus is expressible as a fraction in integral powers of p.

Since the modulus of the mutual factor defines the phase distortion implicitly, it is evident that transient phenomena need not be studied separately but can be regarded as included in all investigations applied to steady-state distortion; it must be appreciated, however, that the transient distortion is only included in the sense that a good steady-state response characteristic indicates good transient response in a general way, and this is the justification for forming an opinion of the quality of apparatus from its steady-state characteristics.

It would lead too far to investigate the relation between frequency distortion and phase distortion taking into consideration the hysteresis effects of iron-cored apparatus; under such conditions the ordinary expansion theorem for the calculation of transients no longer applies, nor in general is the mutual factor expressible in integral powers of p.

APPENDIX 2.

No invariable amplifier or reproducing mechanism having dissipation can have a frequency characteristic that is perfectly flat in any finite part without being flat from zero to infinite frequency, that is, without having a perfectly constant ratio of reproduction for all frequencies.

The square of the modulus of the steady-state mutual factor for a physical system having a finite number of degrees of freedom and built up of single-valued impedance operators is a rational fraction, finite for all real values of the variable. Therefore, if the variable p be given a generalized complex significance, the square of the modulus of the mutual factor regarded as a function of the complex variable is a holomorphic function in a region as narrow as we please but containing and extending along the real axis. It is a property of such functions that they cannot be constant over a finite interval without being constant everywhere in the holomorphic region. It follows that under the conditions assumed for analytical purposes the enunciation above is verified.

Hence, for example, an idealized resistance-coupled amplifier will have a constant ratio of reproduction for all frequencies, but a transformer-coupled amplifier being necessarily inefficient at very low frequencies cannot have a characteristic that is truly flat in any part, although in practice the characteristic may be experimentally indistinguishable from a straight line over a wide range of frequencies.

Discussion before the Wireless Section, 7 May, 1924.

Sir Richard Paget: So far as the observations which I have made by ear are concerned, they agree with everything that the author says as to the nature of speech sounds. As to whether aperiodic sounds are really involved: all the sounds, including all the transitions of the transient sounds, appear to be essentially musical. The only possible exceptions are the sounds of "f" (the unvoiced sound) and "th." There is, to the ear, a component—not the main component—which is what may be described as a faint roar. It is an unstable sound which may be truly aperiodic. In practically all the others (I am speaking of consonants as well as of vowels) the components are all essentially musical. As to naturalness, it might be interesting to point out that, in a bass or baritone voice, the larynx frequencies often fall to as low as 50 or 60 per second. For instance, if I say "Oh, oh" my voice has gone through a phase of this sort—861 to 966 and down to a frequency of about 54, i.e. an octave above the lowest note on the piano. Therefore in order to get true naturalness in reproducing a man's voice the apparatus must reproduce frequencies down to the order of 50 or so; otherwise the natural effect of the voice is lost. Music demands a still larger range, because some instruments operate down to 20 vibrations per second. On the upper limit I should say that apparatus would have to respond at well over 5 000 periods to obtain naturalness. The sounds of "f," "th" and "s" all have components of that order; the "s" sound in my own voice has a frequency of between 6 000 and 7 000. The natural frequency of the cavity of the ear may have a bearing on this subject. In my own case it is about 2 900. If one puts a finger into one's ear and then takes it out gradually one hears a note which rises up to about this frequency as the air cavity is completely opened. If the ear is covered with one hand so as to lower its frequency all sorts of external noises are increased by resonance, but as one comes to the natural frequency of the ear these resonant noises cease altogether, indicating that the ear has ceased to be sensitive to noises of the natural external ear frequency. If instruments could be made to have the same natural frequency as the human ear we might be less conscious of their natural periodicity. The intelligibility of different consonants varies greatly, merely as tested by their range in air. I recently made some experiments which may be of interest. The sound of "f" under those conditions had a range of about 40 yards. Under the same conditions "th" had a range of about 80 yards. Above 40 yards "f" was constantly mistaken for "th." Above 80 yards "th" was mistaken for "s." The "s" sound itself was always clearly heard up to 150 yards. But the sound which had much the greatest carrying power was "sh." That is why we use "sh" when we wish to get silence in a hubbub. A word as to the distinction between different transients. I do not think it is necessary to rely on phase differences. I should think it likely that the ear is as unconscious of phase differences in the transients as it is in the case of persistent sounds. The following has to be remembered in regard to every transient sound. Take the "k" and "t" and "b" and "p" sounds. Each of these has several components—always two or three—and each of those components may be moving in a different direction. Thus the middle component may be kept fairly level while the upper one is going up and the lower one is going down; so that although we may start with three similar components, we can get two entirely different transient sounds, because the different components are moving in different directions, or their

amplitudes are increasing in different proportions. For example, the essential differences between the sounds of "p" and "b," and "t" and "d," and "k" and "g" are, broadly, that in "p" and "b" what we hear is simply a variation of amplitude only; there are no audible changes of resonance. In fact, any method by which the resonances are suddenly started or stopped gives the ear the impression of a "p" or "b" sound. D. C. Miller actually made his group of organ pipes say "papa" by simply turning on the air supply sharply twice in succession. There, of course, the resonances were started suddenly and stopped suddenly. The sounds "k" and "g" and "t" and "d" are quite different. They are essentially due to changes of amplitude and of frequency. In "k" and "g" the most remarkable characteristic is that the sound starts by a double release, like turning on a tap in two stages; whereas in "t" and "d" it is by a one-stage release. The high-frequency components of the sound are also much more pronounced in "t" and "d" than they are in "k" and "g." Figs. 5, 6 and 7 in the paper indicate the inadequacy of the system referred to for dealing with low frequencies. It will be seen that if the curves in Fig. 6 are continued back, there would be no amplification at all at 50 periods, and if the curve in Fig. 7 were continued there would again be an amplification, at 50 periods, of only about one-half that obtained over a very wide range from about 400 to 3 000 periods. A few days ago I listened to the loud-speakers at Wembley and I was particularly struck by the fact that no low frequencies at all were audible. There were some very persistent frequencies due to resonance of the horn or the diaphragm. The intelligibility was good. To sum up: for naturalness in music and in male voices we undoubtedly need responses to frequencies of from 20 to 50 and upwards. For intelligibility we want a greater sensitiveness in the higher regions, from 5 000, I should say, up to about 7 000. Some very interesting experiments on the duration of human speech sounds have recently been published by Mr. Jefferson of the Phonetic Laboratory at University College. The device which he used enabled the actual movements of the jaw to be recorded. From that, exact information could be got as to the actual times occupied by syllables in human speech.

Captain B. S. Cohen: On page 792 there are references to intelligibility, articulation, and traffic efficiency. Intelligibility and articulation are defined in this country very much as the author has defined them; but traffic efficiency has not been considered to any great extent and I do not think that the term will find very much favour. I suggest in its place some such term as "transmission speed factor." That would prevent any confusion with the normally-accepted definition of "traffic." I am glad that the author emphasizes (on page 793) the necessity for reproducing at about the same volume level, as it has been frequently stated that a perfect repeater on a much reduced volume scale is all that is required, and this conception results in unsatisfactory reproduction. On page 796, under the heading of "Measurement of Intelligibility," the author refers to lists of monosyllables for determining the proportion of syllables accurately recorded, and states that the lists are arranged to give equal weighting to the different elemental speech sounds. In this country it is customary to weight these lists in the proportion of the frequency of occurrence of the various speech sounds in average speech. Some occur very much more frequently than others and it is considered better to weight these lists than to take an equal weighting for each elemental speech sound. On page 798 the author refers to five types of high-quality transmitter in use at present. I should like to refer to three other types which it is considered may be of very considerable value for radio-telephony reproduction, but which are at present being utilized principally for measurement purposes. The first is the eddy-current transmitter due to Mr. Hewlett, who terms it a "tone generator." This consists of two rigid slab coils placed close together, with a thin disc of aluminium foil between. This disc of foil can be moved to and fro by impinging sound waves which pass through spaces in the coils. The eddy currents produced in the aluminium foil by the field from the slab coils through which a polarizing current circulates are utilized for reproduction. This gives very faithful reproduction and there are no resonance points over the audio range. The second form is merely a loose-leaf condenser of a few sheets used as an aperiodic transmitter. This offers considerable possibilities and is one of the earliest forms of condenser transmitter. The third form is the Wollaston wire thermophone. The footnote on page 799 states that standard cable has an attenuation constant of 0·109 per mile. This is, however, an obsolescent American standard, and the standard in this country and a number of other European countries has an attenuation constant of 0·106 per mile. With regard to transformer-coupled audio-frequency amplifiers, I propose to exhibit lantern slides showing curves similar to those obtained by the American Bureau of Standards. These have been obtained with apparatus which was demonstrated at a recent meeting of this Institution and are actual reproductions of the photographic curves obtained on an oscillator outfit used for the measurement of frequency-amplitude characteristics. The two sets of curves shown indicate the results obtained with two types of intervalve transformers. There are four curves for each transformer, indicating the variations obtained with reversal of primary and secondary windings. These curves demonstrate the importance of the self-capacity of the windings. Although one of these sets of curves indicates a high-quality article, the other set, obtained with an expensive type of transformer, is decidedly unsatisfactory and indicates a very small percentage of output below 350 periods and above 3 500 periods. I agree with the author that it is somewhat amazing to the telephone engineer to see how unsatisfactorily such results compare with those obtained in ordinary telephony repeatering.

Mr. L. B. Turner: I wish to refer first to transients, of which frequent mention is made in the paper; and secondly to the parasitic frequencies introduced at the demodulator. Hitherto, telephonic theory has rather desperately idealized and vastly simplified its problems in assuming steady-state conditions. The author points out that such conditions are not a close approximation

to facts, and boldly attempts to utilize steady-state analysis to give at least qualitative guidance in respect to transients. I think that the importance of the transient treatment is even greater than the author suggests. Not only must consonants admittedly be so treated, but also clearly vowel sounds whose duration in constant strength is brief; and it seems at least very doubtful whether even steady vowel-like sounds can be expressed as a Fourier series. In a recent issue of *Nature* (26th April, 1924), Prof. E. W. Scripture refers to this matter as follows: "The analysis of a vowel into component tones can be shown to be mathematically and physically impossible . . . The Helmholtz theory that vowel sounds are composed of tones harmonic to the voice tone . . . pushed aside the Willis theory that the vowels consist of independent vibrations aroused by puffs from the larynx. . . . After years of oblivion, the Willis theory has been shown to be true for German vowels by Hermann, and for English vowels by myself." That merely adds force to the author's insistence on the importance of transients. Now what does he do with transients? In Appendix 1 it is proved that "transient phenomena need not be studied separately but can be regarded as included in all investigations applied to steady-state distortion"; but it appears to me a *non sequitur* to deduce that "a good steady-state response characteristic indicates good transient response in a general way." Transient conditions are proved to be determined when steady-state conditions are determined; but I cannot see that circuits which are good or bad with respect to the steady state are therefore necessarily good or bad with respect to transients. Argument from steady state to transients is difficult and dangerous. On page 805 occurs the phrase, "a phase-distorted reproduction of a transient." What, I would ask, is the meaning of "phase" in a non-periodic disturbance? The author states on page 798 that "it has been shown by Moullin and Turner that for strong signals the demodulation is likely to follow a linear law," but reference to our paper * (Section 11, page 717) will show that the signal at the rectifier would have to exceed some 2V before the square law would be departed from appreciably, and practical signals (in the absence of a local heterodyne oscillator) are, of course, very much less than this. Let us assume, therefore, a rectifier characteristic $i = \alpha + \beta v + \gamma v^2$, and (following the symbols used in the paper) let us consider a carrier wave $B \sin ct$ modulated simultaneously at two acoustic frequencies $p_1/(2\pi)$, $p_2/(2\pi)$ so producing in the rectifier a P.D.

$$v = E + B(1 + A_1 \sin p_1 t + A_2 \sin p_2 t) \sin ct.$$

The rectified current is easily shown to consist of a constant term and 24 sinusoidal terms, of which 18 are of inaudibly high frequencies [e.g. $(2c - p_1 + p_2)/2\pi$] and six of acoustic frequencies. Only these six affect the ear, and they are given in frequency and amplitude in Table A.

Of these terms, a and b are wanted, c and d are not wanted, but being second harmonics of a and b they are not likely to be particularly noxious. Terms e and f, on the other hand, are likely to be troublesome. All the parasitic terms can be reduced to insignificance if the expense of sufficiently reducing the modulation can be faced, or if the carrier wave could be replaced or reinforced by sufficiently powerful local oscillation introduced at the receiver. Of the four parasitic terms $c - f$, which must be present in some degree if both side-bands are radiated, three vanish if the valuable Western Electric Co. single side-band method of transmission * is used. If in our example both the lower side-waves $(c - p_1)$ and $(c - p_2)$ are filtered out before reaching the transmitting aerial, the bracketed terms c, d and e in the table vanish (and the remainder are all halved in amplitude). The fact may lie embedded somewhere in the author's bibliography, but I have nowhere seen any reference to this further good feature of the single side-band method. We are accustomed to hear from the British Broadcasting Company that their transmissions are above criticism, and that if we do not get perfect music we must strive to improve our receivers. But I am not convinced. Might not an improvement perhaps be effected on the lines that I have indicated? In considering such matters, one must not forget that, in broadcasting, the familiar

TABLE A.

Term	Frequency × 2π	Amplitude × $4/\gamma B^2$
a	p_1	$4A_1$
b	p_2	$4A_2$
[c	$2p_1$	A_1^2]
[d	$2p_2$	A_2^2]
[e	$p_1 + p_2$	$2A_1A_2$]
f	$p_1 - p_2$	$2A_1A_2$

economic relation between transmitter and receiver is reversed. In two-station wireless the cost of the receiver is only a very small fraction of that of the transmitter; but in broadcasting, great expense should be undertaken lightly at the transmitter if a small gain may thereby be effected in each of its 100 000 receivers.

Mr. P. W. Willans: I should like to refer to Appendix 1 of the paper, regarding which I am in agreement with the views of the last speaker. Undoubtedly, perfect knowledge of the modulus characteristic of a system would imply perfect knowledge of the phase characteristic, but it does not by any means appear to follow that any degree of uniformity in part of the one implies a corresponding degree of uniformity in the other. A Campbell filter is a sufficiently good instance of the contrary. Within my own experience of low-frequency amplifiers, results obtained over a limited range of frequencies only are most misleading, modulus characteristics of the same general form yielding totally different phase angles at corresponding points. In order to illustrate my meaning I should like to describe some work which we have been carrying out recently at Chelmsford on measurements of low-frequency transformers. Most of these

* *Journal I.E.E.*, 1922, vol. 60, p. 708.

* H. W. NICHOLS: "Transoceanic Wireless Telephony," *Journal I.E.E.*, 1923, vol. 61, p. 812.

have been done on a single stage of voltage amplification and consist of comparisons between the input and output voltages in respect of both amplitude and phase. The input voltage v_g is applied to the grid of a valve (see Fig. A) in the anode circuit of which a transformer is connected, the output voltage v_g' being developed across the secondary of the latter. By means of an audio-frequency bridge method the vector ratio v_g'/v_g could readily be measured at amplitudes corresponding to those experienced in practice. The results obtained were most astonishing to us at the

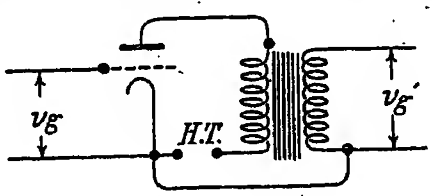

FIG. A.—Single stage of voltage amplification.

v_g = instantaneous input voltage.
v_g' = instantaneous output voltage.

time but have since proved capable of fairly exact interpretation on the basis of simple theory. A pair of curves corresponding to two different transformers is shown in Fig. B. These illustrate the possibility of obtaining over a limited range of frequencies modulus characteristics which are substantially uniform, together with phase characteristics of differing degrees of uniformity. It would be almost impossible from an inspection of the characteristics, as plotted, to deduce that the phase-shift in curve A was double that in curve B over the same extent of characteristic, i.e. between 1 000 and 4 000 cycles per second. In fact, the great degree of uniformity in the characteristic

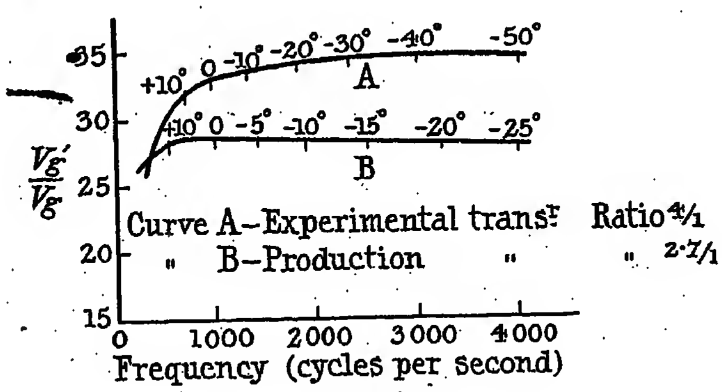

FIG. B.

of curve A might have led to the conclusion that the self-capacity was extremely low and the resonant frequency at about 3 000. The point at which the phase angle is zero, however, indicates that the resonant frequency is about 1 000, and the maintenance of more or less constant amplification at higher frequencies has proved to be due to the magnetic leakage of the transformer. The characteristics exhibited by a previous speaker illustrate the effect of this leakage to an even more marked degree, the abnormal amplifications at high frequencies (which already appear in curve A) being developed into a pronounced resonance hump. This effect would be produced on the transformer of curve A if it were used with a valve of lower internal resistance than that for which the curve was plotted (R type, r = about 45 000 ohms) and it would therefore appear that the curves just exhibited were plotted for valves of lower internal resistance than those for which the transformers were designed. I should like to mention, in passing, with reference to page 800 of the paper, that all intervalve transformers that we have measured which are in any degree efficient exhibit resonance effects well within the audio-frequency range, the phase angle becoming zero at some such frequency. It is not absolutely clear whether the author condemns all transformers exhibiting effects of this kind or only those for which the characteristics

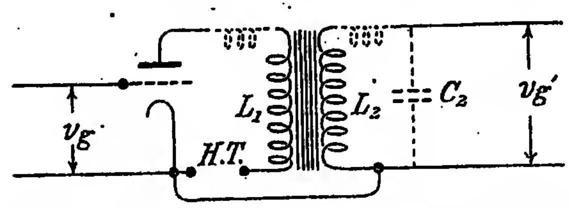

FIG. C.—Effect of magnetic leakage on transformer amplification: diagram of transformer with magnetic leakage and self-capacity in the secondary circuit.

are specially "peaky." Our own experience is that resonance in itself is not only harmless when properly damped by the valve but is practically a necessity if the best results are to be obtained, as otherwise a sacrifice of efficiency on the low notes is entailed. The question of magnetic leakage in intervalve transformers appears to be of the greatest importance. In connection with the theory of this subject I should like to refer to a paper * by Mr. W. L. Casper which certainly deserves a place in the author's bibliography. We had no knowledge of this or any other publication on the subject at the time of carrying out the work which was completed during the course of last year. The theory is interesting, both from the point of view of phase distortion and as accounting for the

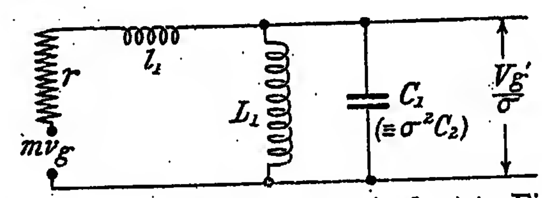

FIG. D.—Simplified circuit equivalent to Fig. C.

abnormalities in the transformer characteristics recently exhibited. Referring to Figs. C and D, the former shows a transformer in circuit having leakage inductance in both its windings and self-capacity in its secondary circuit. The self-capacity of the primary and the resistance of both windings may be neglected. Fig. D shows a simplified equivalent circuit in which the secondary circuit is replaced by a capacity shunted across the primary, equal to the effective self-capacity of the secondary multiplied by the square of the ratio of transformation, and all the leakage inductance is assumed to be located in the primary circuit. The ratio of transformation is not necessarily the ratio of the total number of turns, but nevertheless can, with

* *Journal of the American Institute of Electrical Engineers*, 1924, vol. 43, p. 197.

a fair degree of accuracy, be taken as constant at all frequencies. A study of Fig. D will show the general effects to be expected at different frequencies. At the lowest frequencies the impedance of C_1 will be considerably higher than that of L_1 and the value of the latter will therefore determine the amplification to be obtained. At the resonance of L_1 and C_1 the full valve magnification will be obtained, since the impedance of the parallel resonant circuit may be regarded as infinite in comparison with that of l_1. At frequencies above the resonance of L_1 and C_1 the reactance of the latter will become capacitative and tend to neutralize that of l_1. Ultimately a frequency will be reached at which these reactances cancel each other out and the impedance in the anode circuit of the valve is zero. It will depend on the relative values of the various constants as to whether an increase or decrease of amplification is obtained above the resonant frequency of L_1 and C_1. We may regard this in a somewhat different way. The parallel resonance circuit L_1C_1 is shunted by r; consequently the smaller r is, the more heavily the resonant circuit is damped. On the other hand the resonant circuit l_1C_1 (assuming that the shunting effect of L_1 at this frequency is negligible) is in series with r; as a result, reducing the value of r will make this resonance less damped. If, therefore, we choose a transformer of given ratio and connect with a valve of either very high or very low internal resistance, bad resonance effects will be obtained. The curves recently exhibited give an indication of an exaggerated second resonance, due to the combined effects of an excessive magnetic leakage and a valve of too low internal resistance. With a valve of higher internal resistance a better curve would be obtained at high frequencies, but the "cut-off" at low frequencies would, of course, be more pronounced. The only satisfactory way of avoiding troublesome effects of this kind would appear to be the reduction of the magnetic leakage of the transformer to the utmost extent, and this step has been taken in the design of an intervalve transformer at present in course of production. In considering this leakage it must be borne in mind that the alternating flux densities in the core are so low that only the initial permeability of the iron must be taken as indicating the proportion of the total flux carried by the core. It is thus quite erroneous to assume unity coupling, even if the iron circuit is of excellent design. Transformers in which special attention is given to the reduction of magnetic leakage not only exhibit a greater freedom from distortion over wide ranges of frequency, both in respect of phase and amplitude, but also, owing to the better employment of the valve damping, are more stable in multi-stage amplifiers and will operate more reliably under the slightly varying conditions that are met with in commercial apparatus.

Mr. W. J. Rickets: To reproduce speech correctly it is necessary to give the illusion of a person seated in the studio or central producing room. It is not possible entirely to reproduce the effect because, although it has been proposed, it is exceedingly difficult to produce a stereoscopic or stereophonic effect. It is, however, probably not impossible ultimately to produce sounds of the same quality and intensity as those impinging on the microphone or similar device at the studio or the transmitting station. In all loud-speakers and amplifiers very considerable phase differences as regards components of various frequencies are certainly introduced, and it is yet possible to obtain quite fair results. The ear appears to act as a sort of Frahm frequency meter. If transients were applied to a frequency meter many of the reeds of the meter would probably respond to the sudden jar, whereas if a sustained compound wave is applied it will indicate the particular frequencies that are present. In the same way the ear will probably respond to steady-value sounds which are applied, and all frequencies present will be appreciated irrespective of the phase relationship. It is probable that many consonantal sounds are indicated by the envelopes of the vibratory curves, and not so much by the frequencies that are present. In improved loud-speaker and audio-frequency apparatus the system should respond fairly quickly to any transient changes which are produced. Probably the varying sensibility of the ear to sounds of varying frequencies and amplitudes is the cause of the phenomenon of apparent distortion which can be noticed in the near vicinity of a loud-speaker. The loud-speaker may sound perfectly clear when one faces the front of the trumpet, but, if one moves round laterally, apparently considerable distortions appear. That is probably an effect due to the varying energy radiation along different radii and to the varying sensibility of the ear to the components which are projected. One thing necessary in the production of real naturalness on a large scale is so to arrange the loud-speakers that at any point a person listening shall hear sounds proceeding from one focus. At some demonstrations sounds can reach the listener from two loud-speakers, and by acoustic interference very peculiar effects may be produced. If a large loud-speaker or several loud-speakers are located at one point, probably the sound waves proceeding outward are more or less spherical. The sound which reaches the listener is of one phase, but if more than one loud-speaker is used and the sources of sound are separated it is almost inevitable that some of the component waves arriving from one or other of the loud-speakers are considerably out of phase. This may occur when the individual loud-speakers are giving quite good results. The loud-speaker is sometimes blamed as being a very unsatisfactory device. It is certainly very inefficient from the energy point of view, but when it is considered that all loud-speakers are in effect a multi-frequency single-phase motor coupled to an air pump, which has to operate on current of frequencies varying from about 50 or 60 up to 10 000 per second, and voltages varying in somewhat the same ratio, it is really very wonderful that the results obtained from loud-speakers attached to reasonably good amplifiers are as faithful as they are.

Dr. N. W. McLachlan (*communicated*): The paper is a useful epitome in general analytical form of current knowledge concerning the principal elements which cause distortion in a broadcasting system. There are two omissions, namely, (1) the valve transmitter and its associated circuits, and (2) night effect—including

fading—on distances of 100 miles and upwards. The principles governing faithful reproduction at the transmitter—or more accurately, faithful modulation of the carrier wave—are similar to those at the receiver. Some of these were cited in a lecture which I delivered before the South Midland Centre early last year,* in which the various distorting factors, except night effect, were treated in a simple manner. There are, broadly speaking, two modes of defining distortion: the first is on an artistic basis, whereas the second is on a scientific basis. From an artistic viewpoint, quality must be adjudicated by competent trained musicians or musical critics. The sense of quality in this instance is to a certain extent arbitrary, owing to variations in the aural perceptions of different individuals. From a scientific viewpoint reproduced sounds are undistorted when the fluctuations in air pressure at the microphone and at some suitably situated point in the reproducing room are identical. It might be difficult to fix the proper point, owing to the reaction of the walls, etc. This latter effect could be surmounted in the well-known manner by draping to secure acoustic damping. Strictly speaking, both definitions are inadequate, since the quality depends upon the relative positions of microphone and orchestra or singer. I endorse the author's comments on the distortion accompanying loud-speaker reproduction. The fact that moderate-intensity headphone reception is usually accepted as being of better quality than that of a loud-speaker is probably due to the absence of audible alien tones, since the sounds are relatively weak. On the other hand it would appear—owing to the inherent amplitude and frequency distortion of one's aural mechanism—that there must be aural distortion, since the sounds with telephones are very much weaker than the original. Moreover, it seems that distortion occurs with both loud-speakers and headphones, but the sounds from one are more acceptable than those from the other. It is stated that the reproducer should be arranged to yield the same intensity of sound as that at the studio. The question immediately arises: What point in the studio should be chosen? I expect that the microphone position is intended. Despite distortion due to the reduction in intensity, I think the author would prefer not to hear a military band at full strength in a room of average size. I have listened carefully to the larger types of loud-speaker yielding moderate acoustic intensities, taking care to avoid distortion in the valve circuits. Although accurate measurement is the only safe criterion, I feel that the reproduced version of instrumental music contains tones which are not present in the original. In making comparisons it is well to do so at intervals, because the ear requires a rest of several days to avoid a natural aptitude for becoming increasingly tolerant and optimistic. Assuming my alien-tone diagnosis to be correct, and that such tones do not exist in the modulatory apparatus at the transmitter, it is essential to look to one or more of the sources of asymmetry at the receiver or to impulsing at the reproducer. The various ways in which asymmetry is likely to occur are: (1) Deep modulation of the carrier wave, and the mutual effect of this and the curvature of the rectifier characteristic. The frequencies of the alien tones will depend upon the equation to the rectifier characteristic, and this is not always of parabolic form, which has been assumed. The author states that demodulation will follow a linear law with strong signals. This only holds, however, when the transmitter modulation is not too deep. (2) Operation of valves on the curved portions of their characteristics. In reality only a comparatively small proportion of a characteristic is sensibly linear, and with moderate amplitudes a certain degree of asymmetry is introduced, but this may be sufficiently small to be undetected by the average ear. (3) Improper adjustment of the valves, thus obtaining grid current. For moderately loud sounds, say for an average room, a grid bias of the order of − 18 volts or more is advisable, so that extraordinary maxima do not promote grid current. This means that the valve characteristic should be linear over a range of 36 volts on the grid, i.e. from − 36 to zero grid volts. (4) Hysteretic and saturation effects in iron-cored transformers and in certain types of loud-speaker. Owing to the presence of a polarizing current, the iron operates on a subsidiary and not on a main hysteresis loop. The value of the effective permeability is altering continuously, and its value is the slope of the loop at any instant, i.e. dB/dt. (5) Unbalanced type of reproducer or loud-speaker, in which the force-displacement curve is asymmetrical about the equilibrium position, for example the usual reed or diaphragm class of instrument (not the "Magnavox"). The Gaumont conical-coil type of loud-speaker is also asymmetrical, since the restoring forces on the coil are unequal for the to-and-fro directions of motion, owing to the mechanical construction. (6) Non-linearity of the force-displacement curve of the moving part of the reproducer for large amplitudes. The frequencies of the alien tones in the two latter cases depend upon the curvatures of the force-displacement curves. Lastly there is the influence of the free oscillations of the diaphragm and other parts of the reproducer capable of vibration. During a transient, the reproducing system, consisting of the loud-speaker and its component parts, is impulsed, and imposes its natural frequency and a train of overtones of enharmonic frequencies—with a circular diaphragm there is an exception when it is in two parts *—in varying degree, according to the increment of the transient. The effect of the main free oscillation of the diaphragm can, of course, be curtailed by introducing an acceptor circuit; also a certain degree of damping is exercised by the last valve, which is usually of low impedance. It is probable that the alien tones, to which reference has been made, were associated with causes (4) and (5), and with free oscillations of the loud-speaker assemblage. The faithful reproduction of transients is of

* (1) C. V. RAMAN and S. KUMAR: "Musical Drums with Harmonic Overtones," *Nature*, 1920, vol. 104, p. 500. In this paper a certain type of Indian drum whose overtones are integral multiples of the fundamental is treated. The drum consists of a central circular portion loaded with a special adhesive mixture containing finely divided metal, and an outer supporting ring. (2) R. N. GHOSH: "Musical Drums," *Physical Review*, 1922, vol. 20, ser. 2, p. 526. In this paper the loading of Indian drums is discussed, and it is shown that when the load varies inversely as the square of the distance from the centre, the overtones form a harmonic series, whereas inverse linear loading yields an enharmonic series.

paramount importance, since they form the essential characteristics of either speech or music. The difficulties in accurately reproducing pianoforte transients are well known to those who have studied the subject. The piano is analogous to a spark transmitter with its impulsive effects at the receiver, whereas the violin, 'cello or kindred instrument, during the steady state, is analogous to the carrier wave of a continuous-wave transmitter. In general the initial rates of rise of transients which occur with the violin, etc., are less rapid than those from a percussion instrument like the piano. There is, of course, pizzicato playing on the violin and the beating of drums or clanging of cymbals, also the chiming of large bells, which yield fairly severe transients. As stated in the paper, it is customary to suppose that the phases of the various tones are unimportant during the steady state. I wish to ask the author if this applies to a very complex sound from a full orchestra for all intensities from pianissimo to fortissimo. In treating the topic of transients analytically, he concludes that distortion problems can be regarded in the same class as those during the steady state, but this only applies provided there is no phase-shift. One would expect that with a heavily damped transient, the phases of the resulting spectrum of frequencies into which the transient can be resolved would be of importance in aural interpretation. In this respect the following example of tonality may be of interest: It is known to piano manufacturers that two instruments of similar construction are different in tone. This is said to be due —amongst other things—to the relative intensities of the fundamentals and their partials; also to the phase relationships of these frequencies.* If the latter statement is correct, it is probable that the phases of the component frequencies of a transient play their part in determining the quality of instrumental music and maybe that of speech. Reference is made here to the infinite series of frequencies—within the range of audibility—into which any transient can be resolved. The phases, as well as the amplitudes of the component frequencies, determine the wave-form of the transient. If the phases are of importance in aural interpretation, the relative phases of the air pressures at the studio must be identical with those at some point in the reproducing room. I should be glad if the author would state whether it is possible to secure zero phase-shift throughout a complete radio-telephonic system. It is fairly obvious that the usual type of low-frequency amplifier causes phase-shift. Another example of tonality was brought to my notice owing to the fracture of a copper-loaded string in my pianoforte. A new string was inserted, but beats could never be eliminated from the two strings. An examination of the new string showed that it was loaded with smaller wire than the old one. Although the unisons or fundamentals of the two strings could be tuned, the overtones gave beats, showing that in one or both strings the overtones were not integral multiples of the fundamental. Coming to the other side of the problem, where tones are eliminated in the reproduced version of music, the suppression of the higher tones due to an exalted degree of reaction can be readily demonstrated when reproducing the violin. The instrument then yields comparatively pure tones and simulates the flute, which is not rich in upper partials.

Mr. L. C. Pocock (*in reply*): Sir Richard Paget questions whether aperiodic phenomena are really involved in speech, since he finds that all the transitional sounds are essentially musical in character. I think that this is true; one might say that Nature abhors sudden changes, such as the elemental transient force that I have dealt with in Equations (4), (5) and (6), and it certainly seems that the only way of producing such a severe transient change is the detonation of a small cap or bomb; other sounds such as the drawing of a cork, which to an ear less acute than Sir Richard Paget's suggest mere noise, are highly damped periodic vibrations and the existence of definite pitch is readily observed when several such sounds are made in succession under conditions which give each one a different pitch. For clearness of thought it may be advisable to distinguish between tones which can be resolved into continuous pure tones, and those which are periodic only in the sense that the pressure and velocity are zero at equally spaced intervals of time. Both classes of disturbance may be grouped together under the title of "cisoidal oscillations" applied to them by G. A. Campbell.* It seems evident that as far as aural analysis goes there can be no sharp distinction between steady tones and periodic tones in which the amplitude is changing, for the rate of change of amplitude may be so small that a damped tone (e.g. that produced by a tuning fork) sounds pure; if the value of the damping at which overtones appear is at all critical it may reasonably be expected to be associated with the phenomenon of masking.† The sounds of a third class characterized by continuous change of time between successive pressure zeros characterize certain consonants and the clang of a bell ‡: these have no periodic structure whatever.

The point which I have tried to emphasize is that telephony has developed on a mathematical basis of steady-state vibrations, whereas every change of amplitude and frequency introduces foreign transient responses which depend entirely on the response of the system to the elementary transient dealt with in Equations (4) to (6).

I am obliged to Captain Cohen for pointing out an objection to the use of the term "traffic efficiency" for associating with the intelligibility of the transmission system the time taken to convey an idea. His alternative suggestion, however, appears open to the criticism that although it may not have been already appropriated for that purpose it certainly suggests the reciprocal of the wave-length constant (imaginary part of the propagation constant). I would therefore suggest some such term as "conversation efficiency" or "communication efficiency." I cannot agree that the monosyllables used in articulation-testing should be weighted according to the frequency of occurrence of the sounds in English;

* C. V. Raman: "Partial Tones of Bowed Strings," *Philosophical Magazine*, 1919, vol. 38, p. 573. In addition to the treatment of partial tones obtained by bowing a string at nodal and other points, the question of the phases of these tones is discussed.

* *Journal of the American Institute of Electrical Engineers*, 1911, vol. 30, p. 873.

† See Bibliography (2).

‡ *Ibid.* (21b).

to do this is to attempt to measure something between intelligibility and articulation as I have defined it. As a fundamental principle it is better that experimental observations should aim at the determination of the inherent properties of the matter investigated, with the exclusion of as many incidental variables as possible, in order that the results may possess a broad application. In this case, articulation is the property of the system to reproduce sounds closely similar to the original sounds; if all pronounceable sounds are used with equal weighting the tests measure this property in its simplest form. Measurements thus made have the widest possible significance, and the conversion of articulation percentages to intelligibility percentages can be made for any language from the same basic results. This point of view is worth consideration in connection with the rapid strides now being made towards a higher development of international telephony.

In reference to Mr. Turner's allusions to the nature of vowel sounds, it will probably be agreed that a complete explanation has yet to be presented. The fixed-pitch theory of vowels is not sufficient to enable vowels to be constructed; it is noteworthy that synthetic vowels have been produced only by means of vibrations rich in overtones (probably enharmonic) and it seems to me that the reinforced enharmonic partials on each side of the characteristic vowel tones are essential to vowel character, but whether these owe their origin to independent puffs or not does not appear to me to have been conclusively proved. The meaning of my reference to phase distortion in a transient is as follows: There are two ways of regarding a Fourier integral: (1) as a mere indentity, a function which states the value of any arbitrarily selected ordinate, and (2) as a continuous spectrum of simultaneously existing frequencies. The former view is brought out in Heaviside's treatment * and the latter in Byerley's "Fourier Series and Spherical Harmonics." If the Fourier integral is regarded as a spectrum of frequencies each element has its appropriate phase which is determinable [see Bibliography (28) for an example], and it is to the initial phase of these partial waves that I refer.

The particular advantage of single side-band transmission referred to by Mr. Turner is mentioned briefly by R. V. L. Hartley.†

A very important criticism by Mr. Turner bears upon the relation between the perfection of transient reproduction and the perfection of steady-state reproduction. The difficulty in establishing any relation lies in the fact that only a moderately successful judgment of the faithfulness of reproduction can be made from an inspection of the response-frequency characteristic; if the curve lies evenly between fairly narrow limits over a sufficiently wide range of frequency, reproduction will be good, and if it has excessive humps and hollows, or is not approximately constant over a sufficient range of frequency, the reproduction will be poor; but of two curves both showing frequency distortion it is not possible to say by inspection which is the better unless one obviously approximates to the good type and the other obviously falls in the other category. With the same degree of approximation it may be argued that an ideal response-frequency curve (constant for all frequencies) indicates that discontinuities, and therefore transients, will be accurately reproduced, while a bad response-frequency curve showing excessive humps and hollows indicates inferior transient reproduction characterized by parasitic oscillations depending upon the elements of the system. It is clear that the ideal characteristic for steady-state reproduction is the same as the ideal characteristic for transient reproduction, but any further comparison is rendered difficult by the absence of means of determining the effect upon aural interpretation of alterations in the shape of the response characteristic. It can, however, be shown that the duration of an *oscillatory* response to an impulsively applied force diminishes as the response characteristic grows flatter (the general shape of the curve, that is the frequencies at which maxima and minima occur, being kept unchanged). It is also possible to deduce from the work of J. R. Carson * that in a low-pass filter the response to an impulsive impressed force becomes less sluggish as the cut-off frequency is raised. In these cases, therefore, transient and steady-state reproduction improve concurrently.

Mr. Willans appears to attach considerable importance to the phase characteristics of transformers, because he adopts zero phase angle as the definition of resonance. There are various ways of defining resonance in parallel circuits† and care must be taken to adopt the appropriate definition when, as in transformers, the resistance term is important. In this case maximum current through L_1 of Mr. Willans's Fig. D is the appropriate definition of resonance, because the frequency at which this occurs will give a maximum on the frequency-response curve. When there is appreciable magnetic leakage, the resonance conditions of a circuit simplified even as in Fig. D are complicated and the zero phase frequency has not in general a critical significance. A careful analysis of the transformer equations will be found in the bibliography.‡ I should like to point out that a transformer should be designed to work between certain impedances and should be tested between those impedances; if a valve is used it should be the right valve and the already complicated theory of transformers need not therefore be further complicated by considering the effect of using wrong impedances.

Dr. McLachlan, referring to the aural distortion arising from reproduction at the wrong loudness level, suggests that such distortion is preferable to the hearing of a military band at full strength in a small room. The latter is not the meaning I intended to convey; the intensity of reproduction in a small room should not be the same as that of a band playing in the room, but rather the intensity at which the band is intended to be heard, for example, at a distance of 20 or 30 yards in an open park, and it is indirectly to produce open-air conditions that a studio should be heavily damped for the reproduction of band music. I am inclined to think that the phase of tones in the very complex sounds of a full orchestra is practically as unimportant as

‡ Item (46).

among two or three tones; the various instruments will never be all in phase as heard at a given point, nor will their overtones be in phase; if a large number of instruments were in phase on a single tone a secondary effect, viz. aural amplitude distortion, might occur simply on account of the unduly high intensity of the note, but the resulting increase in harmonic overtones would scarcely be important. According to D. C. Miller the total loudness of two distinct tones is independent of their relative phase, and this is reasonably consistent with the theory of the mechanism of hearing. I am glad to find that Dr. McLachlan agrees with me that phase distortion of the components of a transient are important, but when I say that the reproduction of transients is determined by the steady-state characteristics I include this effect for the reason that, in circuits capable of analytical treatment, the transient reproduction is wholly determined by the mutual factor, which in turn is uniquely determined by the frequency characteristic.

BENEVOLENT FUND.

26TH ANNUAL GENERAL MEETING, 8 MAY, 1924.

(Held in the Institution Lecture Theatre.)

Dr. Alexander Russell, F.R.S., President, took the chair at 5.30 p.m.

The notice convening the meeting was taken as read.

The minutes of the 25th Annual General Meeting held on the 31st May, 1923, were taken as read and were confirmed and signed.

The Report of the Committee of Management (see below) and the Statement of Accounts for the year 1923 (see page 542) were presented and, on the motion of the Chairman, seconded by Captain R. J. Wallis-Jones, were unanimously adopted.

Mr. J. Attfield, F.C.A., was unanimously re-elected Hon. Auditor.

The Chairman reported that the following Committee of Management had been appointed for 1924–25 :—

The President (*ex officio*)
Sir James Devonshire, K.B.E. } Representing
Captain J. M. Donaldson, M.C. } the Council;
Lieut.-Colonel K. Edgcumbe }
Mr. S. W. Melsom } Representing
Mr. W. R. Rawlings } the Council;
Mr. A. A. Campbell Swinton, F.R.S. }
Mr. S. Evershed } Representing
Captain R. J. Wallis-Jones } the
Mr. P. Rosling } Contributors;

and the Chairman of each Local Centre in Great Britain and Ireland.

The meeting then terminated.

[Prior to the Annual General Meeting an Extraordinary General Meeting of the Contributors to the Fund was held for the purpose of confirming the new Rules for the furtherance of the object of the Fund, which had been approved at an Extraordinary General Meeting held on the 27th March, 1924.]

REPORT OF THE COMMITTEE OF MANAGEMENT FOR THE YEAR 1923.

CAPITAL.

The Capital Account stood on 31st December, 1923, at £9 969 11s. 3d.

RECEIPTS.

The Income for 1923 from dividends, interest, and annual subscriptions was as follows :—

	£	s.	d.
Dividends on investments	470	12	9
Interest	9	3	9
311 annual subscriptions	231	1	6
	£710	18	0

In addition to the foregoing, the Fund benefited during the year by the following donations, many of which are non-recurring :—

	£	s.	d.
Electrical Engineers' Ball Committee	63	0	0
W. T. Henley's Telegraph Works, Ltd.	25	0	0
"Twenty-Five" Club	15	15	0
Messrs. Mullard and Graham	15	0	0
R. N. Vyvyan	14	10	0
Incorporated Municipal Electrical Association	10	10	0
F. R. Marsh	10	0	0
and 593 non-recurring donations of under £10	251	13	7
	£405	8	7

The accumulated balance of the Income and Expenditure Account amounted on 31st December, 1923, to

£1 622 17s. 6d., of which £1 002 19s. 3d. was invested, and £500 on deposit with the Institution bankers.

Donors and Subscribers.

Lists of the names of donors and subscribers during 1923 have been published in the *Journal*.

The Committee of Management desire to acknowledge their indebtedness to the donors and subscribers. As will be seen from the Accounts, the Expenditure practically equals the Income, and the Committee venture to urge upon members the pressing need for a generous support of the Fund. Apart from donations, the Committee will be grateful for annual subscriptions even of small amounts.

Grants.

Applications for assistance were made by, or on behalf of, 24 persons during 1923, and the Committee, after due consideration, made grants in 21 cases.

The total amount of the grants was £1 034 2s. 4d.

Wilde Fund.

The Capital Account stood on the 31st December, 1923, at £2 798 10s. 2d., of which £2 797 18s. 1d. is invested and brings in an annual income of £99 11s. 10d.

The balance standing to the credit of the Income Account, from which, under the Trust Deed, full Members only can benefit, on the same date was £182 9s. 7d.

No grant from this Fund was made during the year.

INSTITUTION NOTES.

International Conference on E.H.T. Supply Systems.

The Third Conference [see *Institution Notes*, 1923, vol. 61, pp. (5) and (9), and *Journal I.E.E.*, 1924, vol. 62, p. 132] will be held at Paris about the end of June, 1925. As in the case of the previous Conferences held in 1921 and 1923, discussions will take place in French and English on Reports presented by members of the Conference. Visits to works and excursions will also be arranged. Full particulars can be obtained from the General Secretary of the Conference, M. Tribot-Laspière, 25 Boulevard Malesherbes, Paris.

The Benevolent Fund.

The following is a list of the Donations received during the period 26 July–25 August, 1924:—

	£	s.	d.
Burgum, W. T. (Minas Geraes, Brazil)	1	0	0
Cox, P. H. (Cheltenham)		3	6
Grey, W. J. (Shanghai)	1	5	0
Griffin, J. G. (Hatfield)		10	6
Horowitz, H. (London)		5	0
Lacey, H. M. (London)	1	0	0
Lane, W. E. (London)		5	0
Naylor, W. S. (Manchester)	1	1	0
Oliphant, T. (Shanghai)		10	0
Thomas, A. O. (Sarawak)		6	0
Whitehorn, H. K. (Maidstone)		2	6

POWER CIRCUIT INTERFERENCE WITH TELEGRAPHS AND TELEPHONES.

By S. C. Bartholomew, Member.

(*Paper first received 28th January, and in final form 10th March,* 1924; *read before* The Institution 10*th April and before the* Mersey and North Wales (Liverpool) Centre 28*th April,* 1924.)

Summary.

The subject is of interest to the designer, the power engineer and the communication engineer, and the time appears to be ripe for a review of the situation. The paper is a general survey of the position, describing the features in the modern generation and distribution of electrical energy which are responsible for interference with telegraph and telephone circuits, emphasizing the importance of harmonics in this connection, and indicating some known remedies which may be applied to power plant at its source when trouble is experienced.

The improvements to be expected by the transposition of wires forming overhead power and telephone circuits are described and also the practical applications. The separating distance and length where power lines and communication circuits run parallel is next considered with reference to inductive effects from (*a*) the balanced voltages and currents, (*b*) the residual voltages and currents, and (*c*) the abnormal occurrences due to short-circuits, etc.

The balance of telephone circuits is then dealt with. Telephone circuits in this country are designed to be free from disturbance from telegraph circuits and telephone circuits carried on the same routes. It is considered that a balance which will ensure this is the most that can be expected in such a system as a public telephone service, and if disturbance from power circuits is experienced with such balanced conditions on the telephone circuits, then the injurious affection is excessive. Remedies which may be applied to telephone and telegraph circuits are described.

A review of the problem and general experience in this country is then given under the headings of tramways, railways (direct-current and single-phase), and electric light and power systems, with an account of certain remedies and a discussion of the lay-out of power systems as influencing interference. In the author's opinion the solution of the inductive problem is mainly one for the designer; the power engineer, the telephone engineer and the protective-gear engineer are also concerned in that order.

In an appendix Prof. E. W. Marchant describes a method of removing ripples from mercury-arc rectifiers.

Table of Contents.

Table of Contents—*continued.*

Introduction.

The object of the author in presenting this paper is to provide an opportunity for the different interests concerned to discuss the subject on a common platform, with a confident assurance that nothing but good can result from such a course. Mr. Frank Gill in his Inaugural Address* for the Session 1922–23 made a pointed reference to this matter, and the time appears to be opportune for ventilating a subject which is of importance to the designer and the power engineer as well as to the telegraph and telephone engineer. In passing it may be pointed out that a great part of the general public may be interested in the problem, especially by the effects on land lines used for wireless simultaneous broadcasting.

The greater telephone development and the different conditions as regards the generation and transmission of electricity in the United States have resulted in the problems associated with interference developing earlier, and apparently in a much more violent form, than in this country. This is very evident from the widespread interest in the subject in that country, which has culminated in the appointment of Joint Committees of the National Electric Light Association and Bell Telephone Systems on the physical relations between the electricity supply and signal systems. The National Main Committee consists of 56 members, and there are local committees covering districts and sub-committees on research, field investigations, etc.

* *Journal I.E.E.*, 1923, vol. 61, p. 1.

All those interested in the subject are indebted to the Railway Commission of the State of California for publishing the results of the exhaustive tests carried out by the Joint Committee on Inductive Interference appointed by that body. The technical and other reports are included in a publication of 1 200 pages which gives an indication of the thoroughness with which the investigations were carried out. The treatment of the subject from both the scientific and practical standpoints is of a very high order. It does not deal, however, with the electric traction side of the problem.

In this country we have not had the same widespread problems. The troubles have been more in the nature of isolated incidents, and the need for research on anything like the scale found necessary in America has not arisen. This can partly be explained by the fact that until the last few years there was little distribution of electrical energy by overhead lines, the development being almost wholly underground. Further, where high-pressure and extra-high-pressure lines have been erected, cross-country routes have been the rule, and in few cases are the routes parallel with and in close proximity to the main trunk lines of the Post Office which follow the public roads. In America, it is gathered, it is common practice for the power transmission lines to be erected on public roads, whilst the voltages employed appear to be generally higher than in this country where 33 kV is the highest in use at the moment, although a 66-kV line is under construction.

In presenting the paper the author asks for a certain amount of tolerance from the power engineer and designer for presenting some features of their work in an elementary manner, having in mind the telegraph and telephone engineer; and on the other hand he asks for consideration from the latter in regard to any explanations which may appear unnecessary but which may perhaps be helpful to the power engineer and designer.

It is not claimed that the matter presented is new or the treatment original. A great deal of the technical information is contained in standard textbooks and in papers contributed to various Institutions, but hitherto the salient points bearing on the subject have not been easily available to anyone desiring to make himself acquainted with them.

It is proposed to use the words "communication circuit" to cover both telephone and telegraph circuits, except in cases where the particular type of circuit requires special treatment, and as a preliminary it will be well to consider what is involved by each of those methods of communication.

The technical problem of telephony is concerned with:

(a) The transformation of the spoken word into electrical waves corresponding to it;

(b) The transmission of these electrical waves for perhaps hundreds of miles with the least possible distortion or loss of intensity and without the addition of foreign disturbances; and

(c) The reproduction at the receiving end of an audible sound which is a counterpart of the electrical wave and so of the originating spoken word.

The apparatus employed in this interplay of sound waves and electrical waves is extremely sensitive and delicate, dealing as it does with amounts of energy so small as to be outside the ordinary purview of the power engineer. A telephone receiver will respond to a fraction of a microwatt, i.e. that amount of power will transform an electrical wave into an audible sound wave.

Similarly, telegraph systems, although not so sensitive as telephones, have to reproduce faithfully the originating electric impulse as a signal at the receiving end of the circuit. Here again the apparatus is very delicate and the operating currents are small.

It is obvious from this that if the telephone and telegraphs are to carry out their functions in an efficient manner they must be kept free from foreign currents and voltages, which are relatively infinitesimal compared with the strong currents and voltages employed on power systems.

The working of power systems may have detrimental effects on telegraph and telephone systems by leakage or by induction.

Definition of leakage.—Leakage currents are those which stray from a power system and enter a communication circuit at an earth plate and leave it at another earth connection on the same circuit. Telegraph circuits are usually worked with an earth return, and such circuits are more likely to be affected by leakage from stray currents than are telephone circuits.

Stray currents may emanate from tramway or railway systems using an uninsulated return, or from faulty electric light and power circuits. The strength of a stray current depends upon the voltage between the two earth connections and the resistance in the circuit.

The communication-circuit apparatus may be made unreliable or useless according to the strength of the stray current in the circuit.

Definition of induction.—Inductive effects from power circuits may interfere with the working of telegraph circuits by mutilating the signals, and in the case of telephone circuits may affect the signalling arrangements associated with calling and clearing or, what is more common, disturb the speech on the circuit by producing noises.

Inductive interference with communication circuits may be caused either by the normal operation of the power circuits or by abnormal conditions resulting from short-circuits, switching operations, etc. Further, in certain circumstances, even though the working of the circuits may not be affected, conditions may be set up by induction producing such high potentials in the communication circuit that there is actual danger to life from shock or risk of damage to plant.

With the effects described there is also a danger of acoustic shock to anyone who might happen to be listening on a neighbouring telephone circuit at the time. As regards danger to life, it should not be taken that such conditions exist or have existed in this country.

Inductive interference may be produced by both overhead and underground power circuits, the former being the more usual. It is, of course, unnecessary to discuss here the general laws of the inductive effects of

electrostatic and electromagnetic fields associated with electric circuits, as, with the exception perhaps of electrolytic and heating work, they are associated with every useful application of electricity. The author thinks, however, that it will be helpful to recall briefly the principal features.

Electromagnetic induction.—The strength of a magnetic field round a conductor is directly proportional to the current. If the current is alternating there is a complete cycle of change in the field with every cycle of current. The rate of change of the field intensity is proportional to the frequency, being influenced to a certain extent by the wave-shape. The density of the magnetic field is greatest near the conductor, and at other points varies inversely as the distance from the centre of the conductor. The induced voltage produced by a power line upon a neighbouring wire running parallel with it will depend upon the field strength (which is proportional to the current), the frequency, the length of parallelism and the separating distance.

Electrostatic induction.—Where wires are suspended in the air and insulated from each other and the earth, they may be regarded as two plates of a condenser. Each wire forms one side of the condenser, the earth being the other. Any charge or electromotive force applied to one wire will produce a difference of potential between that wire and the ground, which will affect the potential between the other wires and the ground. With every change of strength in the electromotive force, or with reversals such as are associated with alternating-current systems, the charges induced in the wires will vary accordingly. The electric charge on a wire varies directly with the applied voltage on the disturbing wire. The potential of this charge will depend upon the capacities of this wire to the disturbing wire and to earth. The charging current produced depends upon the value of this potential and on the capacities referred to. It follows from this that while the charging current and therefore the disturbance vary as the length of parallelism, the static potential induced is not affected by the length. The charging current varies also with the frequency. As the electrostatic induction on a conductor depends not only upon the capacity between the conductor and the disturbing wire but also upon the capacity between the conductor and earth, it follows that the presence of other wires and earthed objects in the neighbourhood affects the conditions in this respect.

The following is a comparison of the effects of the two fields:—

Electrostatic induction is proportional to the voltage of the power system but is independent of the current, whilst electromagnetic induction varies with the current in the power system but is unaffected by the voltage. Both electrostatic and electromagnetic effects are proportional to the frequency of the power system. Where power lines and communication circuits are in such proximity that inductive interference may be expected, this is usually referred to as an "exposure." The voltages produced by electrostatic induction are independent of the length of the exposure, whilst the electromagnetic effects are proportional to the length of the exposure. On the other hand, the amount of current flowing is in both cases approximately proportional to the length of the exposure, the current due to magnetic induction being the same at all parts of the circuit, which is not the case with that due to electrostatic induction.

A study of inductive interference in America, the principal work on which has been carried out by the Californian Railway Commission previously referred to, has led to the standardization of terms which are very convenient for describing the conditions associated with the problem. Power-circuit voltages and currents are classified under two general heads: (1) Balanced voltages and currents, and (2) residual voltages and currents, the former being those which are balanced with reference to the earth, whilst the latter are those which are unbalanced with respect to earth. At any instant of time, the algebraic sum of either the balanced currents or the balanced voltages in the several conductors is zero, whilst the algebraic sum of the total currents in the several conductors is the residual current, and the algebraic sum of the total voltages to earth is the residual voltage. As an illustration, a circuit consisting of an overhead trolley wire with an uninsulated rail return is wholly unbalanced with respect to the earth, the total voltage and current being residual. On the other hand, a double-wire circuit with no connection to earth and conductors arranged symmetrically with respect to the earth and other objects would have neither residual voltage nor current, as the voltage to earth on one side would be equal and opposite to that on the other. The same would apply to the current, and in that case both voltages and currents are wholly balanced.

Excepting the cases of traction systems employing earthed returns, it can be taken that the balanced voltages and currents are those which perform useful work in the circuit, whilst the residuals perform no useful part in the operation of the system and are, in fact, a measure of the failure to reach a perfect design in the apparatus and line, having in mind other interests.

The inductive effects of "residuals" are usually greater than those produced by "balanced" voltages and currents of equal magnitude. This is due to the fact that the residual components in the several conductors are all in phase and their inductive effects are cumulative, whilst the balanced components in the several conductors are out of phase. For instance, in the case of a three-phase system they are out of phase by 120°, and the resulting effect is materially influenced by the fact that the balanced components partially neutralize one another. In other words, the residual voltages and currents act like a single-phase circuit consisting of the line conductors in parallel, and an earth return. Inductive effects are therefore relatively great, as there is little neutralizing as is the case with balanced voltages and currents.

The causes of, and remedies for, these inductive effects will be indicated in the sections dealing with the different power systems, but it will not be out of place to point out here the salient differences between the two kinds of inductive effects.

Residual currents and voltages act as though the power system were a single-phase system with the line

conductors in parallel, and transpositions or crosses in the power lines do not reduce the inductive effects, except in so far as such a proceeding brings about a reduction in the magnitude of the residuals themselves; for instance, the line capacities may be brought into better balance thereby. On the other hand, transposing or revolving the wires forming a telephone circuit disturbed by such inductive effects will reduce the interference.

In the case of disturbance due to balanced currents and voltages, transposing or revolving both power lines and telephone wires will reduce the inductive effects.

Residual currents and voltages may be produced in the power system by the following conditions:—

(*a*) Unbalanced capacity and leakage between the various conductors and earth.

(*b*) Unbalanced loads between phases on a system in which the neutral point is earthed.

(*c*) The development of the third harmonic and its odd multiples in generators and transformers on systems using star connections with the neutral point earthed.

As regards (*a*), it is obvious that to reduce these the various conductors must be arranged uniformly, relative to earth or other bodies. Similarly, (*b*) is a matter which can be taken care of by a proper lay-out of the system and its loads.

In the case of (*c*), the remedy lies in the design of an alternator to generate voltages and currents as nearly as possible of sine wave-shape, and in the employment of transformers working with a small magnetizing current and so connected that the effects of hysteresis and changing inductance in disturbing the wave-shape of current and voltage curves are minimized. These and other measures for reducing the troubles under this heading are treated fully in the section dealing with harmonics.

It is important to note that the presence of large residual currents is possible only where there are earth connections on the power circuits, as if earth connections are not used the residual currents are limited to leakage currents and unbalanced charging currents. It should here be pointed out that in this country one earthed connection only is allowed on each distinct circuit, with the exception of electric railways and tramway systems using uninsulated rail returns, and in some special cases, such as the interconnection of large power systems referred to later.

The inductive effects of the different types of power circuits as used commercially will be dealt with under their respective heads: Traction (Railways and Tramways) and Electric Light and Power, but there are certain common features which affect the intensity of disturbance and which may be summarized as follows:—

Avoidance of close proximity between power wires and communication circuits.—This is the only sure way of preventing disturbance.

The use of apparatus (rotating machinery and transformers) designed or worked in such a way as to be free from harmonics.—The bulk of inductive interference with telephones is due to harmonics.

Restriction of residual voltages and currents.—These are particularly difficult to lessen in the case of traction systems using track returns. In the case of ordinary power systems, they can be lessened by line balance, by the avoidance of excessive magnetic density in transformers, by avoidance of certain transformer connections, and in some cases by the provision of supplementary devices which suppress or short-circuit the harmonic components. These effects are not reduced by transposing the power lines, except in so far as such transposing assists in equalizing the capacities of the conductors to earth.

Transposing the power line conductors.—This will reduce the possibility of inductive effects due to balanced voltages and currents.

Transposing the communication circuit conductors.—This will reduce the effects of residuals and balanced voltages and currents. It applies more particularly to telephone circuits which are, with very few exceptions, equipped with two conductors. Telegraph circuits, on the other hand, are, with few exceptions, one-conductor circuits with earth returns, and hence cannot be transposed.

Electrical balance of communication circuits.—This is important. A telephone circuit with its two conductors and apparatus perfectly balanced as regards series impedances, capacities and leakage to earth, and with both conductors exposed uniformly to the inductive effects, would be free from disturbance. Unfortunately, such ideal conditions cannot be obtained in practice. The varying weather, trees, the small boy with the stone, are factors which would defeat the most skilful balancing of the terminal apparatus, even if it were commercially possible to provide apparatus balanced to fulfil laboratory requirements. Circuits in underground cables are, of course, not included in the above list of disabilities.

Abnormal conditions on power systems.—These may cause disturbance of a very serious character in neighbouring communication circuits, even if they are not of long duration.

Noise in Telephone Circuits.

To appreciate the effect of small currents in producing noise in telephone circuits, it should be borne in mind that a small fraction of a microwatt of power at voice frequencies will produce an audible sound in a telephone receiver. The frequencies of voice currents in a telephone circuit are found to vary between 100 and 4 000 cycles per second. This last figure may seem a high one, but it should be borne in mind that we are dealing with the currents produced by the overtones as well as the fundamental pitch of the human voice (the pitch of male singing-voices usually falls within the frequencies 80 to 500 per second, and of female voices between 160 to 700 per second). The mean frequency of these varying currents is found to be 800 per second, which is the figure used for telephone transmission calculations.

Any extraneous currents in a telephone circuit having frequencies within the limits mentioned will therefore have deleterious effects on the efficiency of a circuit, and this is particularly the case with extraneous cur-

rents of frequencies between 800 and 1 200 cycles per second. Mr. Gill in his Inaugural Address* gave a curve illustrating the relative interfering effect of single-frequency currents in a telephone receiver. The matter is dealt with at length also in a paper† by H. S. Osborne. For reference, Mr. Gill's curve is reproduced in Fig. 1 of the present paper. It is based on a number of observations with various listeners. It is obvious that the interference effects of foreign currents are influenced very greatly by the frequency. The effects of an extraneous current at a frequency of 25 cycles per second is about 1/1 000th of that produced by current of the same strength at a frequency of 1 100 cycles per second. As bearing on the same point, Lord Rayleigh stated that the maximum sensitivity of the ear is reached at not less than 1 024 vibrations per second and possibly higher (see *Philosophical Magazine*, 1907, vol. 14, p. 602).

Power circuits do not usually operate at a higher fundamental frequency than 60 cycles per second, and

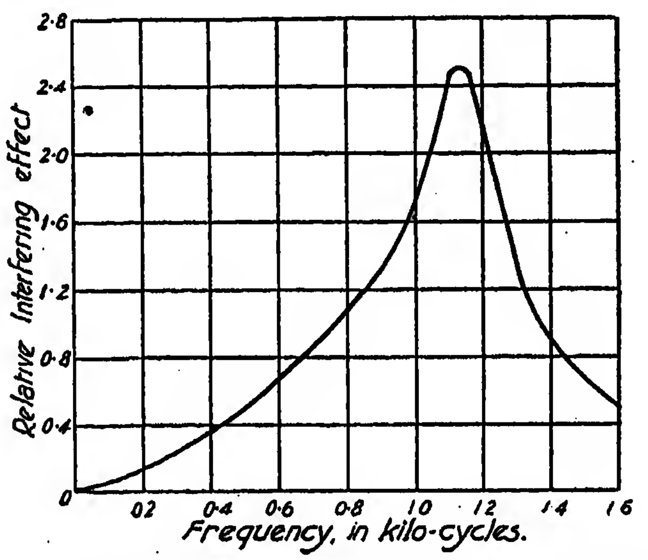

FIG. 1.—Relative interfering effect of single-frequency currents in a telephone receiver.

there is little interference with speech from the fundamental frequency. It is unfortunate, however, that there are usually present, due to various causes, harmonics on the fundamental voltage or current wave which are within the range of the human voice, and it is these harmonics which are the chief cause of interference with telephone circuits.

If the current and voltage waves of power systems were of pure sine wave-shape there would be little or no disturbance of speech in neighbouring telephone circuits, as, apart from the less sensitivity of the ear mentioned above, the telephone receiver itself is not so responsive to these low fundamental frequencies. It is possible, however, for the fundamental frequency to interfere with the telephone apparatus used for signalling, etc., and also with telegraph circuits.

The effect of the higher harmonics is to produce noises in the telephone receiver, which, even if they do not prevent good speech, are always annoying. In cases where the amount of noise is not sufficient to distract the attention of the telephone user, it may interfere with the effective use of the circuit by reducing intelligibility, and so decrease the value of the circuits.

It is possible to operate a telephone circuit which has a good margin of speech efficiency, even though there may be considerable interference, but it will be realized also that with a circuit working near the limits of commercial speech the introduction of a disturbing effect may be sufficient to render the circuit unworkable.

The telephone system of the British Post Office is laid out on a system of definite speech-transmission values, the unit fixing the values being "miles of standard cable," that is equivalent audibility to that received over a circuit of a definite length with standard apparatus for transmission and reception. The standard cable is one having conductors of 20 lb. per mile, and constants of capacity, inductance, etc., which need not be gone into here. Suffice it to say that measurements of audibility are made in terms of standard miles in the same way that pounds and yards are used for measurements of weight and distance. The allowances for audibility vary with the type of service given. Local service should not exceed 30 m.s.c. (miles of standard cable), whilst the general standard for long-distance communication between Great Britain and Ireland aims at a transmission audibility not exceeding 35 m.s.c. between any two subscribers. It should perhaps be observed that the greater the number of m.s.c., the less is the audibility; further, that although 35 m.s.c. is regarded as the standard of good commercial speech, expert telephone users can receive with much higher figures. It will be seen, therefore, that speech values are the basis on which line plant is provided. The saving of an additional mile of standard cable may involve very great cost, and similarly the addition of interfering noise reducing audibility may be represented by monetary loss. As an example, on a 600-lb. aerial trunk circuit 200 miles long, the loss of one mile of standard cable reduces the circuit to that of a 400-lb. circuit, and if a 400-lb. circuit would suffice, then 35 tons of copper would be saved.

The amount of noise that can be tolerated on a telephone circuit without undue interference with speech has not been specially investigated by the Post Office. In one or two cases of interference, measurements have been made of the amount of loss in miles of standard cable introduced by the inductive effects; this method involves comparative audibility measurements being made with the power circuit in operation and when shut down, but the arrangement is not satisfactory unless the interfering noise is considerable.

Two other methods, more suitable for general application, are, however, under investigation.

The apparatus for the first (see Fig. 2) consists of an alternator giving a sine-wave of known frequency and output, and of means for listening to the sound produced by known fractions of this. This known sound is balanced against the induction which it is desired to measure, by the two being rapidly interchanged by means of a commutator, the whole arrangement forming a kind of "flicker" sound meter. A similar kind of arrangement, using relays to change over, has been

* *Loc. cit.*
† "Review of Work of Sub-Committee on Wave-Shape Standard of the Standards Committee," *Transactions of the American Institute of Electrical Engineers*, 1919, vol. 38, p. 261.

used in America for comparing pure sounds of different pitch. A commutator has the advantage that the speed of change-over and duration of the different times of contact are more definite and can be easily reproduced. Precautions must be taken to screen the various parts of the apparatus against spurious induc-

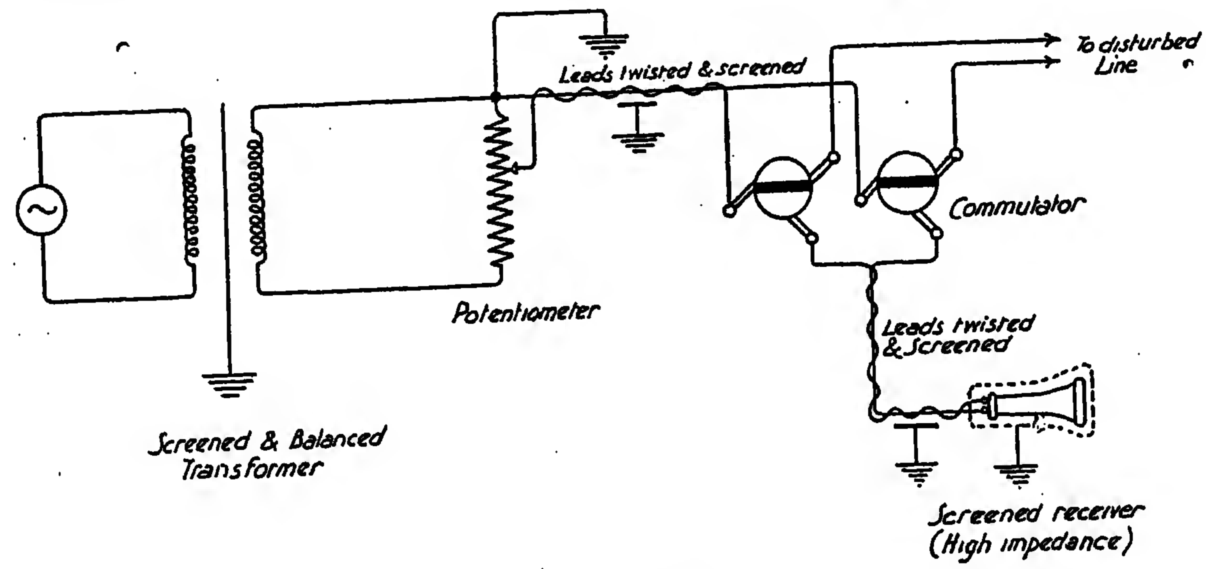

FIG. 2.—Circuit for quantitative measurement of line induction.

tion, and the impedance of the receiver used must be of such a high value as not to upset the line or disturbance under investigation. It is advisable to make tests with two different receivers, one being non-resonant and giving the absolute disturbance, and the other of

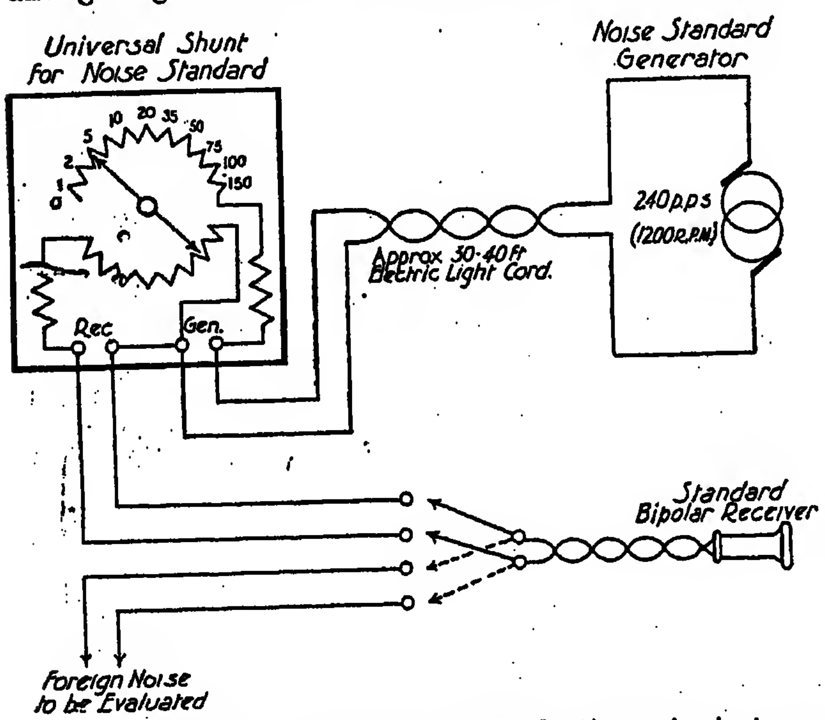

FIG. 3.—Noise-standard circuit for evaluating noise in terms of noise units.

normal type with a resonance point round about 1 000, which will give a measure of the effect that may be expected on a subscriber's instrument. This method enables the induction of practically any character of audible frequency to be directly compared with a standard, though arbitrary, sound, and hence a comparison may be made of the induction found at different times, in different places and of different character.

The second method consists in magnifying by an amplifier the induction up to any convenient value in a circuit containing a potentiometer, the current in which can be measured on any suitable a.c. milliammeter. The line induction is then compared directly with a fraction of the amplified current and can hence be given as a voltage. A great disadvantage of this method is that it is difficult to ensure that the current measured is due only to that producing audible induction. The use of "up" and "down" filters is necessary to cut out all but the audible range, and this involves additional complication. The voltage values obtained from different inductions will not be a definite measure of their relative powers of causing disturbance unless they are caused by currents of the same frequency and wave-form.

In America a standard noise-measuring circuit has been devised, and the arrangement is illustrated in Fig. 3. The method involves the comparison with a standard noise of the induced current in the telephone receiver, the magnitude of the standard noise being changed until the two noises, standard and induced, are judged by the observer to have the same detrimental effect on a telephone conversation. The generator which produces the standard noise is connected to a shunt box by means of which various amounts of standard current are shunted through a telephone receiver. The telephone receiver is connected alternately by means of a mercury switch to the standard noise shunt and to the line under test, and the magnitude of the standard noise is adjusted by means of the shunt until the point of equality is found.

The standard-noise generator is an electric generator of the inductor type, composed of a disc of non-magnetic material in which are inserted a number of soft iron pole-pieces and which revolves between the poles of a permanent magnet. Coils are wound on the poles of the magnet and, as the disc revolves, an alternating current is induced in the winding by the pulsations of the magnetism caused by the motion of the soft iron pole-pieces under the permanent magnet. The voltage of the generator and the resistance of the shunt are so adjusted that when the generator is operated at 240 cycles the calibrations on the shunt give directly

the effective value of the current through the telephone receiver in micro-amperes. In the standard apparatus this shunt is provided with steps up to 150 μA. It is stated that this amount is not sufficient in certain cases, and that as the variations in quality and pitch of the interfering note differ considerably from that of the standard, it is somewhat a matter of individual judgment as to the valuation of the standard noise, and the method cannot hope to be precise. Men who are accustomed to measuring noise, however, usually agree as to magnitude. It is this difficulty which it is hoped to avoid in the apparatus now under investigation. The author does not know the number of noise units which is considered unobjectionable in America, although it has there been suggested as a basis that, as regards important circuits of such length that the speech margin is small, the extraneously induced current in the telephone circuit should not exceed in noise-producing value the effect of 10 μA at a frequency of 240 cycles per second. On unimportant circuits and where there is a surplus of volume of transmission, as on short-distance circuits, current somewhat in excess of the above limit could be allowed. These proposals do not appear to have been agreed as acceptable, however, to the two interests concerned.

There are difficulties in the way of fixing a maximum allowable noise. Any public telephone circuit in this country is likely to be joined through to any other, wherever situated, and should it happen that the various circuits in the series making up the completed connection—local, junction, and trunks—has each its maximum noise, the cumulative effect might be disastrous. Each circuit taken alone might be tolerable, but in combination is unfit for public service.

Harmonics.

It is generally found in power systems that high-frequency components are present in the current and voltage waves. In the case of alternating-current systems these high-frequency components are usually a multiple of the fundamental frequency and are called harmonics. Similar components are often found in direct-current systems, and it is usual to refer to these also as harmonics. Harmonics perform no useful purpose in the operation of the power system and may, in fact, in certain circumstances have deleterious effects. Generally it can be taken that their removal is advisable in the interests of the power undertaking, apart from the effects that they produce by disturbing telephone circuits.

Harmonic currents and voltages are produced in various ways, and a brief account is given below of their principal causes and some known remedies. The author does not profess to cover the whole ground and must refer those who are more deeply interested to the fuller treatment given in many standard textbooks and papers, some of which are referred to in the bibliography.

In alternating-current systems the principal harmonics in generators are due either to slots or to the shape of the magnetic flux curve, and in the case of transformers to the relationship between the flux and the magnetizing current.

Slot harmonics are produced by practically all generators and motors and are the most frequent cause of disturbance in telephone systems. The conductors on the armatures of generators and motors are placed in slots on the surface of what is practically a revolving cylinder, the projections between the slots being known as teeth. It is the breaks in the surface of the iron at the slots which are the fundamental cause of the harmonics. In all types of generators and motors the greater part of the magnetic flux from the field poles to the armature will pass through the teeth, as there is a smaller air-gap at those points. The amount of the flux entering or leaving the teeth may be taken as being proportional to the toothed surface affected by any particular pole, and as the armature revolves there will be a corresponding change in the strength and in the position of the flux in the air-gap. This is illustrated in Fig. 4, which, in an exaggerated

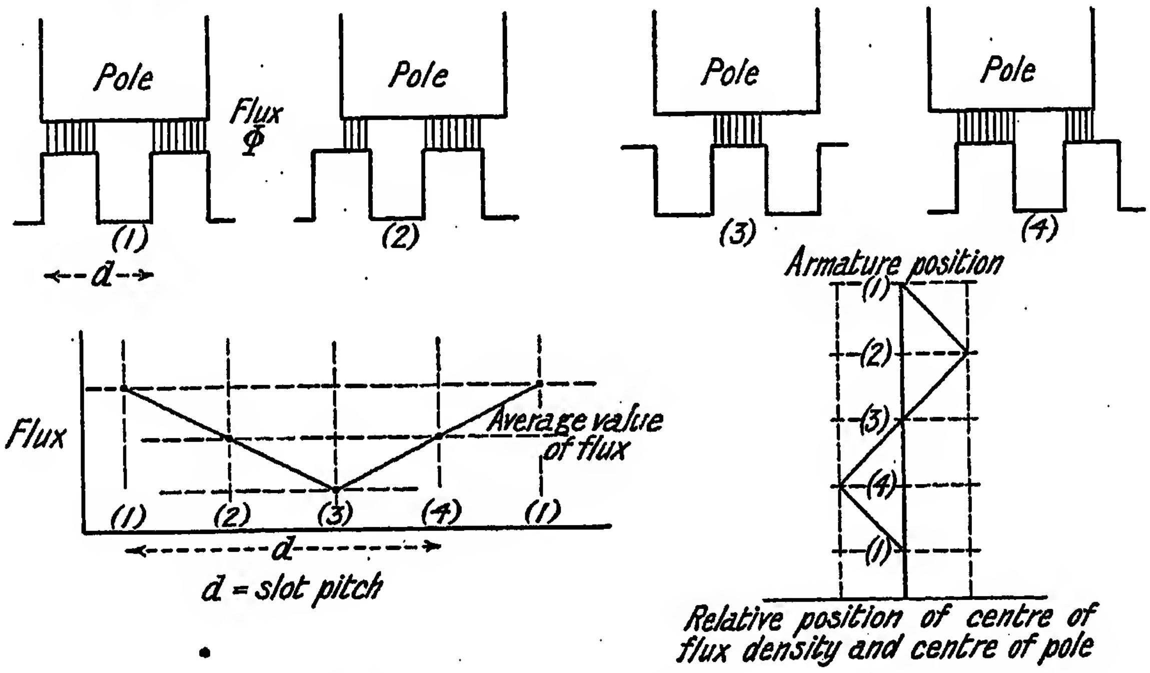

Fig. 4.—Flux variation in gap of generator.

form, for illustrative purposes, shows how the total flux will vary in the case of two teeth when passing through a distance equal to the pitch of a slot, i.e. the distance between the centres of two adjacent slots. It will be seen from this that the strength of the flux passing from pole to armature will vary in a periodic manner, depending upon the time taken by the armature in moving through one slot-pitch, as the armature will again be in position 1 after passing through another quarter of a slot-pitch beyond that shown in position 4. In other words, there is a periodic change in the total number of lines of force, and the point of maximum density moves backwards and forwards relative to the centre of the pole. The frequency of the change will, in effect, equal the number of teeth passing any given point in a second.

If N be the number of armature teeth per pole, S the number of poles, and R the number of revolutions per minute of the armature, then F, the frequency of the ripple $= N \times S \times R/60$. Now the fundamental frequency, P, of a machine is equal to $(R \times S)/(60 \times 2)$, and from this it is evident that $F = 2NP$, i.e. (the number of teeth per pair of poles) $\times$ (frequency of the current). As, however, the amplitude of the ripple is not constant, it cannot be truly represented as a single harmonic of the fundamental in that way.

The correct representation is the sum of two waves of frequency, viz. $P(2N + 1)$ and $P(2N - 1)$. In practice, the resulting ripple has a frequency $F = 2NP$, or $T \times R/60$, where T represents the total number of teeth on the armature.

These slot ripples are usually of such frequency as to be specially objectionable to telephone circuits, as they fall within the speech frequencies. Table 1 shows the ripples at the frequencies in common use and with different numbers of slots per pole.

The reduction of these slot harmonics may be accomplished in several ways, but it is of course preferable to take them into account when a machine is designed, so that they may be restricted to a negligible quantity. The main consideration is to avoid variations in the magnetic field in the air-gaps, and conditions may be ...d by arranging for the gradual increase in the ...owards the tips of the pole. There will then ...responding gradual change in the flux in any particular tooth as it passes into or out of the influence of the pole. Further improvements may be introduced by skewing the pole-tips so that the teeth come gradually into or out of the influence of the pole. This is usually effected by cutting the pole-tips diagonally (see Fig. 5).

Harmonics are not so prominent if large air-gaps are used or if the slots are nearly closed. Harmonics are also reduced by making fractional the number of slots per phase per pole, i.e. by arranging that the number of slots per phase is not a multiple of the number of poles. With those conditions, the position of the slots and teeth under one pole will be reversed under another pole, and in that case the slot harmonic voltages in the conductors are out of phase under the two poles and tend to neutralize each other.

TABLE 1.

Slots per pole	Order of harmonic		Frequency							
			25 Cycles		40 Cycles		50 Cycles		60 Cycles

Skewed Pole Tips

FIG. 5.

Harmonics due to flux.—In order to produce in the armature conductors an E.M.F. of sine wave-shape, it is necessary that the flux density should have a similar wave-shape, because as the conductors move at uniform speed the E.M.F. produced has the same wave-shape as the distribution of flux. It is possible to design machines with flux distribution at the poles approaching a sine wave-shape. This can be done in salient-pole machines by gradually increasing the air-gap from the centre to the tips. In non-salient-pole machines (in which the field is developed in an iron cylinder by

field windings placed in slots cut in the surface) it is possible so to distribute the field windings as to vary the strength of field to produce a flux corresponding approximately to a sine curve in shape. Fig. 6 illustrates the two types of pole and the shape of the flux distribution. In actual practice the method of distributing the conductors in the armature results in higher harmonics due to the flux density being neutralized to a great extent. If only one slot be taken for the armature conductor per phase, then the E.M.F. of the machine will have the characteristic of that conductor. The armature conductors per phase do not, however, occupy one slot only but are so arranged that the phase windings take up several adjacent slots. The result is that although the wave-shape of E.M.F. in each conductor is influenced in the same way by the distribution of the flux, the harmonics in the different conductors are not in phase and tend to neutralize one another. This is particularly the case with the higher harmonics.

"406. The deviation of wave-form from the sinusoidal is determined by superimposing upon the actual wave (as determined by oscillograph) the equivalent sine wave of equal length in such a manner as to give the least difference between ordinates, and then dividing the maximum difference between corresponding ordinates by the maximum value of the equivalent sine wave. A maximum deviation of the terminal voltage wave on open circuit from sinusoidal shape not exceeding 10 per cent is permissible except when otherwise specified."

The Sub-Committee on wave-shape standards of the Standards Committee of the American Institute have done a great deal of work in investigating the question. Both the British Committee and the American Committee had before them the evidence that harmonics between certain frequencies are particularly harmful

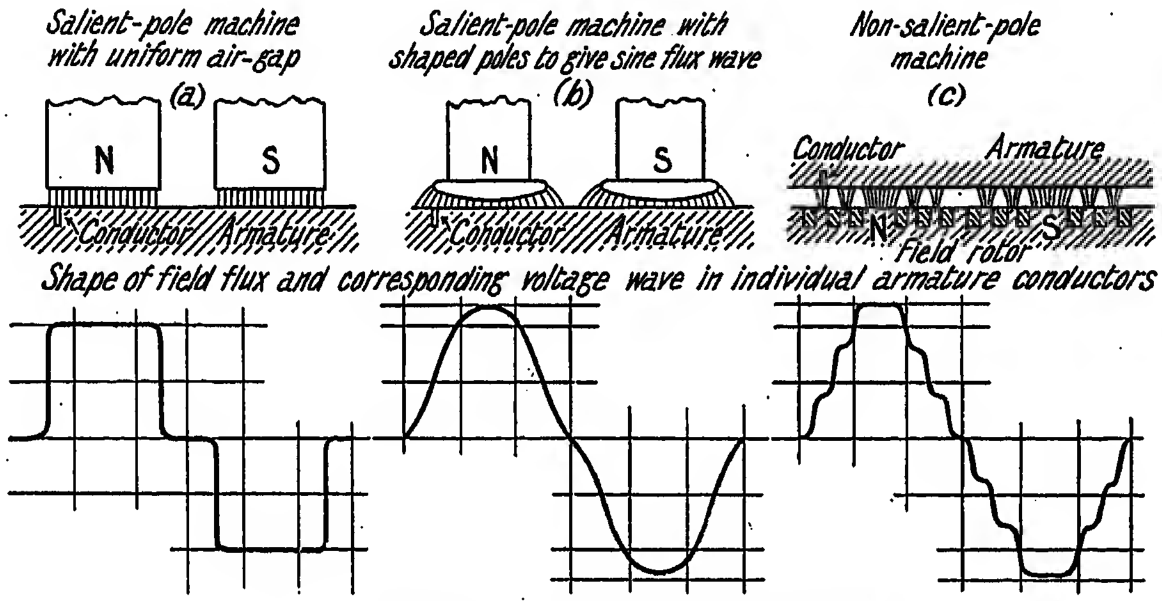

FIG. 6.—Flux distribution with different field poles.

The B.E.S.A. Standardization Committee on the wave-shape of alternators have considered that subject with reference, among other things, to the effects of irregularities in producing interference with telephone circuits. The present standard reads as follows, but the author understands that it is now being reconsidered and is in fact in the melting-pot :—

Wave-form of alternator.—The wave-form of an alternator on open circuit must approximate to a sine wave. In cases where wave-form is stated to be of importance at the time of ordering the machine, the maximum deviation of the actual wave from the equivalent sine wave when superimposed on it so as to give the least difference shall not exceed 10 per cent of the maximum ordinate of the sine wave; the equivalent sine wave being one having the same R.M.S. (root-mean-square) value and the same wave-length.

The Standardization Rules of the American Institute of Electrical Engineers on this matter read as follows :—

"405. The sine wave shall be considered as standard, except where deviation therefrom is inherent in the operation of the system of which the machine forms part.

so far as inductive interference is concerned. As a result of the American Committee's investigations, a telephone interference-factor meter has been devised which gives a direct reading showing how the wave-shape is loaded in this respect.*

The sensitiveness of the telephone receiver to the same current at different frequencies has been determined by observation. By multiplying each sensitiveness by frequency, a curve is obtained which shows the relative amount of sound interference caused by unit voltage of different frequencies in the power circuit. (It is of interest to note that Osborne states in his paper that "from the curve it is estimated that at 1 000 cycles the interference per volt is approximately 9 000 times that at 60 cycles, and 60 000 times that at 25 cycles.") The actual testing apparatus is based on the assumption that the interference effects of several harmonics can be obtained by taking the square root of the sum of the squares of the separate interfering effects. The testing circuit contains a filter network which gives readings according to the frequencies of the harmonics

* H. S. OSBORNE: *Transactions of the American Institute of Electrical Engineers*, 1919, vol. 38, p. 261.

present. It is stated in the same paper that approximate analyses of a number of cases show very clearly that, in general, the machines with high telephone interference factors are machines with large slot harmonics. It is believed to be the intention of both Committees to penalize wave-shapes which contain the frequencies mostly affecting telephones.

It should not be overlooked, however, that the third harmonic, although not in the range, is one very likely to cause disturbance to telegraphs. If a three-phase generator with earthed neutral point is feeding directly into a power line, i.e. one in which the voltage is not stepped up, it is nearly always the case that, as the conductors or load. Fig. 8 illustrates the conditions. If there is only the one earthed connection on the system the effect could be considered as a voltage effect only, except that a charging current alternates between the neutral point through the winding of the machine and through the capacity of the lines to earth. If the system is extensive this charging current may be very considerable, it being understood to be as much as 90 amperes in some cases in this country.

It should be pointed out that in addition to the third harmonic, odd multiples of the third may appear and act in the same way.

Two different methods of overcoming this trouble at

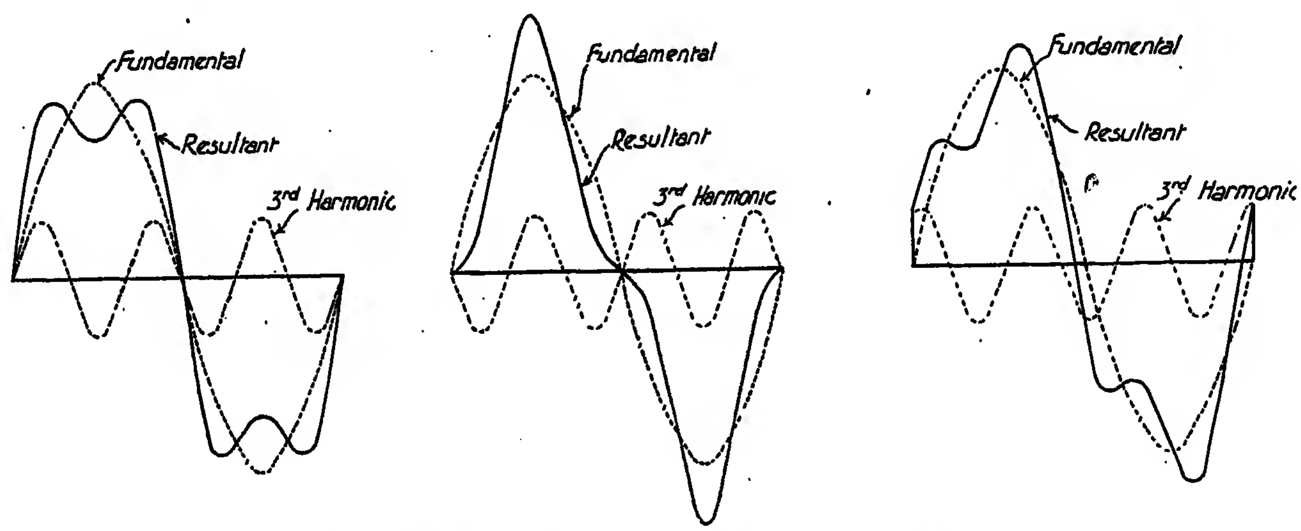

FIG. 7.—Resultant wave-shapes of fundamental and third harmonics.

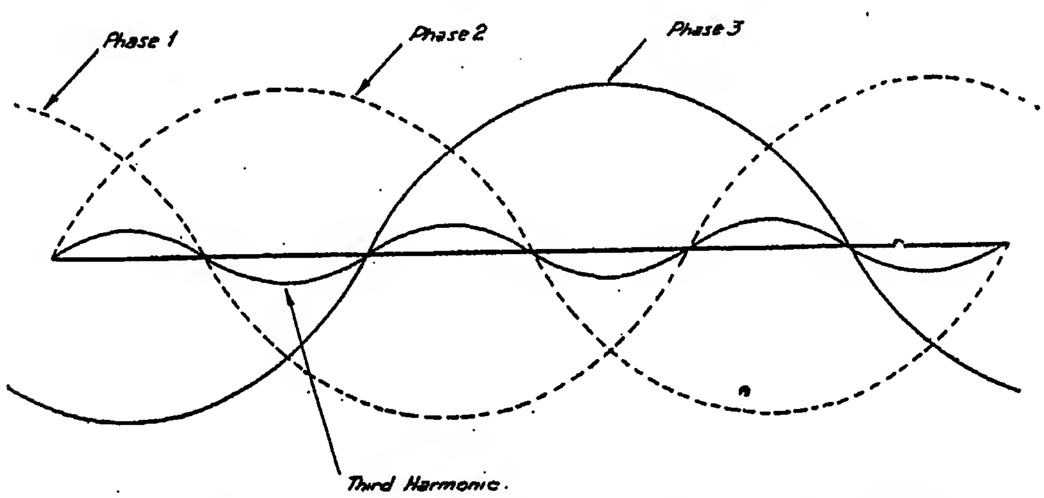

FIG. 8.—Fundamental waves and third harmonic in a three-phase system.

harmonics are in phase, a pronounced third harmonic shows itself as a heavy charging current oscillating between the earth connection and the three lines in parallel.

The effect of the third harmonic in distorting the wave-shape is dealt with in many textbooks and it may be considered superfluous to deal with it in detail here, but it has such an important bearing on interference from three-phase systems that the author would like to touch briefly upon it. Fig. 7 shows the three ways in which the fundamental and the third harmonic can combined, producing different resultant wave-shapes. each case, however, the third harmonic is in phase, s it completes one period in 120 degrees of the nental it does not appear between the three

the source have been suggested and, the author believes, have been successfully used on a small scale. The first was described by Prof. E. W. Marchant and T. H. Turney in a paper read before the British Association at Liverpool in September 1923. This method depends upon the placing of resonant shunts across the phases, the shunts being tuned to the harmonic that it is desired to suppress in the phase. Fig. 9 is taken from the paper.

The other method appears to have been applied by the British Thomson-Houston Co. to a machine causing trouble to telephone circuits and to lamps, and was described in correspondence in the *Electrician* and *Electrical Review* of the 2nd November, 1923, following on the published description of their device by Prof.

Marchant and Mr. Turney. This method is shown diagrammatically in Fig. 10 and depends for its effectiveness on the use of filters tuned to reject the frequency current which it is desired to suppress. This method has been employed in wireless reception for some years and is usually referred to as a "rejector" or "stopper" circuit.

In both cases the inductance and capacity are such as to produce resonance at the particular frequency,

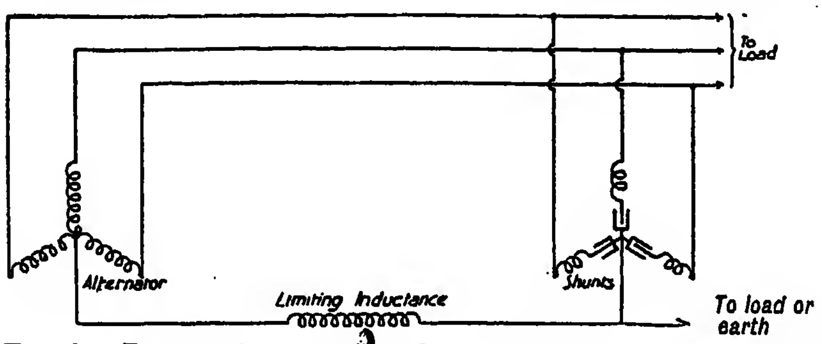

FIG. 9.—Resonant regulating shunts used with a three-phase machine.

but in the one application they are in series and so placed as to shunt the harmonic, whilst in the other they are in parallel and so placed as to prevent the circulation by producing a path of very high impedance to that frequency current.

Transformer harmonics.—With a transformer having an air core the flux and current have the same wave-

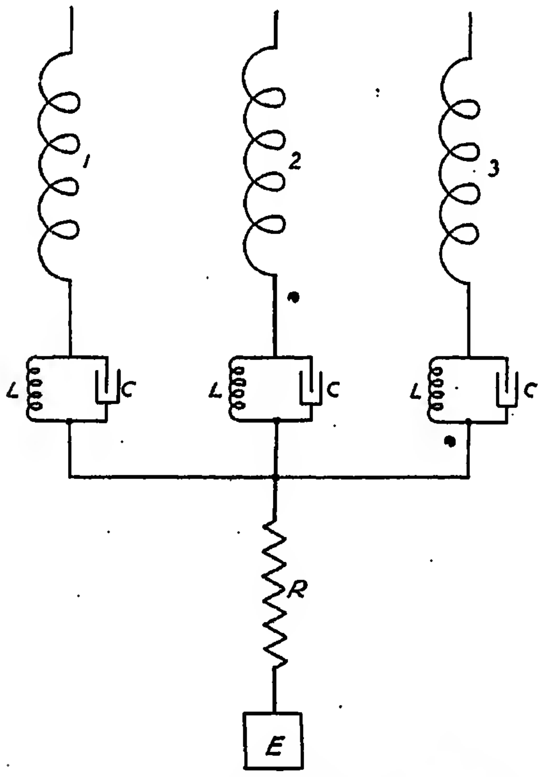

FIG. 10—Stopper circuit used with a three-phase machine.

shape, but that does not hold good where the core is of iron, which is usually the case in power systems. The relationship between flux and magnetizing current is $H \propto IL$, where H is the magnetizing flux, I the magnetizing current, and L the inductance. If L is constant for all values of current, the flux and the current will have the same wave-shape.

In the case of iron-core transformers, owing to the varying permeability, the inductance does not remain constant at all values of the magnetizing current, and the consequence is that the flux and the current cannot have the same wave-shape because the relation H/I must vary as direct changes. Further, if the usual hysteresis curve for iron is studied, it will be seen, that the flux is not proportionate to the current, there being a greater rate of increase at small current values than at large. Similarly, when current is decreasing, the

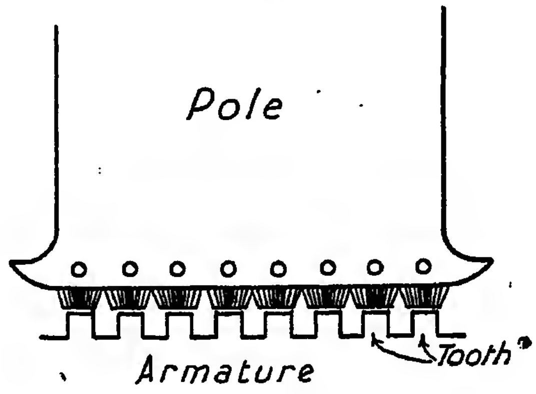

FIG. 11.—Density of field affected by damper bars.

flux is greater and changes at a slower rate than when the current is increasing.

The counter E.M.F. in a transformer has the same relative E.M.F. as the primary voltage at any instant of time, so that if the primary voltage is a sine wave, the counter E.M.F. and also the flux will be a sine wave; the current, however, will have some other shape and will contain harmonics. On the other hand, if the primary current is a sine wave the flux will not be a sine wave, and this will result in the counter E.M.F. not being a sine wave. In both cases the third and fifth harmonics are likely to be prominent.

As in the case of three-phase generators, the presence of the third-harmonic components or multiples thereof may be the cause of residual voltages and currents in

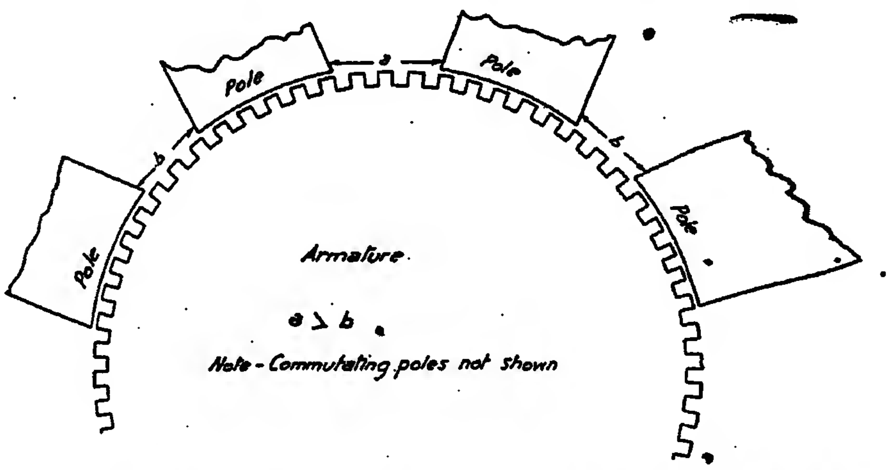

FIG 12.—Method of reducing ripples by shifting alternate poles half a slot-pitch.

the power line. The harmful effects can be modified and reduced by the type of connection used on the transformer and by limiting the exciting current. Star-connected banks with the neutral point earthed will result in voltage harmonics of three times the fundamental frequency and its odd multiples appearing between the lines and the neutral point, as the triple harmonics are in phase. If one side of the transformer is delta-connected, this provides a shunt path for the

triple-harmonic exciting current, and these harmonics reduce the residuals on the earthed star-connected side. The provision of a tertiary delta winding on a star-star connected bank of transformers will act in the same way. The general effects of the different combinations and connections are referred to later in the section dealing with electric light and power systems.

The magnetic density at which transformers are worked is a most important feature in the production of harmonics, as if the exciting current is large the effect is to develop large higher harmonics, i.e. to produce a flat wave. The reduction in the maximum magnetic density can be accomplished by lowering the impressed voltage per turn. Attention can perhaps be drawn here to the Californian Commission's General Order No. 52 on this point, which reads : "Transformer connections. In order that the wave shape of voltage and current may be distorted as little as possible by transformers, all connections on Class H power circuits shall have an exciting current as low as is consistent with good practice, which current shall not at rated voltage exceed 10 per cent of the full current. Except that for transformers without neutral ground connections on the line side, the exciting current at rated voltage need not be less than 0·2 ampere."

Class H power circuits are those having 5 000 volts or more between any two conductors, or 2 900 volts or more between any conductor and earth.

Core-type transformers are to be preferred to shell-type and single-phase units, as in the former the triple-harmonic exciting currents are to a certain extent suppressed by the mutual interaction of the cores, and the construction is such that the triple-frequency flux component has a very high resistance, the path being partly through the air or oil in the transformer.

The subject has formed the matter of many valuable papers, references to which are given in the bibliography, and the author is conscious that his description of the phenomena must accordingly appear sketchy.

Harmonics in direct-current systems.—As previously stated, harmonics are found in direct-current as well as in alternating-current systems. In the case of direct current, the ripples are usually slot harmonics and are produced in the same way as in alternating-current generators. There is, however, the difference that the slot harmonic in the case of direct current is not the combination of two harmonics. The amplitude of the harmonic is constant and its frequency is equal to the number of slots which pass a given point per second, e.g. in the case of an armature with 120 slots and running at 500 revolutions per minute the frequency of a slot harmonic will be 120 × 500/60 = 1 000.

Harmonics or ripples may be caused also by commutation, i.e. by changes in the current as the segments pass under the brush. The frequency of the ripple will be equal to the number of segments which pass a brush per second.

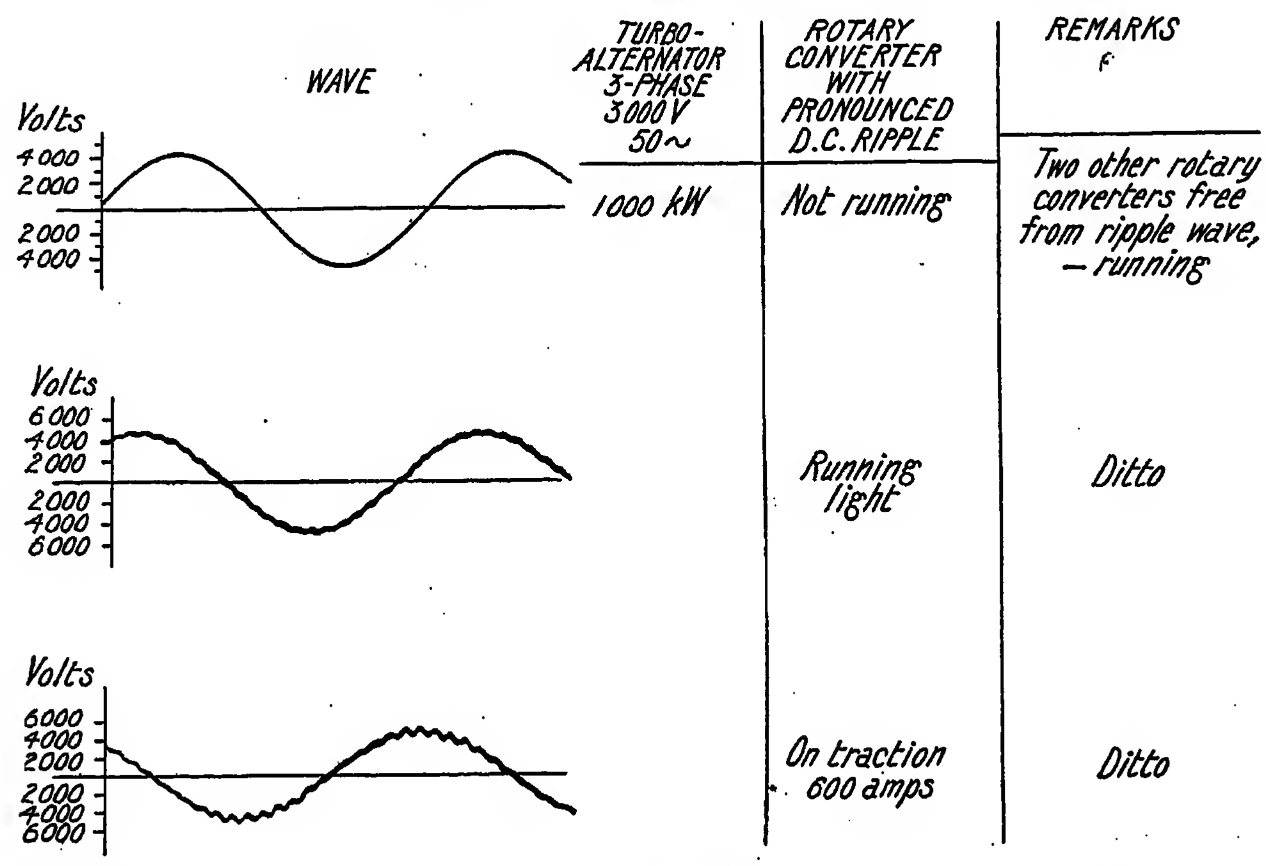

FIG. 13 (*a*).—Oscillograms showing reactive effect on a.c. wave (three-phase, high-tension) by rotary-converter d.c. ripples.

Rotary converters.—Of recent years a great deal of trouble has been caused by harmonics produced by rotary converters, as they are now commonly used for supplying direct current to traction systems where the power system is usually unbalanced and where the residual voltages and currents are considerable. As is well known, in this type of machine alternating current is collected by slip-rings on one side of the armature and taken to the commutator on the other side of the armature, where it is collected from the brushes as direct current. Slot harmonics are produced in the way already described, and in modern machines these have been found to be very disturbing to neighbouring telephone circuits. The speed of machines is usually such as to produce harmonic frequencies likely to

disturb speech. It has also been found that the slot harmonics may be greatly accentuated by the arrangement of the damper bars in the pole-shoes. The number of these bars varies in different makes of machine, and in certain types where severe interference has occurred the distance between the damper bars has been found to be equal to the pitch of the slots (see Fig. 11). It is thought that the damper bars cause changes in the density of the flux or tufting of the field in their neighbourhood, and, as the pitch or distance between

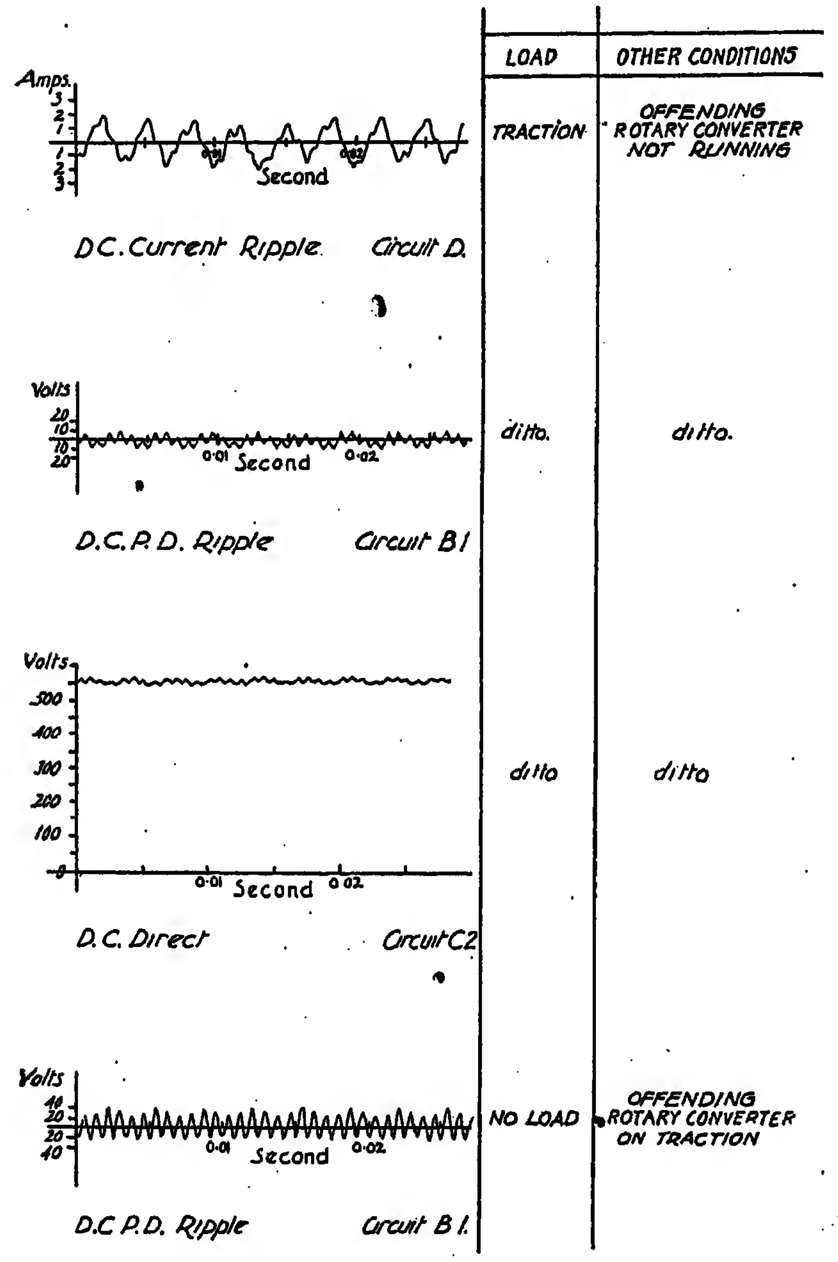

Fig. 13 (*b*).—Oscillograms showing d.c. ripples on other rotary converters in same station.

the slots is equal to the distance between the tufts, there is simultaneous cutting of the denser parts of the field by all the conductors of the armature and the amplitude of the harmonic is consequently increased. One of the remedies is to shift alternate pole-shoes or poles half a slot-pitch, or each pole-shoe or pole a quarter of a slot-pitch, one in one direction and the next in the opposite direction. In either case there will then be alternate short and long gaps between adjacent pole-shoes, and, as the conductors will not be affected simultaneously by the tufts, the harmonics will be out of phase and the ripple will be largely wiped out (see Fig. 12).

It may be of interest to show here the improvements effected by alterations to machines which had been found to offend in this respect, in this case by altering the spacing between pole-shoes. The interference was caused by a tramway system, the direct current for which was obtained from rotary converters run from a three-phase 3 000-volt 50-period supply. There were three rotary converters, two by the same maker and of 600 kW and 300 kW respectively, and the third, by another maker, of 1 000 kW. The disturbance was found to be due to the latter machine only. Oscillograph records were taken and it was seen that there were ripples superposed upon the direct current. These ripples were of two frequencies, 1 200 and 300 per second, and of 30 and 40 volts R.M.S.; the 1 200-frequency ripple caused serious interference with the telephone service. Among other things the oscillograms showed that the main a.c. wave was free from objectionable ripples except when the 1 000 kW rotary converter was in use, indicating that the ripple originated with the converter and reacted on the a.c. side. Figs. 13 (*a*), (*b*), (*c*) and (*d*) are copies of selected oscillograms taken before the machine was altered, followed by similar ones taken after the alterations to the machine. The alterations had the effect of reducing the value of the ripples to about 5 volts R.M.S., the frequency being increased to over 2 000 per second and the result being that the interference was rendered inappreciable.

Similar improvements have been effected in other towns and it should be observed that this trouble has not been confined to one make of machine. In one instance where the trouble was thought to be uninfluenced by the spacing of the damper bars it was found that to shift alternate pole-shoes was more effective than to skew the pole-tips.

The oscillograms reproduced in Fig. 14 are of interest as showing the results when machines of the same type are worked in parallel, some having been altered and the others unaltered. In the figure, converters 1 and 4 have been altered by shifting the poles, 2 and 3 being as originally designed. It will be seen that the unaltered machines dominate the effects and that there is a marked change when the altered machines are run singly and in parallel.

M. B. Field in a paper on "The Study of Phenomena of Resonance in Electric Circuits by the aid of Oscillograms," read before the Institution in 1903,* showed that in the cases he was investigating the ripples originated in the generator, i.e. the high-pressure a.c. side, and not in the rotary converter. This does not appear to be the case in most instances, but it was definitely proved in one investigation by the Post Office that the sixth harmonic, which was present with the converter working normally, disappeared when the machine was driven from the starting motor. This is shown in the oscillograms in Fig. 15.

The subject of harmonics or ripples in rotary converters is very fully dealt with in F. P. Whittaker's paper on "Rotary Converters, with special reference to Railway Electrification," read before the Institution in 1922.† The paper is particularly interesting as

* *Journal I.E.E.*, 1903, vol. 32, p. 347.
† *Ibid.*, 1922, vol. 60, p. 501.

showing that in certain cases the sixth harmonic may originate in the supply side of the system.

It appears that this may be due to the presence of the fifth and seventh harmonics in the a.c. supply for the following reason: If the converter is worked with six phases, then the third harmonic on the supply side will have no effect; but if there is a fifth harmonic to the d.c. brushes, and therefore it induces at the d.c. brushes an E.M.F. of sixth frequency.

The seventh harmonic, however, rotates in the same direction as the fundamental and also therefore produces a sixth harmonic at the brushes. Similarly the 11th and 13th harmonics produce the 12th harmonic.

Mercury-arc rectifiers.—The mercury-arc rectifier

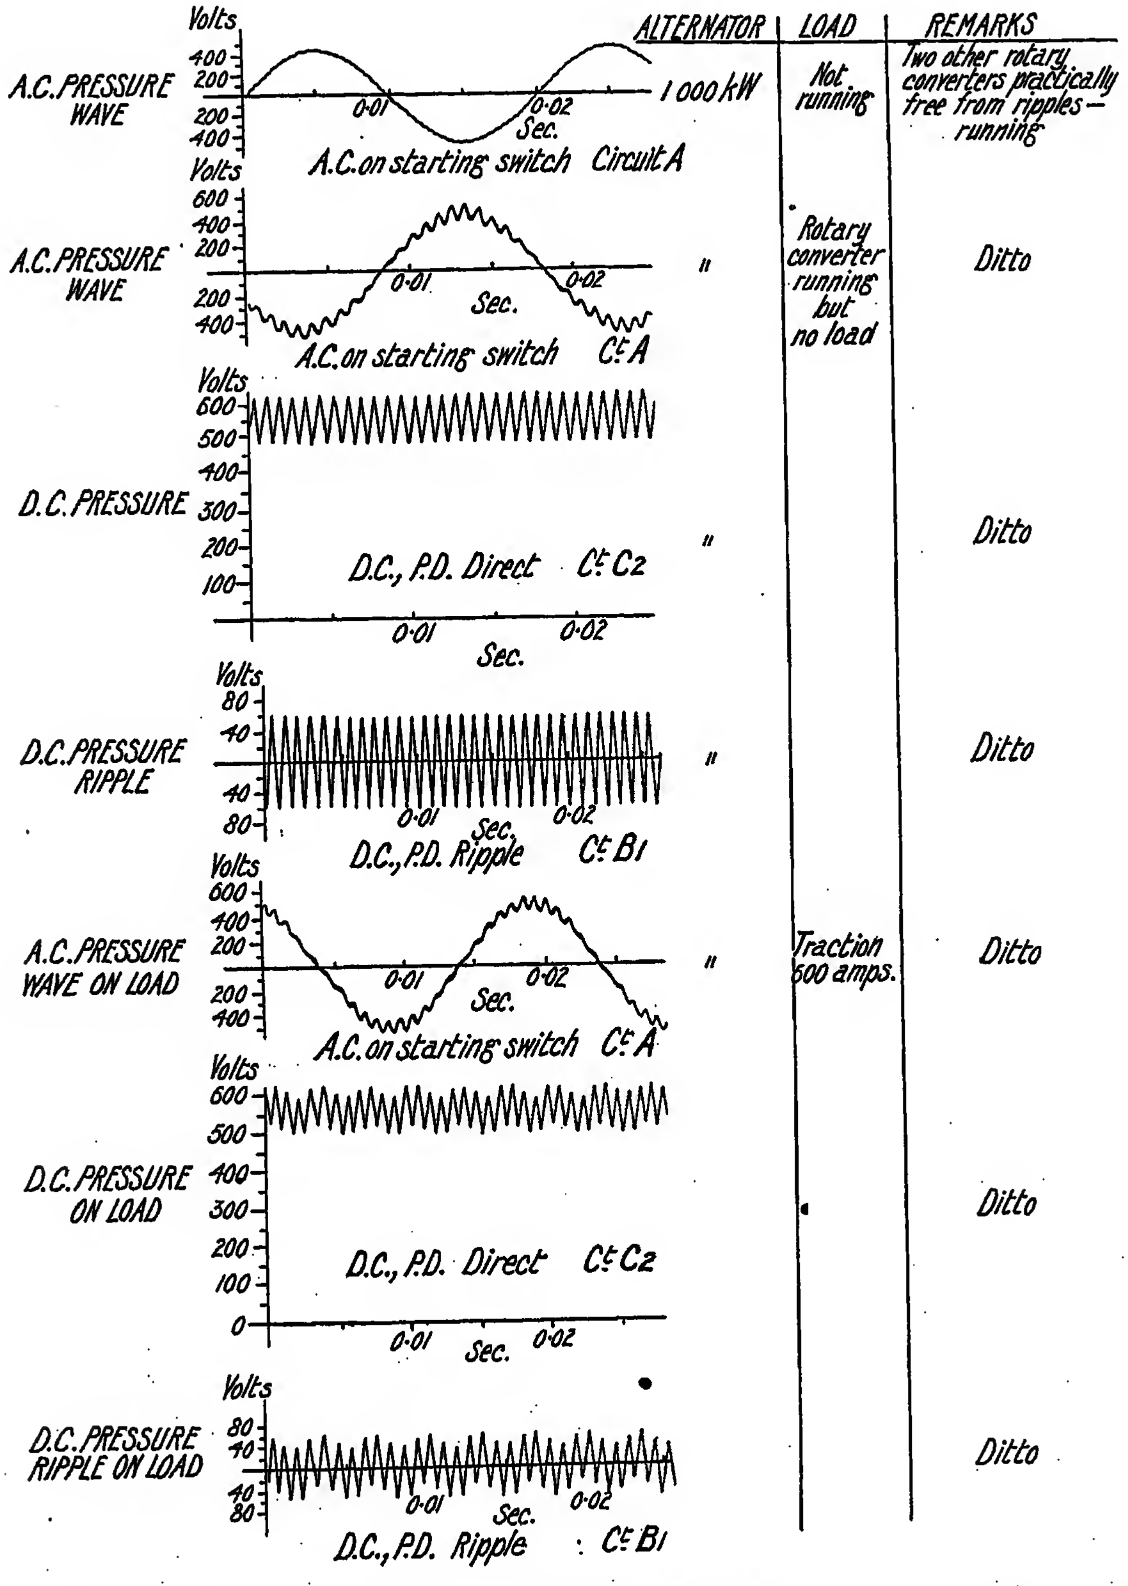

FIG. 13 (*c*).—Oscillograms showing rotary-converter d.c. ripples and reactive effects on a.c. wave at slip-rings of converter.

present this will flow, as the transformer and converter form a closed circuit. These currents will then form a rotating field of five times the normal synchronous speed relative to the armature, the rotation, however, being in an opposite direction. Since the rotating field of the fifth frequency rotates with five times the normal synchronous speed relatively to the armature, it must rotate with six times the synchronous speed relatively appears to have entered the field as a serious rival to the rotary converter for the conversion of alternating into direct current. There is therefore a piquant interest in any information which will compare the two in the matter of inductive effects. The author does not know any cases where the rectifier is being used for traction work which would be a severe test in this respect, but there are many places where it is

used for lighting, etc. One would expect rectifiers of this character to produce harmonics, and this has proved to be the case. Telephone interference has been caused and the author is fortunate in having had placed at his disposal an account of the successful methods adopted to overcome the trouble. Prof. E. W. Marchant was called in to advise on the case in question, and his description of the steps taken is given in an appendix.

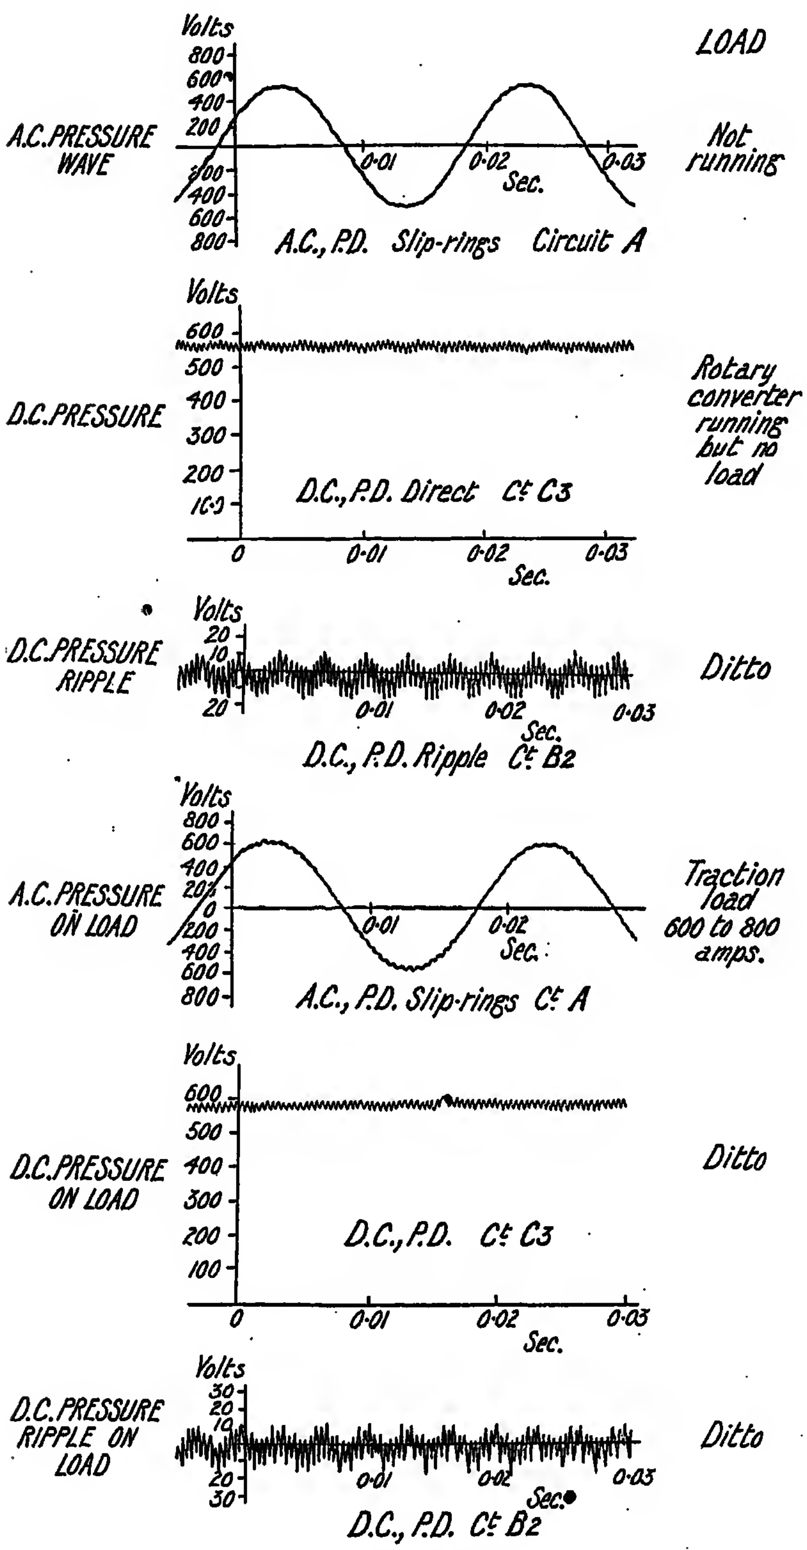

Fig. 13 (*d*).—Oscillograms showing effect of altered rotary converter.

Transpositions.

The voltages produced in a telephone circuit by the electric and magnetic fields may be separated into two effects, usually referred to as transverse and longitudinal induction. The transverse induction is that produced between the two sides of the circuit, whilst the longitudinal induction is that produced between the two sides of the circuit and earth, or along the circuit. The induced voltages due to the former effect will cause currents to circulate through the terminal apparatus, whilst the latter may result in currents through the apparatus if there is a difference in the impedances and capacities to earth of the two sides of the circuit.

The author may perhaps be pardoned for indicating in its simplest form the effects of the electric and magnetic fields on a neighbouring telephone circuit, and the benefits to be obtained by transposing the latter. The simultaneous occurrence of electric and magnetic induction is the normal result of the proximity of power lines and communication circuits. Fig. 16 shows a non-transposed telephone circuit and a disturbing power line. The effect of one wire only of a power circuit is considered. The (*a*) wire of the telephone circuit, being nearer than the (*b*) wire, has a higher induced potential due to the electric field and at the same time a larger E.M.F. from the magnetic field. Assuming that the potential of the wire of the disturbing circuit is increasing in the positive sense as shown, and the current increasing in the direction shown by the arrows, then the illustration indicates what is occurring at that time. The telephone receiver at B will be more disturbed than that at A.

If now a transposition is made in the telephone circuit at the right point the magnetic effect at the terminals can be eliminated, as shown in the figure. On the other hand, however, the electric field effects are not so completely neutralized. There are four points at which a current divides and flows in opposite directions, i.e. 1, 2, 3 and 4. Single transpositions are of course not effective with long exposures, and theoretically the result of electric induction could be eliminated only by an infinite number of transpositions.

It should be observed, too, that the actual induced voltage on the wires due to the electric field, i.e. the longitudinal voltage, is not reduced by the transpositions, although the effect of that voltage on the apparatus may be neutralized with the lines in good condition. Further, it is extremely difficult, and sometimes impossible, to secure such an accurate electrical balance to earth of the two sides of a complete telephone circuit as to reduce the disturbance of its electrical field to a sufficiently low figure for satisfactory working. The use of the earth for signalling purposes is an essential feature of modern telephone practice, and although relays and retardation coils are tested for balance, which ensures that they will be unaffected by neighbouring telegraph and telephone circuits, this may not be the case in the very much stronger fields produced by power circuits. To enable this part of the problem to be visualized, Fig. 17 has been prepared, which shows in skeleton form the principal types of standard circuit with speaking conditions. For the sake of simplification, the subsidiary apparatus for signalling and clearing has been omitted from the diagram.

The transposition in the positions of wires forming the circuits of telephone and power circuits, where these

circuits run parallel, is a most important method for reducing inductive interference. The object of transpositions in a communication circuit is to equalize the electrical effect of near-by influences so that the wires are similarly affected in a given length. The transposition of power wires will produce neutralizing effects in the telephone circuits due to balanced voltages and currents, whilst to transpose the telephone wires tends and a very good balance of the telephone circuit is required for satisfactory working.

Two methods of transposition are employed in this country. The older system is known as the "twist," in which four wires (two circuits) are taken as a unit and occupy at the insulators the four corners of a square, the diagonals comprising a circuit. At successive poles each wire changes its position to the next

to equalize the inductive effects in the two sides of the circuit, whatever may be the cause of such effects.

It has been the practice of the Post Office for many years to transpose telephone wires in order to prevent disturbance from telegraph circuits and cross-talk between the telephone circuits themselves. The inductive effects produced by a single-wire telegraph circuit on a telephone circuit carried on the same pole line may be considerable, as the length of parallelism may be great and the separating distance as low as 12 inches, corner of the square and thus in four spans completes a spiral, the twist being right-handed (Fig. 18). The other system is that employed in America for many years by the American Telegraph and Telephone Company, in which the wires are run straight for a certain number of spans and their position is changed at definite points. The wires comprising the circuit in this system are erected on the same arm, and the transposition points vary according to the position of the arm and of the wires on the arm. There are several

variations of the system and it would occupy too much space to go into them in detail here, as they are all more or less complicated. Both the "twist" system

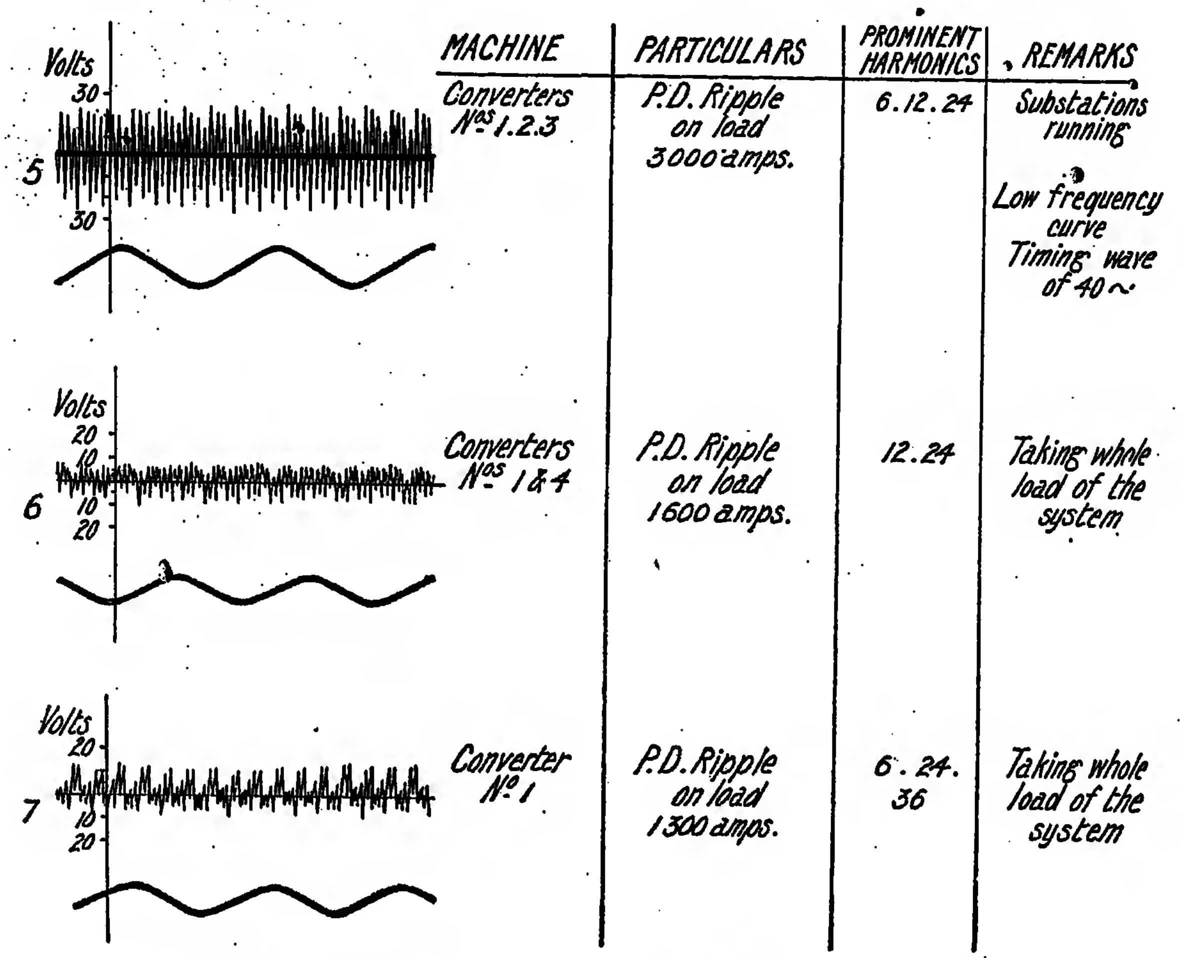

FIG. 14.—Characteristics of rotary converters running in parallel.

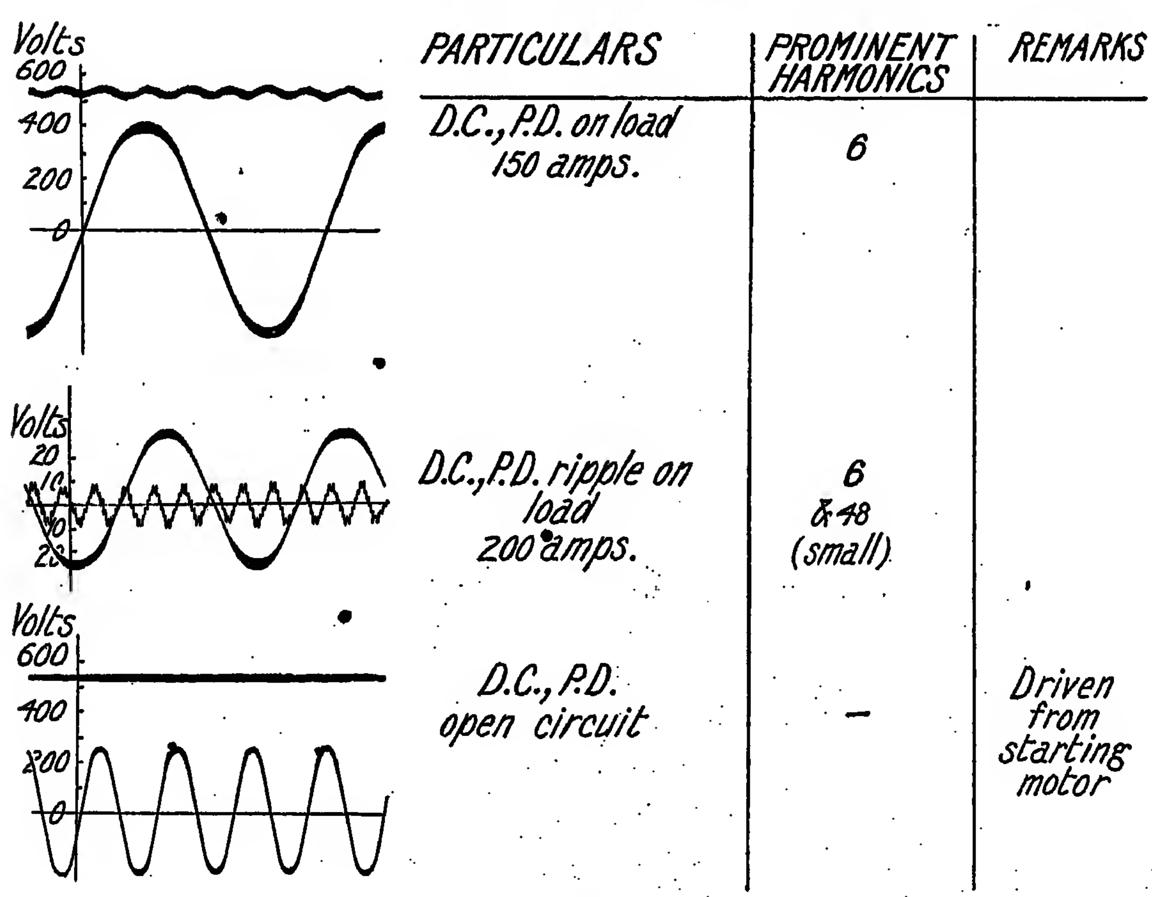

FIG. 15.—Oscillograms showing sixth harmonic originating on a.c. side.

and the latter transposition system are equally efficacious in preventing inductive effects and cross-talk from neighbouring telegraph and telephone circuits. The American system adopted by the Post Office is based on a unit length of 8 miles. Fig. 19 shows the type of transmission scheme and is self-explanatory.

As pointed out previously, the transposition of power wires will not reduce the effects of residual voltages and currents except in so far as it effects an improve-

ment by balancing the capacities to earth of the several conductors. The transposition of power conductors will, however, reduce the effects of balanced voltages and currents by producing mutually neutralizing effects in neighbouring communication wires. Power wires on traction systems cannot, of course, be transposed. In the usual case it is a three-phase three-wire extra-high-pressure line, as there is little single-phase overhead

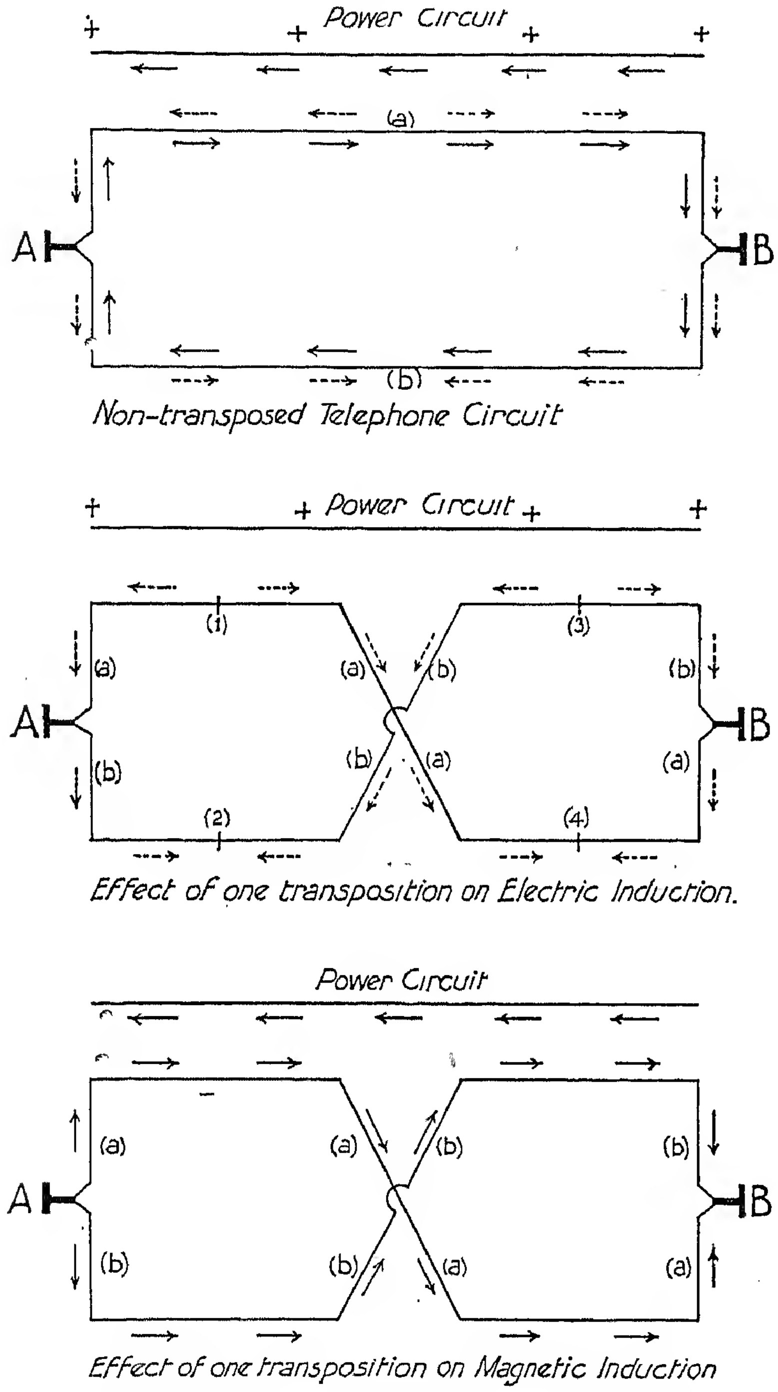

FIG. 16.—Effect of transposition on induction.

--> indicates current due to electric induction.
—> indicates current due to magnetic induction.

work. The section of the power circuit in which each conductor occupies each of the conductor positions for equal distances is usually defined as a "barrel." Fig. 20 shows a co-ordinated scheme where a three-phase and a single-phase line run parallel with a telephone line.

The Californian Commission's report limits the maximum length of barrel in the case of a single-circuit three-phase line to 12 miles for circuits of triangular configuration, and to 6 miles for other forms. Single-phase and two-phase circuits have to be transposed at intervals not exceeding 4 miles.

PARALLELISM.

It is obvious that one of the most important factors in preventing and minimizing inductive interference is to avoid conditions where power lines and communication circuits will run parallel to each other. It should be an axiom that where parallelism cannot be avoided the greatest possible separating distance should be provided. This is important not only in connection with inductive effects resulting from the normal working of the power line, which may be small if proper precautions are taken, but because it is impossible to guarantee that some abnormal occurrence on the power system may not by its unbalancing effects cause serious disturbance. One naturally asks what are the permissible conditions, and one seeks for a simple rule which will apportion due weight to the factors and give a safe answer. Unfortunately, these factors are very complicated, involving, as they do, not only such simple matters as separating distance, lengths of exposure, normal voltages and currents and frequencies, but also wave-shapes of transformers and generators, capacities and inductances of power and communication circuits, and the configuration and separation of the power and communication wires.

The Californian Joint Committee did not commit themselves beyond stating that "every reasonable effort shall be made to avoid parallels and where there are parallels they should be as short as practicable." Further, "the power lines and communication lines shall be kept as far apart as practicable and this separation should be at least equal to the height above ground of the power wires, except when closer proximity is unavoidable."

There are three considerations to be borne in mind. These are the induced effects which may be produced by (*a*) balanced voltages and currents, (*b*) the residual voltages and currents, and (*c*) abnormal occurrences arising out of faults, switching, etc. The first-mentioned may, perhaps, be forecast and allowed for; (*b*) is a more difficult matter, and (*c*) more difficult still, the factors being modified by all types of fault and by the position of the communication line in respect to the generating station and the position of the fault. The inductive effects of balanced voltages and currents are the most tangible to handle, and in the case of a three-phase overhead line the theoretical effects have been considered by several investigators. To forecast the results of those effects and those of the residual voltages and currents on neighbouring telephone and telegraph circuits in terms of noise value and mutilating effects on telegraph signals is, in the opinion of the author, to enter into the region of prophecy and he is not in a position to commit himself on the matter. As regards actual maximum tolerable values, those taken in the Californian report are no doubt near the mark in the case of telephones; that is, the extraneously induced current in the receiver should not exceed in its noise-producing value the effect of 10 micro-amperes at a frequency of 240 periods per second; but those taken in the case of telegraphs, viz. the extraneously induced current at the circuit terminals, should not exceed 2 milliamperes at a frequency of 60 periods per second, or its equivalent at any other frequency, e.g. 1 mA at

25 periods per second appears to be on the high side. The types of telegraph apparatus and their sensitivities vary considerably and the author would place the maximum figure at 0·5 milliampere for this country.

The method of calculating the electric and magnetic effects would form the subject of a separate paper, and the author would refer those sufficiently interested to the treatment by L. P. Ferris, in the Californian Report, and by E. Parry in the *New Zealand Journal of Science and Technology*, 1919, vol. 2. Parry's theoretical calculations of the electric effects were concerned with the Lake Coleridge–Christchurch 66 000-volt three-phase transmission line. Figs. 21 and 22 are reproduced from the paper and refer respectively to the calculations of the electrostatic and electromagnetic fields upon a neighbouring telephone circuit. Fig. 21 shows the maximum value to earth of the electrostatically induced E.M.F. in the telephone wire 18 ft. above the ground at varying separating distances from the power line which has an equilateral triangular formation with 6 ft. spacing and the bottom wires 32 ft. 2 in. above the ground. In the case of wires actually erected on the power-line poles 6 ft. 5 in. below the bottom arms, Parry's calculation gave a maximum pressure to earth of 4 940 volts, and he remarks: "Hence the necessity of ample drainage coils and transformers insulated for high voltage, insulated platforms and other devices for the security of the employees."

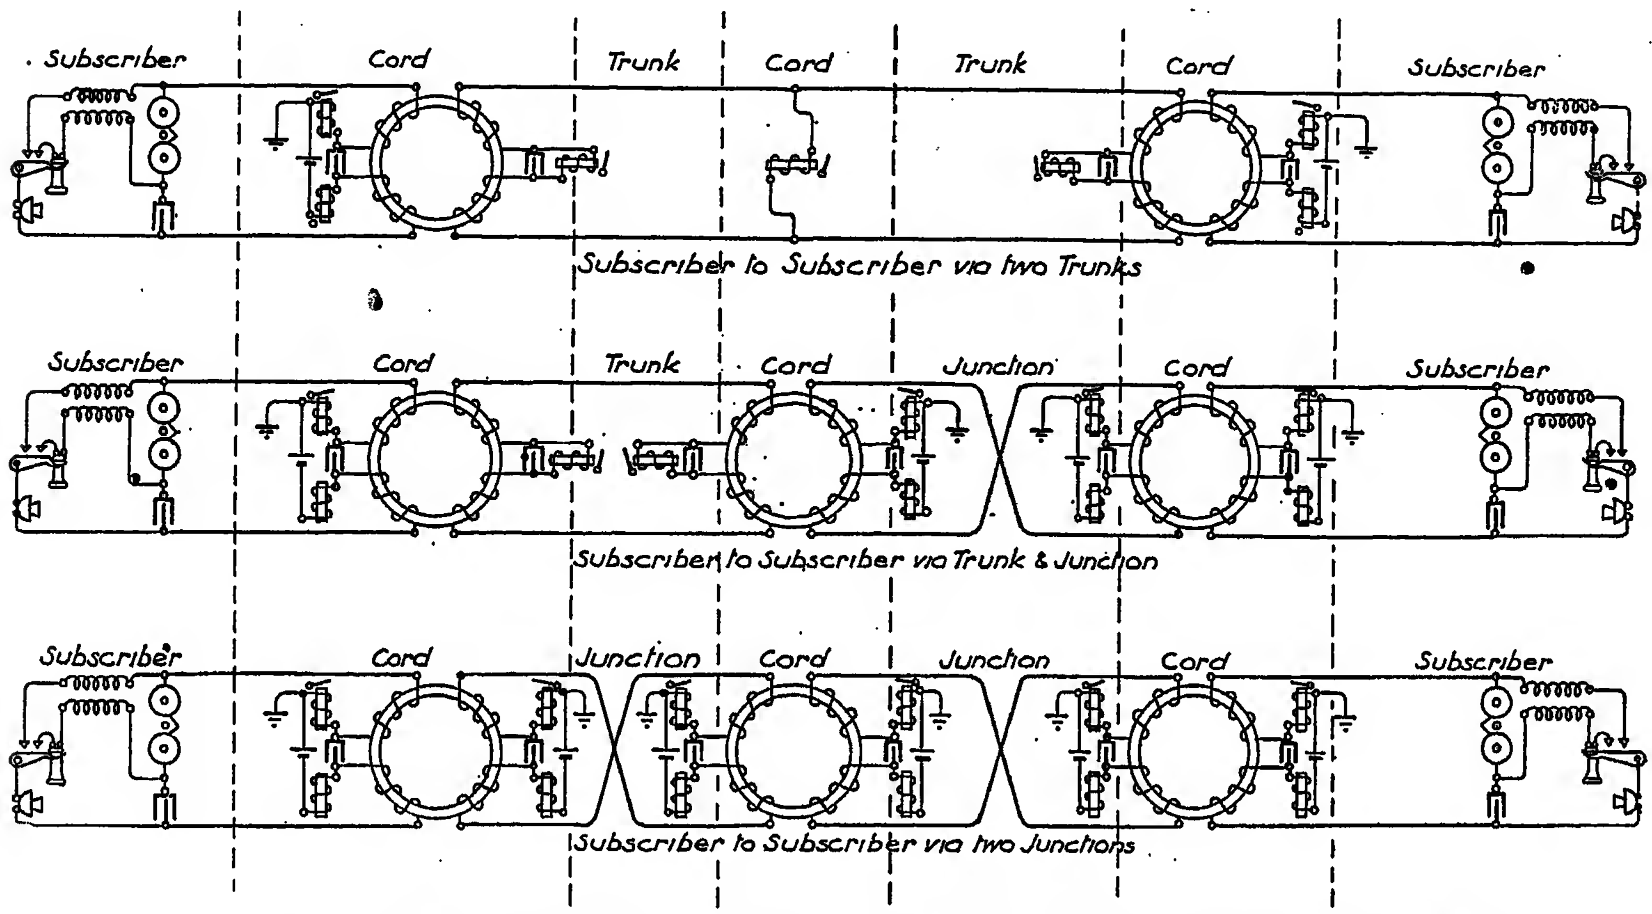

FIG. 17.—Typical long-distance telephone connections. Skeleton diagram showing all earth connections.

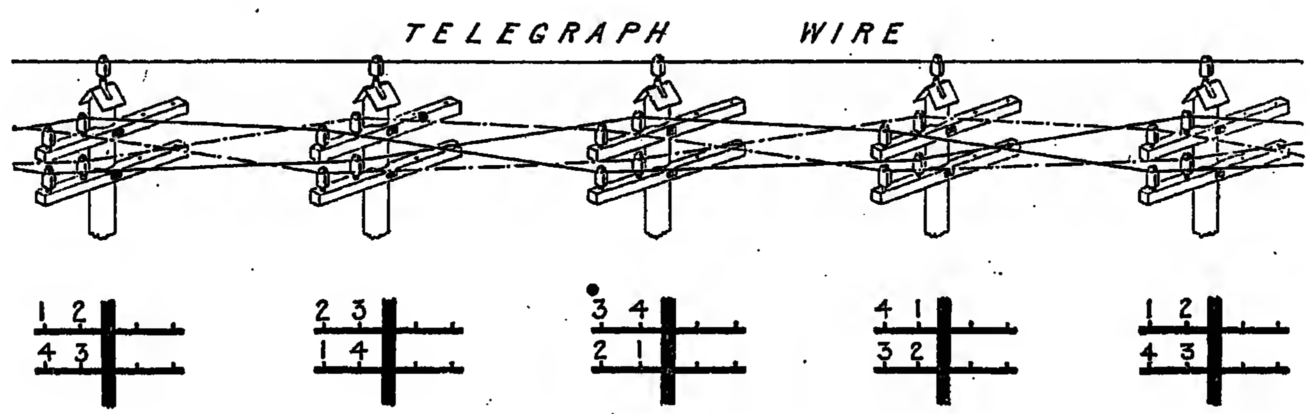

FIG. 18.—Twist system of transposition.

Fig. 22 shows the maximum voltage per mile induced in a telephone circuit with 100 amperes in the power line. The calculated induced voltage per mile of wire in the case of the telephone wires on the power-circuit poles was 5·03 volts per mile, and this applied equally to each leg of the circuit. Owing to the difference in phase of the effects, however, there would be a difference of 2·1 volts between the two sides at any instant of time.

Parry's calculations of the effects of the electric field were verified by actual measurements made by Caldwell and Marsden (See the same *Journal*, January 1921). Observations made on a line situated 26 ft. from a 66 000-volt power-transmission line showed voltages between 100 and 1 140 on various wires under varying conditions caused by earthing neighbouring conductors. Insulated telephone wires erected on the poles carrying the power wires had pressures to earth of between 150 volts and 1 850 volts according to the different conditions as regards earthing of adjacent wires. Using Parry's formula the authors state that for a long telegraph wire of No. 11 S.W.G. (200 lb. copper) 18 ft. above the ground the induced voltages for different separating distances will be as shown in Table 2.

The quantity of electricity Q induced on the wires should they be earthed is roughly proportional to the voltage indicated above, so that the energy of discharge, which is proportional to QV, will fall off with the distance at a rate proportional to the squares of the above figures. It should also be pointed out that the induced voltage will be less if the wires concerned extend beyond the influence of the power line, as the effective capacity per unit length will be increased accordingly.

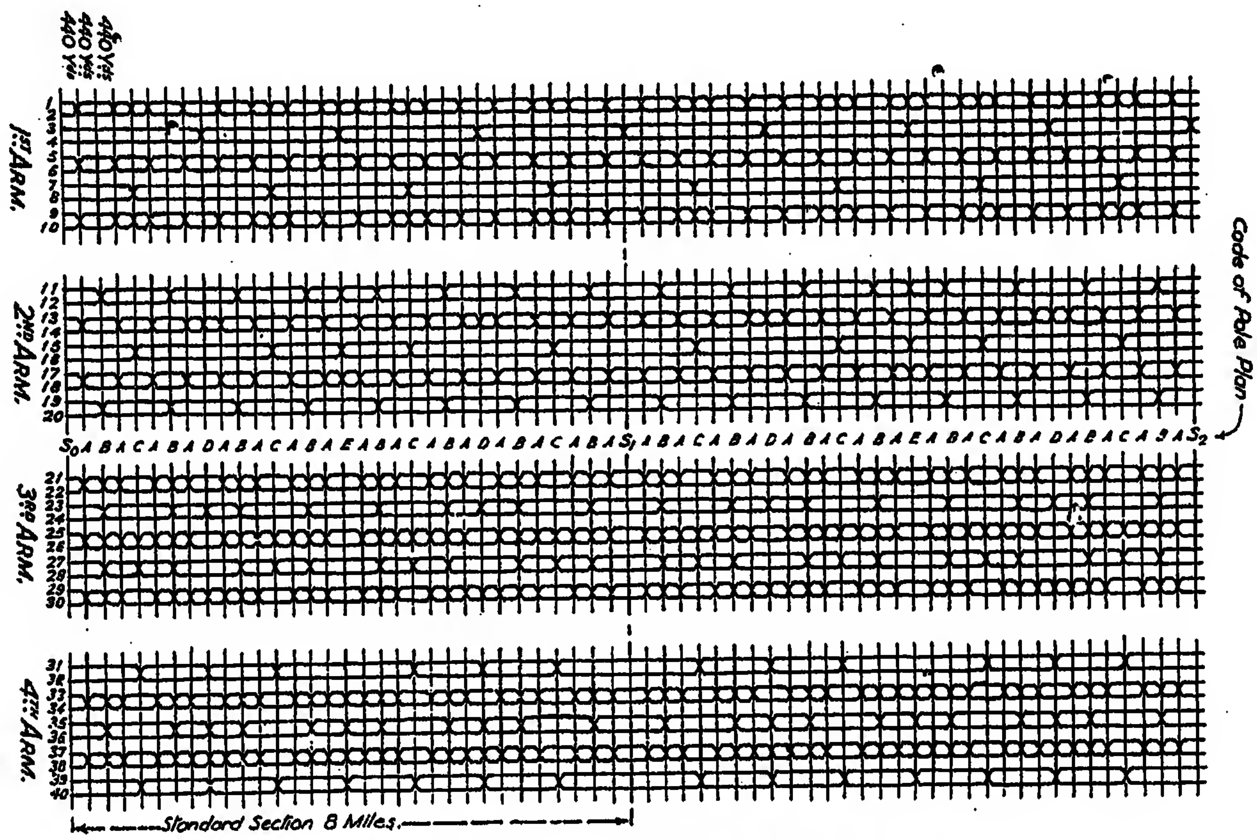

FIG. 19.—American system.

The 5th, 6th, 7th and 8th arms will be transposed like the 1st, 2nd, 3rd and 4th arms respectively, with the exception that at the 1st, 3rd, 5th, etc. S poles, all pairs except 43–44 will be transposed.
For a saddle pair cross as shown for 35–36. For two-wire arms or pole brackets cross as shown for 5–6, 15–16, etc.
For four-wire arms cross as shown for 3–4, 7–8, 13–14, 17–18, etc. For six-wire arms cross as shown on plan, omitting 1–2, 9–10, 11–12, 19–20, etc. For eight-wire arms cross as shown on plan, omitting 5–6, 15–16, etc.

Although the Californian Joint Committee did not commit themselves to definite proposals as to what constitutes a dangerous parallel, they included in their report proposals for arriving at a basis. The Committee did not agree as to the acceptability of these proposals should be transposed to reduce balanced voltages and currents, and other charts which deal with residual voltages and currents and indicate the conditions from which interference with telegraphs and telephones can be anticipated.

but put them forward solely as a preliminary study and a guide to those undertaking further studies of this nature. In their report are a number of charts which are the suggested basis of conditions that should be a guide for deciding whether power circuit wires

In the case of balanced voltages and currents the charts are based on the assumption that balanced voltages will interfere with telephone circuits if the product of the length of parallel running in miles and the induced pressures between conductors and earth

in volts exceeds 200 volt-miles, and that from balanced currents will interfere if the average induced voltage along conductors exceeds 0·5 volt at 60 cycles per sec. For telegraph circuits the figures are respectively 300 volt-miles and 1 volt at 60 cycles. An indication of what this means can be gathered from the exemption from transposition given to lines on private rights of way in the Californian final report, subject to the conditions in Table 3 and to the power line not paralleling the highway or communication line with a closer proximity than that given by 1 mile in 30 miles of parallelism.

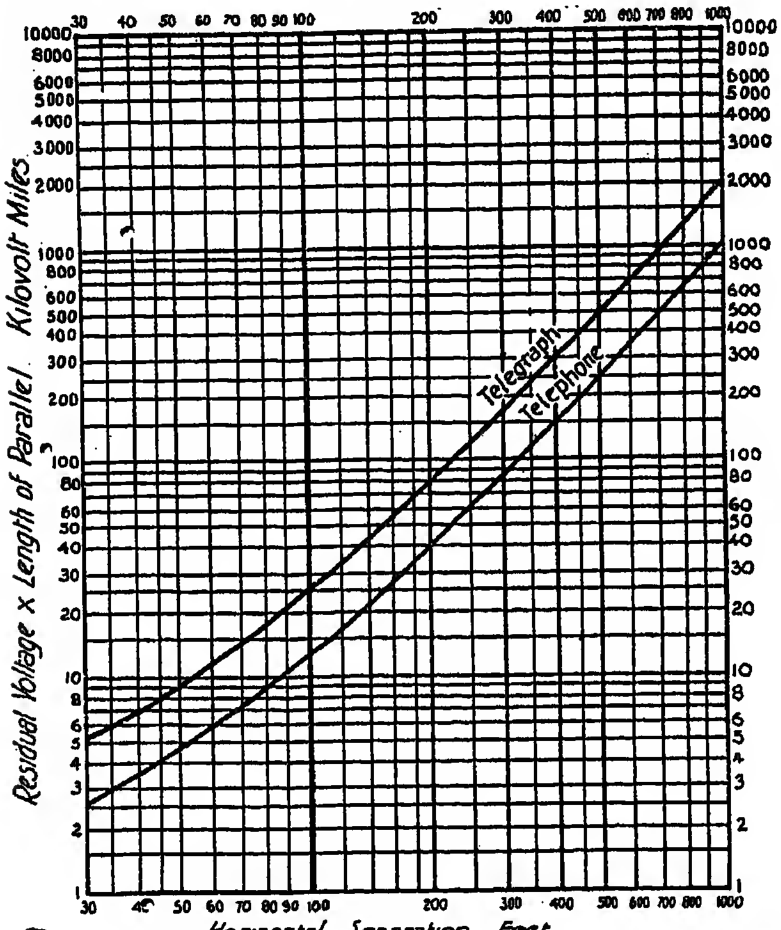

FIG. 23.—Residual voltage for parallels of 60-cycle, three-phase power lines and telephone or telegraph lines.

When the product of residual voltage (in kilovolts) and length of parallel (in miles) for a given horizontal separation exceeds the value given by the appropriate curve, interference may ordinarily be expected, under the assumptions given.

The charts referring to residual voltages and currents are given in Figs. 23 and 24. The figure for parallels involving telephone circuits is in the case of residual

TABLE 3.

Voltages between power conductors	Separation from highway and communication lines
	ft.
Below 50 000	600
50 000 to 75 000	750
75 000 to 100 000	850
100 000 to 150 000	1 000
150 000 to 200 000	1 200

voltages based on a value of the product of the length of parallel and the induced voltage between the conductors and earth of 150 volt-miles, and in the case of telegraphs of 300 volt-miles. In all cases referring to telephone circuits it is assumed that there are harmonics present which fall within the range harmful to speech. As an example of the use of Fig. 23 let it be assumed that it is proposed to parallel a telephone line over 10 miles at a separation of 60 ft. From the chart it is found that the value of the product of length of parallel and residual voltage corresponding to a horizontal separation of 60 ft. is 6 kilovolt-miles. Dividing by 10, the given length of parallel, the residual voltage permissible under the condition assumed is found to be 600 volts (effective value).

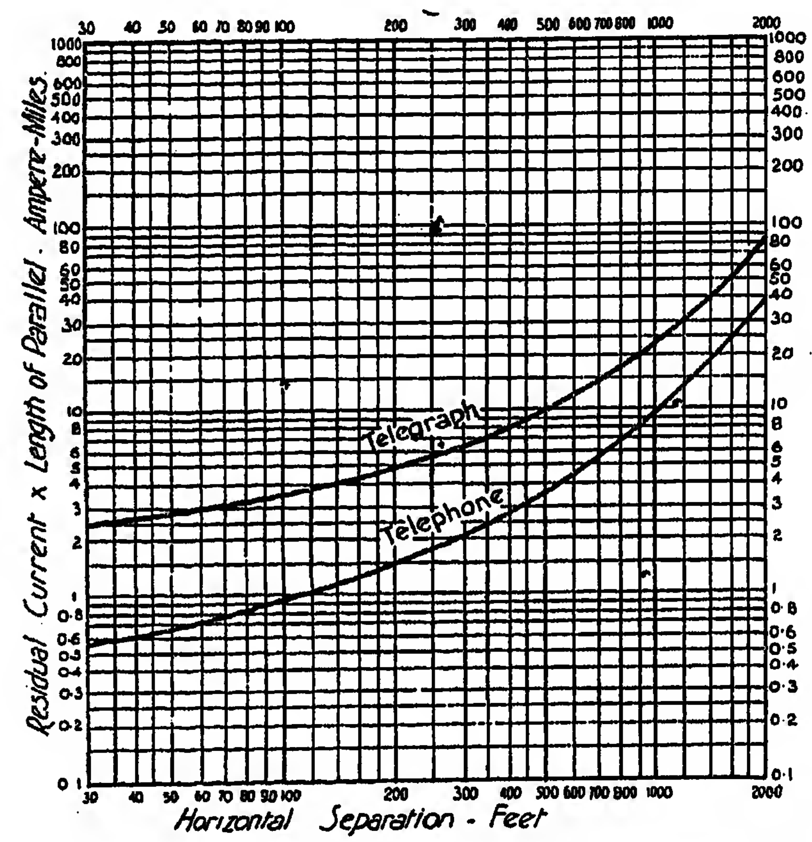

FIG. 24.—Residual current for parallels of 60-cycle, three-phase earthed-neutral power lines and telephone or telegraph lines.

When the product of residual current (in amperes) and length of parallel (in miles) for a given horizontal separation exceeds the value given by the appropriate curve, interference may ordinarily be expected, under the assumptions given.

In the case of residual current the curve is based on an induced voltage along the telephone conductors of 0·20 volt at 60 cycles per sec., and for telegraphs a value of 1 volt at 60 cycles.

As an example of the use of Fig. 24, assume that it is proposed to parallel a telephone line for 2 miles at a separation of 60 ft. with an earthed-neutral power circuit.

From the chart it is found that the value of residual ampere-miles corresponding to the horizontal separation of 60 ft. is 0·75. Dividing this by 2, the given length of parallel in miles, the residual current permissible under the conditions assumed is found to be 0·37 ampere (effective value).

Turning to the question of the clearance to be given to prevent the harmful effects of short-circuits, etc., in the *Elektrotechnische Zeitschrift* of 17th May, 1923, draft rules prepared by the Verband Deutscher Elektrotechniker are proposed for the protection of telephone

loop wires against influence by alternating-current systems. These rules lay down, *inter alia*, separating distances between power lines and telephone lines which are regarded as not dangerous should a power line be started up during the existence of an earth on the system. The values are shown in Table 4.

TABLE 4.

Up to 15 kV, more than 60 m.
Above 15 kV and up to 20 kV, more than 75 m.
Above 20 kV and up to 35 kV, more than 100 m.
Above 35 kV and up to 60 kV, more than 150 m.
Above 60 kV and up to 110 kV, more than 200 m.
Above 110 kV, more than 250 m.

The author does not know whether these rules have been approved.

The calculations in the case of single-phase electric railways where the power system is largely unbalanced have been made by various investigators. Here again, owing to the great number of factors involved, many of which are difficult to appraise, it is not easy to forecast on theoretical grounds what will be the result in any particular case. The current effects from such systems are usually the most troublesome and the amount of current returning in the earth path is the controlling factor, this naturally depending upon the measures taken to confine the current to the rails or to supplementary return conductors. If no special measures are taken, from 40 to 60 per cent of the current usually flows in the rails, the remainder returning via the earth.

Where communication circuits are erected at the side of a railway the track conditions usually limit the separating distance, and the physical conditions control the situation.

TELEPHONE CIRCUIT BALANCE.

The presence of power circuits in the vicinity of telephone circuits necessitates an unusually high standard of maintenance of the latter. Small defects that would cause little trouble were the power circuit non-existent, now prove annoyances of considerable magnitude, whilst apparatus that was thought to be accurately balanced is found to be wanting when exposed to the searching effects of strong fields. This is specially noticeable if the apparatus is earth-connected, as the capacity discharges through the apparatus will effectively show up any want of balance in the impedances. Further, it is possible to have trouble even if the exposed telephone circuit be perfect in balance as regards insulation, capacity and conductor resistance, and taken alone no disturbance is experienced, as this circuit is liable to be placed in connection with any number of other circuits any one of which may be more or less faulty. A faulty circuit at once introduces trouble in a violent form by unbalancing the combination. The trouble can be met to a certain extent by making all connections between the exposed circuit and others through transformers or repeating coils, as by this means an unbalanced circuit is prevented from upsetting the balance of the line subject to the interfering field. Such a procedure necessitates in some cases changes in the signalling arrangements, and there is always a certain loss in speech efficiency.

In all cases of inductive interference with telephones the first steps taken are to see that the circuits are properly balanced electrically. If a telephone circuit were perfectly balanced and transposed it would of course be possible for it to work undisturbed in any electrical field, but such a circuit is not obtained in practice. For a circuit to be perfectly balanced each leg of the loop should have the same series impedance, the same capacity and insulation resistance to earth, and the same capacity and insulation resistance to each other at all points. This is impossible in practice with overhead lines, and a properly balanced circuit for commercial purposes is taken as one which would be undisturbed by other telephone or telegraph circuits working on the same route. It follows that the better the balance of a telephone circuit the less likely is it to be disturbed, and the following points are looked into when trouble is experienced :—

Apparatus.—Listening tests are made directly on the lines, i.e. with all relays, repeating coils, etc., cut out. If the noise is reduced, the apparatus removed is examined. Standard apparatus is designed to be balanced to ordinary inductive effects when placed in a telephone circuit, but trouble may be introduced by the following defects :—

(*a*) Partial or intermittent contacts due to projections of solder on contacts and terminals of apparatus.
(*b*) Defective contacts in relays.
(*c*) Imperfect contacts at protective devices (fuses, heat coils and protectors).
(*d*) Badly soldered joints on frames or switchboards.

Line wires.—Methods of transposing line wires to prevent inductive interference in the case of telephone circuits have already been dealt with. The two wires of the loop should have the same series impedance; unequal resistance causes trouble, a difference of a few ohms being sufficient to accentuate interference. In making tests of resistance the circuit should be divided into sections which should be as short as practicable, as it is possible for inequalities of resistance to average out on a long length, but, nevertheless, the local unbalance will cause a circuit to be noisy. Where unbalance is detected, all connections should be examined for dry joints.

Insulation.—Insulation balance is of great importance, and noise may be due to local differences of insulation where a test of the whole line shows no great disparity. This is especially so if the whole insulation is low, as there may be great local differences which have considerable noise effect. When the insulation is high the local unbalances are not likely to be considerable.

Where insulation is not up to standard careful line inspections should be made. Defective insulators and partial contacts caused by trees or debris should be removed. Protective fittings should also be examined.

When the circuit is partly in cable, listening tests should be made with the cable sections in and out of circuit, and it should then be possible to ascertain whether the insulation of the cable is a factor in the unbalance.

Inductive effects are sometimes experienced in circuits not directly affected by power circuits, owing to their proximity in a cable to circuits which are affected. In one instance the circuits comprising a great part of a telephone exchange were very badly disturbed following the commencement of electric traction on a railway, yet none of the circuits disturbed was close to the railway. The cause of the trouble was traced to a telegraph circuit which ran adjacent to the electric railway for a portion of its route and for another small portion in the cable in which there were also telephone circuits terminating at the exchange. Inductive effects from the railway power line were thus carried over a wide area by the telegraph line and telephone circuits following the common route for a short distance.

Methods for Minimizing Telephone and Telegraph Interference.

Remedies applied to telephone circuits.—Various methods have been devised for reducing the effects of induction upon telephone circuits by modifications or alterations in the apparatus. In the early days when single-wire telephone circuits were more common and relatively short, some kind of success was achieved by methods which reduced the sensitivity of the circuit. One of these was to increase the clearance between the diaphragm and the coils of the receiver by inserting a brass ring. This made the noise less offensive, but it of course reduced the volume of speech and was only a palliative dependent for success on the circuit having a good speech margin. In some instances a condenser placed across the receiver was effective.

A rather more elaborate arrangement was one in which impedance coils were joined in the circuit to choke out the interfering currents, and incidentally the speech currents, and then improvement was made in the latter by increasing the transmitter voltage; this met with a fair amount of success, but it had the drawback that the increase in working voltage caused overhearing in neighbouring circuits.

Specially designed loud-speaking telephones used on circuits deliberately made insensitive by capacity-coupling connections have answered in some cases.

Endeavours to shunt the interfering note by means of tuned inductance and capacity have not been very successful. The note to be removed is generally composite and, even if well defined, is of a frequency that falls within the vital speech range, and speech in its removal is degraded.

It is important to bear in mind that none of these methods is suitable for public telephone circuits—the most that can be claimed for them to-day is that they may be of use in dealing with private lines, e.g. between collieries, etc., of which there are still no doubt many left in the country.

The coupling of the power circuit with the telephone line at a transformer has been suggested at various times. One early reference is given in Hopkins's "Telephone Lines and their Properties," published in 1898. The connection of the windings on the transformer is such that the current induced in the transformer is 180° out of phase with that induced in the line section of the circuit. A development of this by Mr. J. Sayers is referred to later in the section on single-phase railways.

A more modern development is attributed to Marius Latour. The telephone current is amplified for transmission and in the terminal apparatus the strength of this current is brought down to the value corresponding to normal audition, which at the same time reduces the intensity of the disturbing current. The amplification can be regulated as required at the transmitting end, and the disturbing effect can be reduced to a value sufficiently low as not to interfere with telephone conversation. Ordinary vacuum-tube amplifiers are employed. Such an arrangement would be satisfactory on single-circuit routes, but overhearing would occur on lines carrying two or more circuits, owing to the greater power used.

Remedies applied to telegraph circuits.—It is possible to reduce within certain limits the inductive effects on the working of telegraph apparatus. Telegraphs are usually only affected by currents of the fundamental frequencies in the case of power-transmission lines, and by the fundamental electromagnetic effects in the case of single-phase railways, these frequencies being within the working range of such apparatus. It has been the last-named effects which have caused most trouble and have, in consequence, led to the trial and application of remedial measures. Telegraph circuits are, in the great majority of cases, worked with an earth return. The types of apparatus are numerous, depending upon the service required, the speed of working varying from 20 to, say, 200 words per minute, although speeds as high as 600 words per minute can be attained under suitable conditions. By duplexing, quadruplexing and multiplexing, it is possible to provide from 2 to 12 channels by means of one wire. The currents required to operate the different telegraph apparatus when worked directly in a line, i.e. short-distance circuits, varies between 1 mA for a polarized sounder to 69 mA for the old-fashioned inker. Where the actual telegraph apparatus is worked from relays, the minimum current required to work the relays varies between 0·5 mA for the most sensitive, up to 6 mA. For very high speeds, however, some of the relays require a larger minimum current, according to type, but much smaller currents will interfere with the working.

It will be gathered from this that very small foreign currents are likely to mutilate telegraph signals.

The highest pressure employed on telegraph circuits in this country is 120 volts. Somewhat higher pressures are used in some other countries. The voltage employed depends upon the length of line and the apparatus in the circuit. The magnitude of the interference effects will therefore depend not only upon the foreign voltage impressed on the circuit, but to a certain extent also upon the frequency of the interfering current and the speed or number of words per minute at which the telegraph circuit is operating. Trouble may result in some cases when a foreign voltage as low as 10 per cent of the working voltage is impressed upon the circuit. The higher the speed of the telegraph working, the more likely it is to be mutilated. The length of the marking signal or the time the marking current is flowing depends upon the speed, and at low speeds a portion of this

length can be lost without interference with the signal, i.e. there is enough effective current left to produce the signal. At high speeds, however, the time the marking current is flowing is reduced and, as further clipping cannot be tolerated, interference which may be unnoticed at low speeds is sufficient to cause faulty reception.

The remedies that can be applied depend upon the values of the induced voltages. With the very high induced voltages experienced in America, very special steps had to be taken to reduce these by employing neutralizing transformers in the communication circuits. These are referred to in the section dealing with single-phase railways. The most successful remedies have been those based on the fact that telegraph apparatus is inserting an inductive resistance which has a high effective value at the frequency of the interfering current but a relatively small one with direct current.

Slight perturbations have been prevented in relays by the provision of a copper tube between the electro-magnet and the windings. This damps out the high-frequency effects.

The greatest success has been achieved with resonant shunts. Fig. 25 shows the application of such shunts to duplex and simplex telegraph circuits in this country. The shunt is based on the well-known resonant formula, and for a frequency of 25 has a capacity of $0 \cdot 2\ \mu F$ and an inductance of $20 \cdot 05$ henrys. There are disadvantages with high capacity or high inductance. If a high capacity is employed it will seriously reduce the

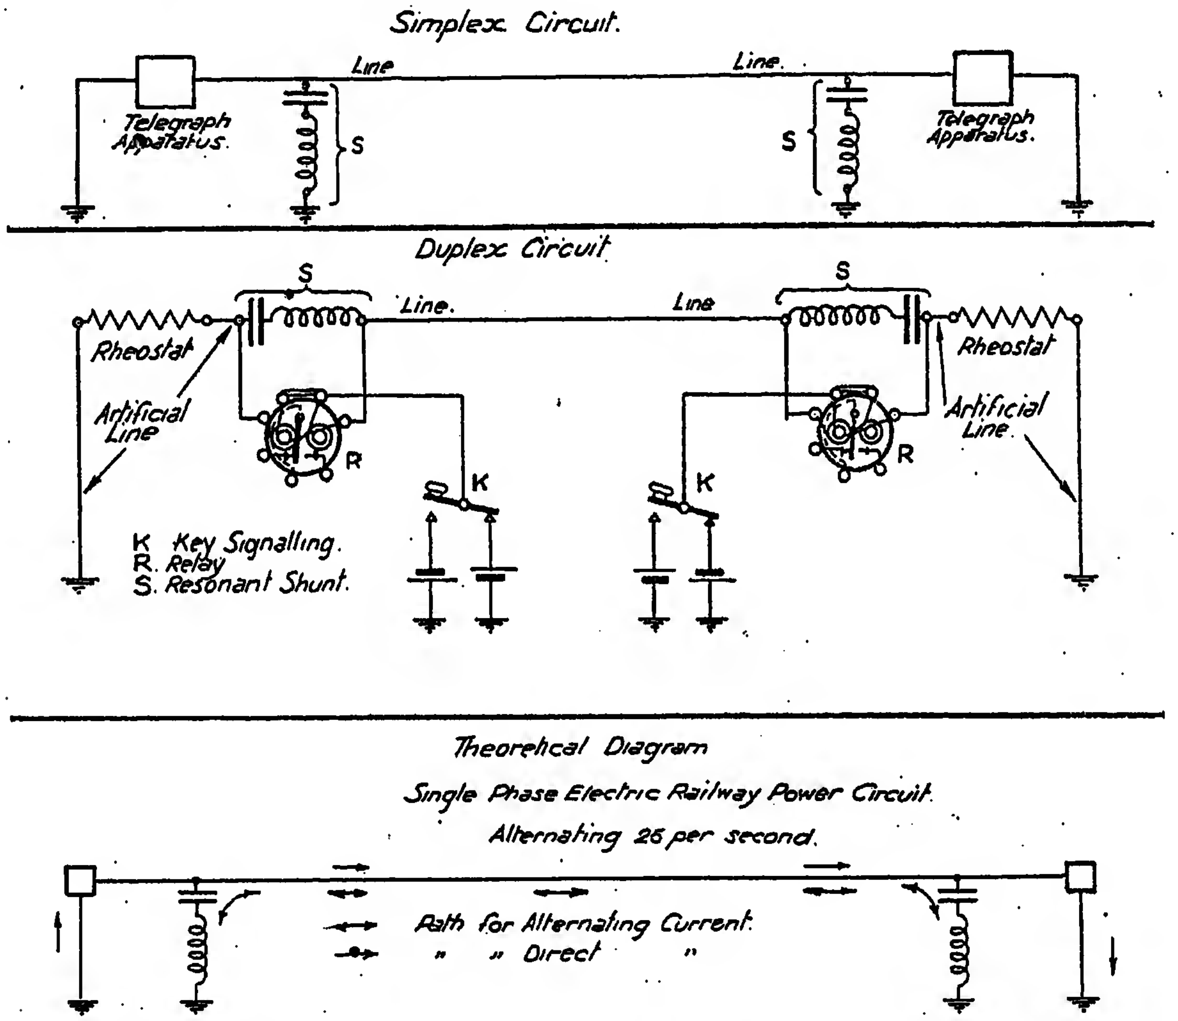

FIG. 25.—Resonant shunts applied to telegraph circuits.

usually worked with direct current, and as the interfering current is alternating it is possible to arrange for the alternating current an easy path which is closed to the direct current, and, further, to arrange a path which is closed to the alternating current but open to the direct. There are, however, a few other methods which may be applied where the interference is not excessive, e.g. resistance can be added to the circuit and the working voltage increased. This has a limited application, as the induced voltages are usually high and to overcome them would require excessive working voltages. Moreover, a higher working voltage than the normal will cause interference between telegraph circuits themselves.

Interference with signalling systems where direct current is used can be overcome in some cases by signals on certain types of circuit which are worked with condenser impulses, whilst a high inductance involves a high resistance to produce the inductance, unless considerable iron is used with the coil; and a high resistance will defeat the object of the shunt. Again, if iron is used the inductance will vary with the current passing and the shunt will cease to be resonant at all values of current. It can be said, however, that it is possible by means of these shunts to make certain circuits workable which would otherwise be unfit for use. Their use is limited, however, to circuits worked at hand speed, as with automatic working at certain speeds the signals are distorted owing to the shunt coming into action and providing a path for the working current. With a shunt fitted to Wheatstone apparatus good signals are obtained until a speed is reached which,

in effect, results in alternations approaching the frequency of the shunt or multiples of the same. For instance, on a Wheatstone circuit there will be good

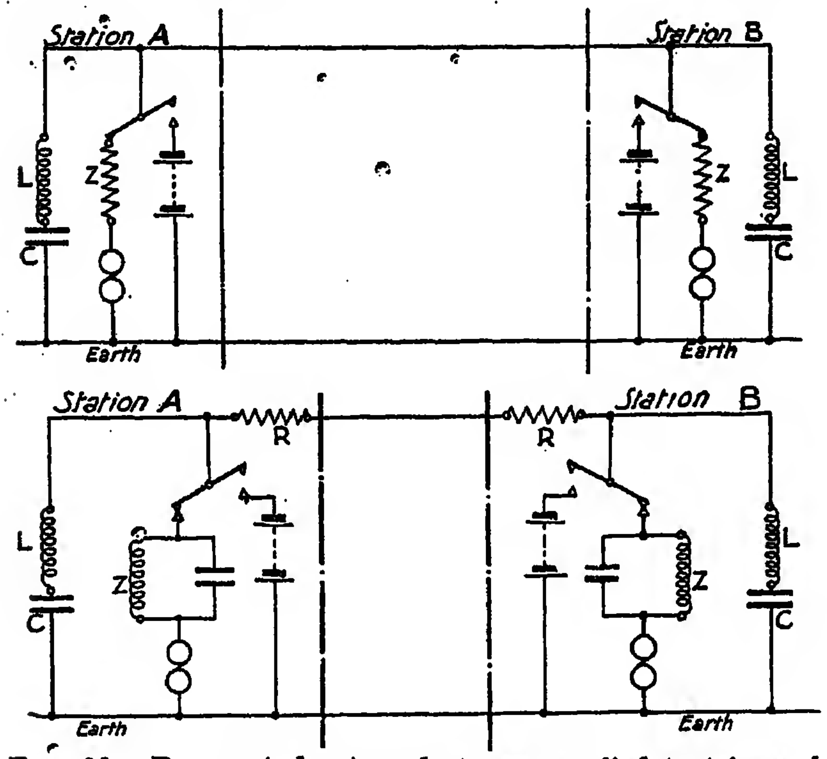

FIG. 26.—Resonant shunts and stopper applied to telegraph circuits.

signals up to 50 words per minute, but between 55 and 80 words per minute they are badly broken up. After that the signals are again good until a frequency multiple of 55 words is reached. Wheatstone working at 55 words per minute is roughly a periodicity of 25 per second.

As regards the actual prevention of interference, these methods naturally fail if the induced voltage is very high. In an actual case of a circuit fitted with a shunt and working with a 50-volt battery an induced pressure of 22 volts was sufficient to interfere with the operation.

M. Latour, in a communication on H. S. Warren's paper,* describes the application of the same kind of shunt with improvements in the shape of a stopper circuit in the telegraph instrument path. His first and final arrangements are shown in Fig. 26. In the last Z is the stopper, i.e. the capacity and inductance in parallel having the same values as those required for resonance. The application was made to telegraph circuits subject to influence by a single-phase railway working at a frequency of $16\frac{2}{3}$ per second, the values being 50 henrys and 2 μF.

Other palliative arrangements are shown in Fig. 27, and these are self-explanatory. It should be borne in mind that all the remedies referred to are for use with single-wire telegraph circuits. A double-wire circuit should not require devices of this character.

TRACING THE SOURCE OF THE INTERFERENCE.

Tracing the source of a disturbance may present difficulties where a circuit passes through many power areas. The simplest method is to go over the route with a search coil and a telephone receiver, listening at the likeliest spots and comparing the pitch of the note with that heard on the actual telephone circuit. Search coils can be made up in many forms. The most effective is that in which the impedance of the coil itself is equal to the impedance of the receiver, which in practice means that a low-resistance receiver should be used with a coil of few turns, and a high-resistance receiver with a coil of many turns.

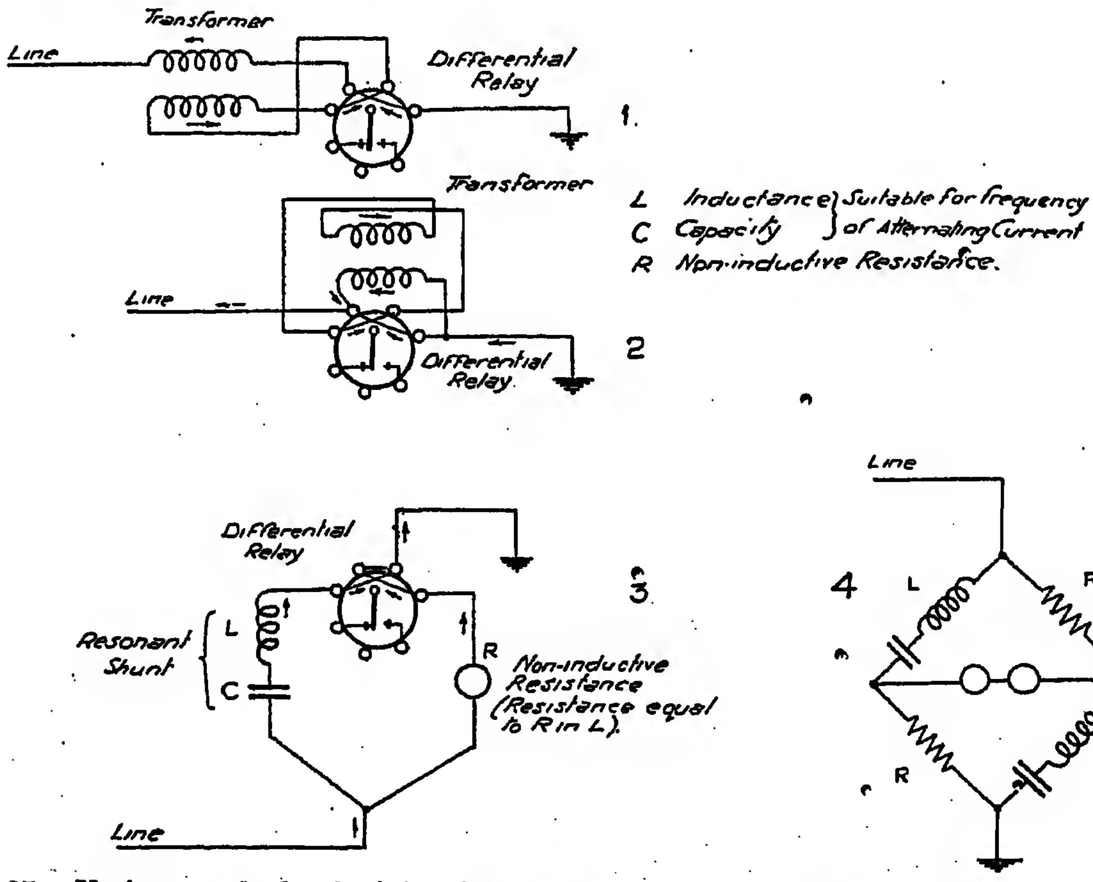

FIG. 27.—Various methods of minimizing effects of alternating current on telegraph circuits.

* *Transactions of the American Institute of Electrical Engineers*, 1918, vol. 37 p. 503.

If more than one system gives the same note, which is not an unlikely contingency, then it may be necessary to shut down one or other of the systems specially to find the offender.

The frequency of a ripple can be obtained fairly accurately by comparing the pitch of the note heard on the telephone with that of a tuning fork, pipes, or a piano. The pitch of all pianos is not based on a common fundamental frequency, however, and the accuracy of the comparison of the pitch of notes depends upon the musical faculties of the individual making the test, and observers differ unless they have specially trained hearing. It is possible to ascertain accurately the frequency of a ripple by means of apparatus that impresses a note which can be varied, and the frequency of which is known, on the same circuit as that having the unknown note; synchronism can be ascertained by the beats, or rather the intervals between the beats. Fig. 28 illustrates such an arrangement diagrammatically.

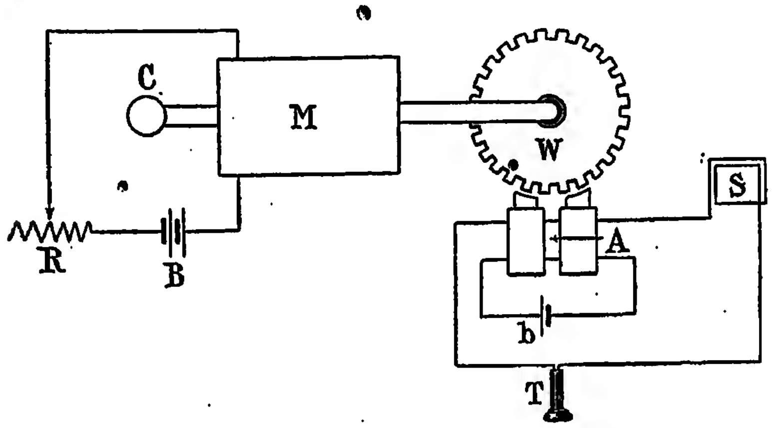

FIG. 28.—Method of ascertaining pitch of note.

M = Motor.
R = Resistance (adjustable).
B = Battery (100-volt).
W = Cog-wheel, 60 teeth.
A = Stator of alternator (2 poles).
b = 1 cell.
C = Counter.
S = Search coil or telephone circuit.
T = Telephone receiver.

The motor, the speed of which can be varied by means of the adjustable resistance, drives a cog-wheel having 60 teeth, the rim of the wheel being so placed that it acts as the rotor of a small alternator, the stator of which consists of two poles, the field being supplied by a single dry cell. As the cog-wheel revolves, the teeth cut the field at the same periodicity per second as the motor speed per minute. The speed per minute of the motor is obtained from a counter on the armature, and it is possible, therefore, by noting this figure to know the frequency of the note produced by the alternator. When, by adjustment of the resistance, the alternator note approaches the frequency of the note under test, beats are heard which become separated by longer intervals as the notes come into synchronism. When this point is reached, the counter figure gives the information required. This method was employed by Prof. Miles Walker in some investigations in which the Post Office was concerned.

The Problem as Affecting Different Power Systems.

It is now proposed to deal more specifically with the different types of power circuits as used commercially in this country, viz. tramways, railways, and electric light and power circuits, indicating in a general way the steps taken to overcome interference, and any other features that may be of interest in connection with the matter under consideration.

Tramways.—The most usual system employed in this country is the single trolley wire with an insulated rail return. There are a few miles of track in the neighbourhood of Greenwich Observatory where double trolley wires are used. In London the conduit system with positive and negative conductors is common.

Interference with telegraphs by stray currents is likely to occur where an uninsulated rail return is employed. The Ministry of Transport Regulations limit the difference of potential between any two points on the uninsulated return to 7 volts. This has an important bearing on interference with telegraphs and the signalling on telephone circuits. Trouble does not usually occur where this regulation is complied with. If the undertaking is working within the limits laid down, it is usual to apply the remedy to the telegraph or telephone circuits. Trouble can usually be overcome by artificially increasing the resistance of the circuit so as to reduce the strength of the foreign current. Incidentally, this may of course involve increased battery power for the operation of the apparatus. A change in the earth connections may be effective; for instance, use of earth plates instead of connections to water pipes may be desirable, especially if the tramway negative busbar is earthed on a water main.

The currents and voltages in the usual tramway system with uninsulated rail return are totally residual, but as the current is direct, one would not anticipate trouble from induction, and, in fact, that was the experience until a few years ago when the rotary converter came into general favour. The earlier types of rotary converter did not, however, cause trouble. It is not for the author to explain this, but, superficially, one is struck with the great difference in size for the same output, and the greater air-gaps in the older and larger machines. It would seem that the general overall increase in efficiency brought, as usual, an evil in its train. In passing, it may be remarked as a strange development that in recent years there has been more interference trouble on this account from d.c. systems than from a.c. systems, which is a warning to those inclined to prophesy.

As explained earlier, harmonics are produced in d.c. as well as in a.c. systems. In the case of tramways there are two kinds of high-frequency pulsations which may affect the neighbouring telephone circuits. One of these, (*a*), is produced by the motor on the car, and results in a varying note being heard in the telephone receiver as the car gathers speed; whilst the other, (*b*), originates in the machine supplying the current and produces a constant note of high pitch in the telephone receiver.

In the case of (*a*), the disturbance is likely to be more intense if the bonding of the tramway rails is not in good order, and is more marked on systems where the trolley wires carry the whole of the current without supplementary underground feeders. Interference is not usually great unless the telephone wires and the tramway

run parallel for a considerable distance. In such cases good balance of the telephone circuits is essential in order to reduce the interference.

As regards (*b*), the effect upon the telephone service is more serious, as a strong disturbing field is sometimes produced, which may be detected at a considerable distance from the tramway system. The machine producing the disturbance is usually the rotary converter, and the causes and some remedies which may be applied to the machine are referred to on page 828.

If the tramway system is extensive, with substations feeding the system in common, the disturbance is usually more severe owing to balancing current constantly flowing in the trolley wires and feeders between the substations. Improvement will usually result if the substations work independently, i.e. if each substation feeds a portion of the system and there is no connection with other portions.

If the tramway undertaking has a stand-by battery at the station, the inductive disturbance will be reduced by placing the battery across the offending machine (see Fig. 29). The battery affords a low-resistance path for the ripples and, in addition, will tend to flatten the ripple in the external circuit by resisting changes due to the rise and fall in the voltage of the ripple. This method is not effective if there is an automatic booster machine in the battery connection.

If the ripple is of a well-defined frequency it should be possible to shunt it at the machine by an arrangement of capacity and inductance tuned to the frequency of the ripple (see Fig. 30). If the capacity and inductance are of the correct values the shunt will form a low-resistance path for the ripples, whilst affording no path for the d.c. supply to the system. The author tried this method experimentally some years ago with a certain amount of success, but the best results were obtained when a choke coil was added between the machine and the busbar. This method is similar to that described for use with mercury-arc rectifiers by Prof. Marchant in the appendix to this paper. It is understood that it is also used successfully in America. The best values for C (capacity) and L (inductance) are those which provide a resonant circuit, and this is obtained when

$$n \text{ (frequency of the ripple)} = 1/[2\pi\sqrt{(CL)}]$$

With these conditions the resistance of the shunt to the ripple will be the simple ohmic resistance in the shunt, and the effectiveness of the shunt will therefore depend on that being kept low.

Electric railways.—The electric railways of this country are in the majority of cases worked with direct current, exceptions being a short section of the London, Midland and Scottish Railway between Lancaster, Morecambe and Heysham, and a portion of the Brighton section of the Southern Railway in the London district.

Direct-current railways.—The conditions giving rise to interference are electrically comparable with electric tramways. There are, however, in this country relatively more systems using insulated returns, and with such systems interference by leakage and induction is not so likely to occur. On most of the systems a medium pressure is employed, viz. 550–600 volts, but there are two cases where a higher voltage is used. The London and North-Eastern Railway employs a 1 500-volt overhead contact system on a mineral railway between Shildon and Newport, near Stockton, whilst the L.M. and S. Railway employs between Manchester and Bury a contact rail at a pressure of 1 200 volts.

As railway tracks are usually well drained and the rails are on sleepers, leakage currents should be less

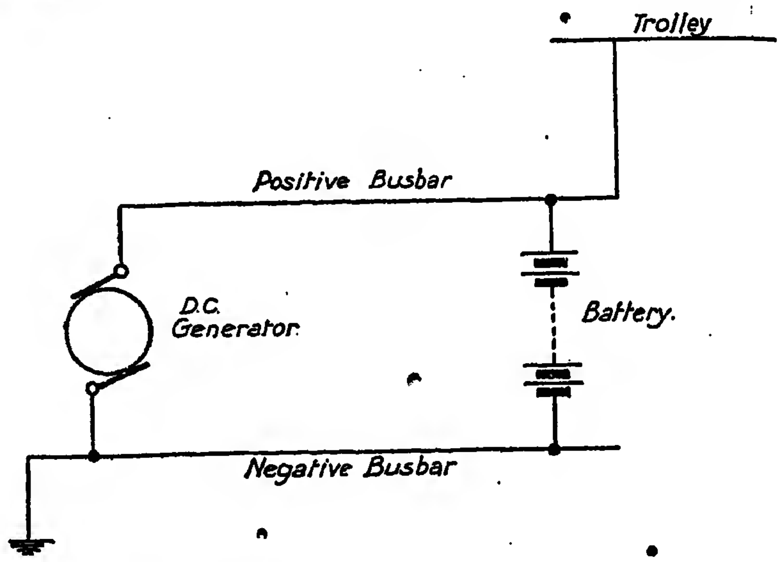

FIG. 29.—Shunting harmonic by means of stand-by battery.

than on tramway systems on public roads. Against this, however, has to be set the fact that some electric railway systems are not specifically limited by Ministry of Transport regulations as to voltage drop in the rails. The Ministry of Transport regulations referring to electric railways in metal-lined tubes limit the fall of potential in the uninsulated rail to 7 volts.

In the early days of tube working in London, a certain amount of trouble was caused to telegraph circuits. It

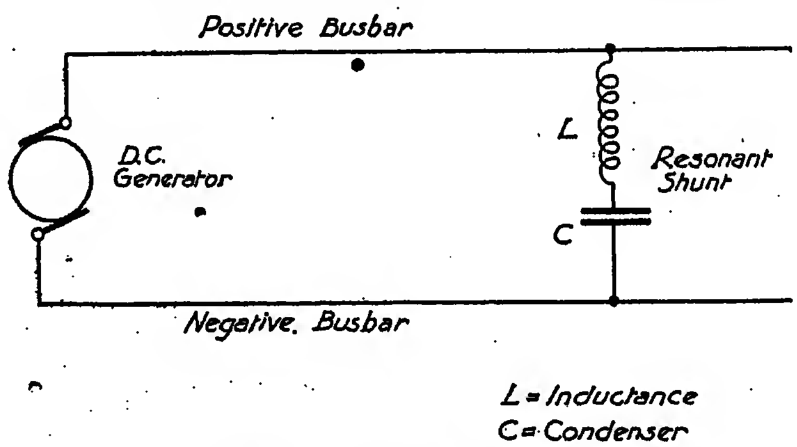

FIG. 30.—Resonant shunt across d.c. machine.

was found necessary to insert resistances in the lines and consequently to increase the battery voltages. In the case of the City and South London Railway, great improvement came with a change in the method of working to what is practically the same as the 3-wire system of electric light distribution, the live rails on the two tracks being the outer conductors, with the running rails as the neutral.

The great increase in the extent of electric railways in London has not brought about a corresponding increase in disturbance to telegraphs, and the author attributes this to the fact that, coincident with this

development, the Post Office brought the high-resistance polarized sounder into general use in London.

There was a certain amount of interference with fire-alarm circuits when the Metropolitan Railway electrification commenced in 1905, but this was overcome by changes in the earthing arrangements and by increasing the resistance of each circuit. The faults caused were more numerous when the first experimental trains were run, and, no doubt, certain weaknesses were removed on the railways as time went on.

Inductive effects will be influenced by the type of lay-out of the system. With the third-rail contact system in which the ordinary running rails are used for the return current the effects will generally be the same as with the tramway systems, modified by the fact that there will be less leakage to earth on a well-drained railway track, tending to produce less out-of-balance electromagnetically, and by the close proximity of the positive conductor to the earth surface reducing the electrostatic effects.

With the overhead contact system the conditions approximate to those of the street tramway systems except that the leakage currents should be less. In the case of railways using the fourth rail the system is more nearly balanced electrically and should be better from the point of view of interference.

Rotary converters are generally used for supplying direct current, and methods of reducing the harmonics produced by such machines have already been described. A certain amount of trouble has been caused by interference with telephones by d.c. railways employing rotary converters, and machines have had to be altered to overcome the interference.

The telephone circuits in these cases run alongside the track for a few miles with a relatively small distance separating them from the live rails and cables. The alterations to the machines to reduce the harmonics have resulted in the circuits being made workable with the telephone lines in good balance, but slight faults which previously would not have affected the working to any extent now make the conditions intolerable. To that extent the maintenance costs are increased, and, in addition, loss is incurred owing to the circuits being more frequently thrown out of use and having their earning power reduced.

Single-phase systems.—It is not for the author to take part in the old controversy of direct-current versus single-phase traction in its efficiency aspect, but one cannot avoid making certain comparisons between the two systems where interference with communication circuits is concerned.

The direct-current system, as developed in recent years, has certainly produced unpleasant and unexpected features in this respect, but undoubtedly the general experience with single-phase railways in many countries has shown that system to be the worse offender. The lay-out of the system has a most important bearing in this connection and many varying methods have been adopted, some of which will be described. It is difficult to obtain in all cases definite particulars of all the results in this respect, and there is some conflict of evidence. In some cases complete success in overcoming trouble is claimed, whilst, on the other hand, statements of a pessimistic character have appeared. An instance of the latter is an article by Zehme in the *Electrical World* of 5th March, 1921, which calls attention to the doubts in Germany as to the advisability of selecting the single-phase system for all German lines, especially in view of the induced voltage of 4 000 which was found to be rapidly destroying the signal cables on the Silesian mountain road. Further, a Swedish Commission reported against the alternating-current system and the Swedish Riksdag approved the plans of the new railway from Stockholm to Gothenburg only on condition that a satisfactory solution of all inductive disturbance should be found. On the other hand, there is a statement in M. Bachellery's recent paper* on "The Electrification of the French Midi Railway," to the effect that in the section experimentally operated on the single-phase system it was possible by taking apparently simple steps to work the communication circuits quite satisfactorily.

However that may be, the use of this system of traction is considerable. In Germany it is in favour and in Switzerland the system is very successfully used. In America the New York, New Haven and Hartford Railway is the principal railway working on the single-phase system, and a great deal of information on the results of the working of that railway has been published. The author has first-hand information on the inductive effects of the Lancaster–Heysham section of the London, Midland and Scottish Railway and of the more extensive Brighton section of the Southern Railway. Before giving details of the various experiences, he proposes to indicate briefly the conditions of working and the electrical arrangements which affect the question of interference. As members are aware, alternating current is supplied at extra-high pressure, usually at a periodicity of $16\frac{2}{3}$ or 25 per second, into an overhead contact wire fixed above and parallel with the track rails at a height of about 16 ft. The current is fed through a bow collector to a transformer on the train and from this returns through the motors to the source of supply via the wheels, rails and earth, and in some cases through subsidiary cables or wires. The effects upon neighbouring communication circuits can be summarized as follows :—

(*a*) Due to earth currents or leakage from the track rails;

(*b*) Electromagnetic induction from the trolley wires, track rails and (if any such are provided) conductors in the cables at the side of the track; and

(*c*) Electrostatic induction from the trolley wires.

(*a*) Earth or leakage currents are likely to be greater than with a direct-current system, as the impedance of steel rails is greater with alternating current. The Ministry of Transport do not appear to have laid down regulations as regards voltage-drop on the uninsulated rail return for this type of railway. A drop of 20 volts has been suggested as a reasonable figure, but it is a difficult matter to ascertain what the actual drop on the rails really is, as a reading, if made in the ordinary way, would include in addition to leakage the inductive effects of the system upon the testing leads and upon

* *Journal I.E.E.*, 1924, vol. 62, p. 213.

the rails and pipes in the ground near the track. It is possible partly to avoid these effects in the testing leads by using wires running nearly at right angles to the track with a long loop, but as regards rails and pipes it is a much more difficult matter, as the testing wires will form a closed path for the currents induced in the earthed bodies, and the direction of the current will be in opposition to the leakage current.

(*b*) Electromagnetic induction is the most serious feature of this system of traction. The power system of this type of railway is totally unbalanced in the case of the simple lay-out described later, and to some extent whatever precautions are taken. The fundamental frequency of the alternating current, which is usually 25, is such as to affect telegraphs, and it is generally telegraphs which are most seriously disturbed.

(*c*) The trolley wires being charged to a high potential, alternately positive and negative, produce static inductive effects or electric charges in all neighbouring open wires. The effects are reduced if there are earthed structures or wires in the vicinity of the overhead power conductors or of the communication circuits.

The results of induction or leakage to be expected theoretically have been worked out by a number of horizontal separations between the trolley and the communication circuit and the different percentages of the trolley current in the rails. For example, it has been determined that with 60 per cent rail current, that is, 40 per cent of the trolley current return flowing in the earth as stray current, the induced voltages per mile per 100 amperes in the trolley are in general about 10 volts, 5 volts and 1 volt, at 50 ft., 300 ft. and 1 000 ft. separation respectively. Thus at 50 ft. separation with 1 000 amperes in the trolley a 10-mile exposure would result in an induced pressure of 1 000 volts. These are maximum figures, in that they are based on the assumption that power is supplied in one direction only.

The worst conditions occur when the system has a simple lay-out, shown in Fig. 31, where the power system is quite unbalanced. Examples of this type of working are the Lancaster–Morecambe–Heysham section of the L.M. and S. Railway, the original New York, New Haven and Hartford Railway in the U.S.A., and others on the Continent. Experience with the system led subsequently to the introduction of modifications in the lay-out of the New York, New Haven and Hartford Railway and, it is believed, of many of the Continental lines.

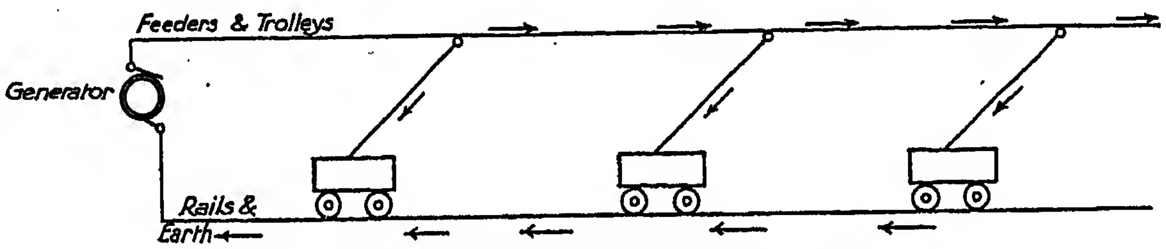

FIG. 31.—Single-phase system—simple lay-out.

investigators, but, as in all these cases of interference, the assumptions are many and the treatment is complicated by the very numerous factors. The electrostatic effects are very considerably modified by the presence of earthed bodies, wires, etc., in the neighbourhood of the power circuit and the communication circuit under review, and the electromagnetic effects are similarly greatly influenced by the amount of current straying from the rails. Where calculations have been made, however, very fair agreement with actual effects has been recorded. Such a comparison between theory and practical results is given in the *Elektrotechnische Zeitschrift* of the 6th, 13th and 20th May, 1915, in a communication from O. Brauns of the German Telegraphs Test Office on the disturbances to telegraphs in the neighbourhood of the Albtal Railway, the Wiesental Railway and the Dessau–Bitterfeld Railway. A most informative paper on the effects of a.c. railroads on communication circuits, by H. S. Warren, is contained in the *Transactions* of the American Institute (1918, vol. 37, p. 503). This gives particulars of the effects produced by four important American railway electrifications on telegraph and telephone circuits, and, whilst many of the effects are very serious, Mr. Warren is not pessimistic even as to the reduction of the excessive interference during abnormal conditions on such railways. As indicating the values of induced voltages, Mr. Warren takes 100 amperes in the trolley wire for different

It may be of interest if a few figures are given which indicate generally the effects experienced on circuits running parallel with the New York–Hartford line. In one case on a length of 23 miles, with a separation varying between 100 and 5 600 ft., the circuits had pressures of 300 volts induced in them. Circuits in cables situated from 300 to 5 600 ft. from the railway and roughly parallel for 25 miles had 170 volts induced at times of heavy load. Even a line 4–5 miles distant and parallel for 30 miles had induced pressures of 40 volts. In addition to the above voltages which were produced by the fundamental current of 25 frequency, there were higher frequencies produced by the motors when the trains were running, and these had a serious effect on the telephone circuits. When short-circuits occur between the railway trolley wires and the rails the voltages induced in the communication circuits reach values much larger than under normal conditions. These higher voltages operate the protectors and ring the subscribers' bells.

To overcome the large induced voltages, "neutralizing transformers" have been used on the telegraph and telephone circuits, with fairly satisfactory results. The application of these neutralizing transformers is based on C. F. Scott's patent specifications Nos. 14752–3/1907. Fig. 32 illustrates the underlying principle. The transformers contain either 18 secondary pairs and 8 primary pairs, or 22 secondary pairs and 8 primary pairs. The

wires joined to the primary coils are earthed at each end of the route or section exposed to the influence of the electric railway, and it is arranged that the induced effects of the primary wires tend to neutralize through the transformer the induced effect of the power circuits on the secondary circuits, that is, the circuits to be protected. The transformers are so designed that at a frequency of 25 cycles per second, and with a normal E.M.F. induced by the railway power circuit, an induced potential of 75 volts is produced on the secondary circuits opposing that due to the railway circuit. By arranging for a sufficient number of these transformers in series, it is therefore possible to nullify any induced potentials, each transformer disposing of 75 volts. The transformers give a transmission loss on all telephone circuits to which they are connected. This amounts with three transformers in a circuit to 0·6 mile of standard cable. It is stated that there is no appreciable "cross-fire" between the telegraph circuits working on the transformers, which will probably be the case with circuits worked at hand speed, but it is doubtful whether high-speed working would not be affected. It should be noted that the transformers are effective only in reducing voltage effects and have yielded no improvement in respect of the high-frequency noise on the telephone circuits. The transformers are very weighty, the heaviest type weighing about 1 500 lb., and they have to be protected by lightning arresters, which give considerable trouble. The railway company subsequently altered their system of distribution, and details of this are given later in the paper.

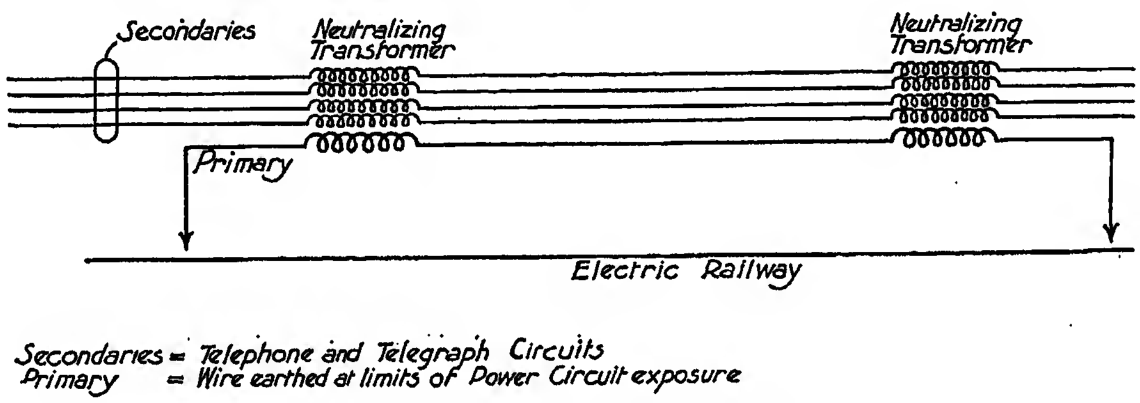

FIG. 32.—Neutralizing transformers.

The original single-phase railway between Dessau and Bitterfeld, Germany, was also worked with the simple lay-out referred to, a voltage of 15 000 at a frequency of $16\frac{2}{3}$ per second being employed. With the commencement of working, the telegraph line in the vicinity carrying foreign circuit could not be used, the circuits having to be diverted to other routes. Some tests made on the abandoned wires by O. Brauns are of interest. From the observed tests it was shown that with a 25 miles' exposure, and with full load on the power line, a voltage of 800 would be induced in neighbouring telegraph circuits. With a moderate load, 250 volts was actually measured, and to quote from a translation of an article on the subject: "It is consequently no longer remarkable that arc lamps which were connected to the wires at the Dessau Telegraph Office burned well."

The results of subsequent investigations on other wires in the neighbourhood as to the neutralizing effects produced by earthed wires and negative boosters are given in the paper in the *Elektrotechnische Zeitschrift* previously referred to. The amount of current found to stray from the rails varied in the three railways, it being 65 per cent on the Albtal Railway, 40 per cent on the Wiestental Railway, and 36 per cent on the Bitterfeld line. By the use of an earthed wire with an impressed "reverse" voltage, i.e. a voltage 180 degrees out of phase with the trolley wire, the electrical effect on a neighbouring wire, as measured by the charging current, showed a reduction of 53·7 milliamperes to 3·95 milliamperes, i.e. a reduction to 7·4 per cent.

As regards electromagnetic induction, it was found that wires in cable were affected to the same extent as open wires at equal distances from the rails. On the wires running parallel to the Bitterfeld railway for 22 km, with 100 amperes in the trolley wires the induced voltage varied between 90 and 95 volts according to the position of the wires on the arms. Four booster transformers of a type described later were provided to reduce the current straying from the track. This had the effect of reducing the induced voltage to between 5 and 19 per cent of the previous figures, according to the position of the train in the booster section.

The single-phase line on the London, Midland and Scottish Railway between Lancaster, Morecambe and Heysham was opened in 1908. The system is worked with a voltage of 6 000 to 7 000 at a frequency of 25, and the simple lay-out is employed, the feed being into the trolley wire with a rail return. The rails are connected to earth plates in the River Lune at Lancaster and in the sea at Morecambe and Heysham. It is stated that recording instruments in these earth connections have not indicated any current passing to earth. The Post Office had a few wires on the railway, the greatest exposure being a distance of about 3·5 miles. A number of tests made showed that the electromagnetic effect resulted in a pressure of 13 volts being induced in these circuits. This was at a time of light load and would no doubt be considerably higher with heavy traffic. There was a certain amount of interference with the telegraphs, but it was found possible to bias the instruments so that they work satisfactorily.

Some interesting experiments were carried out in co-operation with the railway company's engineers. In

the first case tests were taken to ascertain what actual loss of speech was occasioned by the noise induced in a telephone circuit by the railway. It was found that a telephone circuit running for a portion of its route on the railway had a speech value of 7 miles of standard cable with the railway not working. This was increased to 18 miles of standard cable with the railway in operation, i.e. there was a loss of 11 miles in audibility owing to the inductive effects of the railway. The wires of the circuit concerned were not twisted, however, and the railway company erected a properly revolved loop to ascertain whether the trouble could be overcome by that means. The experimental loop was found to be noisy, although the wires were properly regulated. With the railway not working, the circuit had a standard cable measurement of one mile; and with the railway working this was increased to 8·8 miles.

Another point was also investigated at the same time by the aid of this specially erected line. That was to ascertain what reduction in the electrostatic effects was produced by earthed wires in the neighbourhood. The railway company had provided an earthed wire between the contact wire and the telegraph route for this purpose. The position of affairs is shown in Fig. 33, which also indicates the position of the specially erected experimental line. The effect of this earthed wire, combined with that of the earthed telegraphs on the same line as the circuit under test, resulted in a

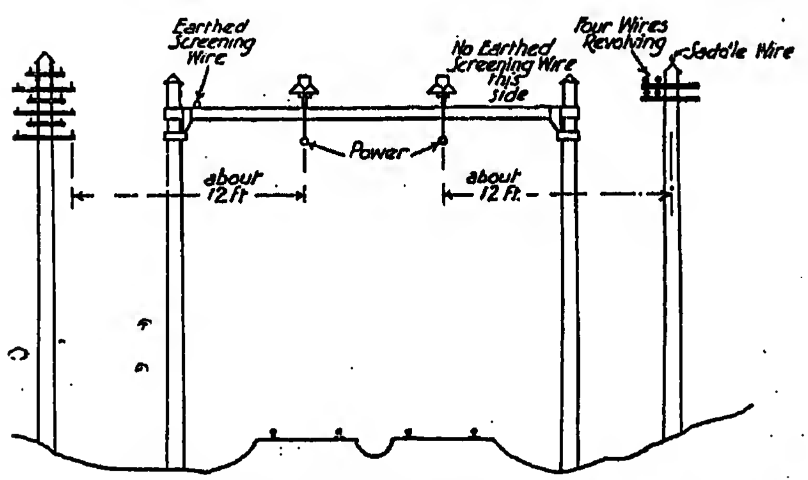

FIG. 33.—Showing relative positions of experimental lines and contact wires.

considerable reduction of the electrostatic potential. By comparison it was proved that the wire shown in the saddle position on the right-hand side of the figure, that is, on the side not provided with an earthed screening wire, was 320 volts, whilst the wire on the ridge of the screen side and of the same length as the other wire was charged to 48 volts only, a reduction of about 85 per cent. At the time these tests were taken, the saddle wire was the only one in position on the unscreened side. The tests were taken with a multicellular voltmeter and were roughly checked with a current measurement of the charge by earthing at one point through a high resistance, a thermo-milliammeter being used for the current measurement. These tests were taken with no trains running.

To ascertain more definitely the screening action of one or more wires on the same poles, No. 1 wire (shown in Fig. 33) was earthed at one point through a thermo-milliammeter, and the other wires were systematically earthed or disconnected as shown in the following table, in which are also shown the current readings with the varying conditions:—

TABLE 4.

The current strength will depend upon the resistance of the connection to earth. With similar conditions the charging current will be $I = 2\pi fCV$, where f = fre-

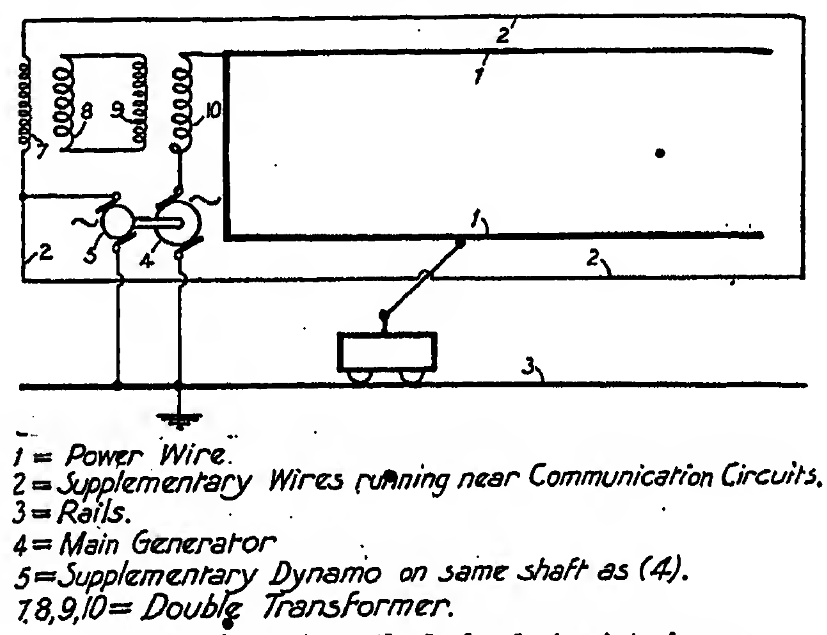

FIG. 34.—Sayers's method of reducing interference.

quency, C = capacity of communication circuit to earth, and V = charging pressure in the wire.

It may be of interest here to refer to a method, patented by Mr. Sayers* of the L.M. and S. Railway Company, for eliminating or reducing electrostatic and electromagnetic induction between contact wires and electric traction systems and adjacent communication circuits. Fig. 34 is a reproduction of the drawing in the patent specification. The method is briefly as follows:—Two special wires run in proximity to the wires interfered with where they are parallel to the railway. The special wires are charged from a dynamo which is running off the same shaft as the generator supplying the contact wires. The effect produced by this dynamo in the special wires counteracts the electrostatic disturbance produced by the trolley wires on the neighbouring circuits, as the two effects are 180° out of

* Patent No. 15 158/1909.

phase. In addition, the trolley wire is taken through a double transformer, of which the special wires form one of the windings. This arrangement is for counteracting the electromagnetic effect produced by the contact wire, as the currents in the contact and special wires will be similarly 180° out of phase. The author understands that this system was not actually brought into use.

Mr. Sayers also devised another method for reducing interference, and this was quite successful when tried

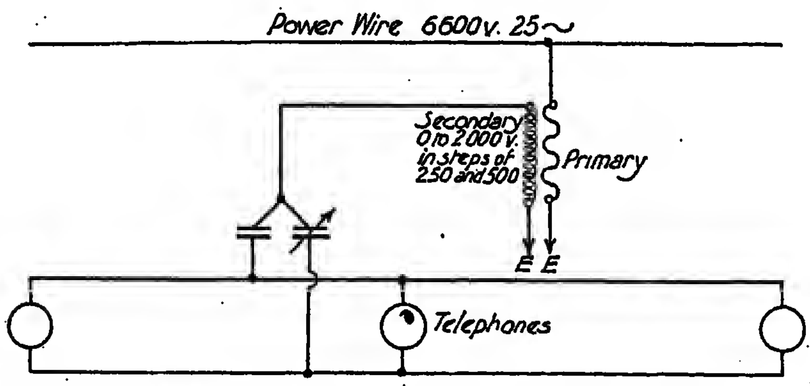

FIG. 35.—Sayers's method of reducing noise in telephone circuits.

experimentally by him. This is illustrated in Fig. 35. It will be seen that the telephone wires are electrically connected through condensers to the secondary of the transformer, the primary of which carries the power-circuit current. One of the condensers is variable.

The Brighton section of the Southern Railway is of interest in that a serious attempt has been made in the lay-out to prevent leakage and electromagnetic induction, and, although complete success has not been attained, the steps taken have undoubtedly minimized considerably the injurious effects likely to arise from those causes. The contact wires are sectionalized and are fed from feeder or distribution cables laid alongside the track. This reduces the electromagnetic disturbance to some extent, compared with the simple lay-out, as the current being fed into the trolley wire from opposite directions tends to neutralize the effects on neighbouring circuits. The principal steps have, however, been taken with the return of the currents, two conductors being employed to assist the return, apart from the rails and earth. One of the return conductors—the "distributor outer"—is connected to the rails by a copper bond. In the original installation between London Bridge and Victoria, each rail was connected to this distributor outer, but on the subsequent extension this has been modified, the rails being bonded together and connected to the distributor outer at intervals. The other return conductor, called a "booster" cable, is connected to the distributor outer, and thus to the rails, at a few points only. Both these cables run beside the track, and if the whole of the current returned in them it would have a considerable effect in counteracting the electromagnetic induction from the contact wires and the distributor. The action of the booster cable is as follows:—

At most of the feeding points a portion of the current is taken through a 1 to 1 transformer, to the secondary of which is connected the booster cable. The effect of this arrangement is to suck back the current through the booster cable, the E.M.F. produced by the transformer on the rails opposing any current returning in the rails. This action is illustrated in Fig. 36. Sir Philip Dawson has stated * that the distributor outer and the booster cable accounted for the whole of the return current between them, tests showing that with the booster cut out the distributor outer carried 84 per cent of the current and the booster 16 per cent. With the booster in operation, however, the booster cable carried back 100 per cent.

In spite of this arrangement, however, a considerable amount of trouble occurred with the opening of the section to the Crystal Palace and Tulse Hill. Many police and fire-alarm circuits were interfered with, and some public telegraph circuits. The operation of the latter was improved by the use of resonant shunts of the type already described. The faults caused on the police and fire-alarm circuits were sporadic and it was considered best to divert these and the police circuits from the track. The noise produced in the few telephone circuits concerned was not great—certainly not so disturbing as that experienced on circuits near the Lancaster–Heysham line. It should be observed, however, that the majority of the circuits affected were only exposed for short sections of route. A number of tests were made which showed that the electrostatic effects were inconsiderable. This is probably due to the earthed structures carrying the contact wires and to the numerous earthed telegraph wires on the routes. The electromagnetic effects could not, however, be ignored. On a telegraph line running parallel to the track for about 6 miles, with a separating distance

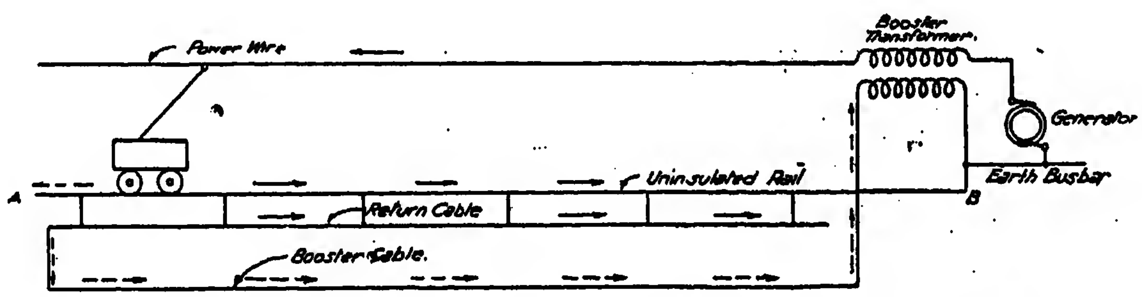

FIG. 36.—Booster and booster cables—Southern Railway (Brighton section).

The booster transformer produces between A and B an E.M.F. opposing that of current returning in the rail, return cable and earth, whilst providing an alternative low-resistance path through the booster cable.

varying between 20 and 90 ft., 30 volts (R.M.S.) was induced.

There are no high-speed telegraph circuits on the railway as at present electrified, but tests with high-speed transmission showed that satisfactory working would not be possible on this particular line. Perfect signals could be transmitted, with the railway not working, at 200 words per minute. With an induced voltage of 20 these signals were unreadable. Even with lower speeds, such as 40 words per minute, an induced voltage of 11 mutilated the signals.

There are other methods of producing better balance on this type of railway which are variations of that employed on the Southern Railway (Brighton section). Figs. 37, 38 and 39 indicate the application. The method can be followed from the figures, the object being in all cases to reduce by means of boosters the current straying from the rails, with the addition in the last two cases of line connections which tend to neutralize further the effects of the current in the contact wire by providing return overhead conductors.

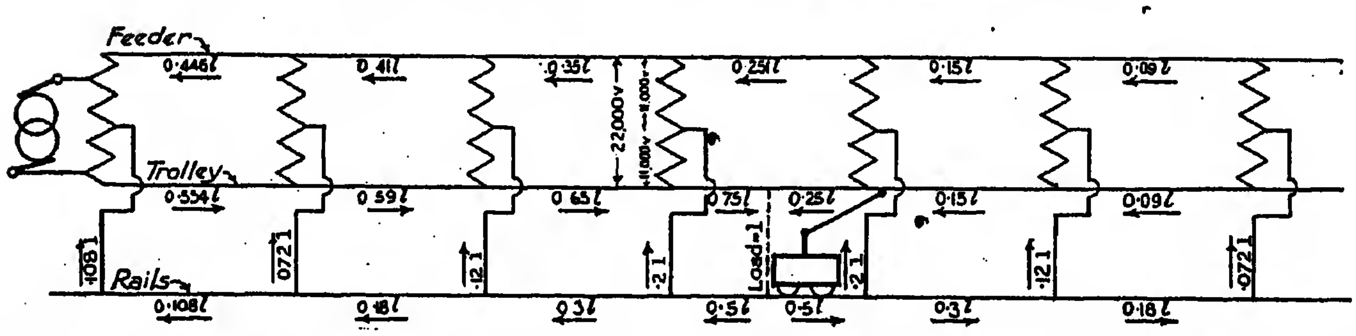

FIG. 40.—Lay-out of New York–New Haven Railway. Single-phase railway electrification: auto-transformer distribution system.

The New York, New Haven and Hartford Railway adopted a different method of working in the early part of 1914, the general lay-out being shown in Fig. 40. A 25-frequency current is delivered from the power station at 22 000 volts. One terminal of the 22 000-volt

transformers is connected to four feeders, two on each side of the track. The other terminal of the 22 000-volt transformer is connected to the trolley wires in multiple, the middle point of the 22 000-volt transformer being connected to the rails. There is thus 11 000 volts between the trolley wires and rails, 11 000 volts between the feeders and rails, and 22 000 volts between the trolleys and feeders. At intervals of about 2 miles west of the power station, and at greater intervals east of the power station, there are connected between the trolleys and feeders 2 000-kVA auto-transformers having the middle point connected to the rails. These transformers are for the purpose of balancing the load on the system. With this scheme of distribution, assuming a train to be located in a section between two auto-transformers, the current delivered to the locomotive from the trolleys would flow along the rails in opposite directions from the locomotive, the division of current east and west depending upon the location of the train, and portions of the current would be delivered back to the overhead wires by the auto-transformers on either side of the location of the locomotive in about the following ratio:

Assuming that the current flowing in the rails in one direction from the locomotive is unity, 40 per cent would be delivered to the overhead system by the nearest auto-transformer; 40 per cent of the remainder, i.e. 24 per cent of the total, by the second, and 40 per cent of the remainder by the third, and so on. This scheme tends to minimize disturbances upon paralleling telephone and telegraph lines, for the following reasons:—

(1) Excepting where the load is near the end of the line or near the power house, the unbalanced currents in the rail and earth flow in opposite directions from the location of the locomotive and in about equal amounts; and
(2) The distance over which the track currents flow is greatly reduced.

It is stated that this method has been of much benefit in reducing stray currents and has effected improvements in the inductive problem connected with this railway.

The author is, perhaps naturally, prejudiced against a system of electric traction which is likely to have such deleterious effects on communication circuits, but he is not without hope that a satisfactory solution of the problem will be found. It has apparently not been found so far, as a recent communication in the *Teknisk Tidskrift* (vol. 53, pages 45–51) by A. Holmgren, states that the shifting of the telephone lines from the Stockholm–Gothenburg railway will cost 68 million kronor (say £400 000) for the ordinary lines, and 17 million kronor (£100 000) for the railway communication lines. This fact is significant, following, as it does, an inquiry by the Swedish Government into the matter.

Electric light and power systems.—Electric light and power systems in this country are classified according to voltage employed under four headings:

Low pressure: up to 250 volts.
Medium pressure: 250 volts to 650 volts.
High pressure: 650 volts to 3 000 volts.
Extra-high pressure: above 3,000 volts.

It has not been usual to employ direct current at higher pressures than 500 volts on electric light and power circuits. Distribution of energy in the great majority of cases is by means of underground plant, but there has been a considerable increase in the number of overhead lines in recent years.

Leakage.—Electric light and power systems are not allowed to have more than one earth connection on each distinct circuit, with certain few exceptions, and this restriction has an important bearing in preventing interference by leakage currents. The Regulations of the Electricity Commissioners lay down that the insulation of a power system shall be such that not more than 1/1 000th part of the maximum supply current returns via the earth connection.

Interference by leakage currents occasionally occurs as the result of faults on low- and medium-pressure power systems, but they are not common. Faulty insulation on a power system may not in itself actually result in leakage currents affecting telegraphs or telephone circuits, but may produce inductive disturbance owing to the unbalancing of the currents in the different conductors of the power system. An example of this type of case was that which occurred many years ago when practically the whole of the telegraph service to the Continent was stopped owing to the use of the earth as a return on the 10 000-volt single-phase system between the West End of London and Deptford. The power-cable route followed the South-Eastern Railway, on which were also the Continental telegraph circuits, and it was the inductive effects which interrupted the service. The interruption was reported in the Press at the time as having been due to "an electric storm."

Induction.—So far as inductive effects are concerned, the great majority of electric light and power systems used generally for distribution purposes do not materially affect communication circuits. Only metallic circuits are allowed, and the use of underground cables predominates. Where underground power mains cause trouble, it is usually associated with the employment of a generator having a bad wave-shape on a three-phase system with the neutral point earthed. In other cases, trouble may arise from faults. For instance, the outer of a concentric cable carrying single-phase current may develop an earth, and this may result in different values of current in the inner and outer conductors owing to the leakage, as concentric cables are usually definitely earthed at the feeding point. Cases of interference with overhead telephone circuits have occurred from both these causes. The author has had experience with one rather severe case of interference from an underground three-phase line affecting an overhead trunk line running parallel to it for about 3 miles, some features of which are perhaps worth mentioning. The system was a 6 000-volt one with the generator earthed at the neutral point and feeding direct into the cables, which were of the usual type, armoured, lead covered and laid direct in the ground, except for certain sections where the cable was placed in troughing filled in solid with bitumen. The inductive effect was found to be entirely due to the charging current produced by the third harmonic and its multiples. The noise in the trunk circuits disappeared with the removal of the

earth connection. A curious result was noticed when listening with a search coil on the cable route. Whilst a very pronounced note was picked up at all points where the cable was laid direct in the ground, at places where the cable was laid in the bitumen, and in the station where the cable sheathing was isolated from earth, hardly any noise could be heard. This effect was no doubt due to the whole of the earth capacity current being in the sheathing at these latter points and so neutralizing the effect of the capacity current in the cores. In passing, it should be remarked that the trouble was cured in the first instance by removing the earth from the alternators and providing an alternative earth at a transformer in the generating station. Later, a very high resistance (paper layers) was substituted for the direct earth connection at the generators, with satisfactory results.

As might be anticipated, overhead power lines are more likely to produce interference than those underground, and serious cases are confined to high-pressure and extra-high-pressure systems. The fact that overhead power-transmission systems follow cross-country routes has no doubt been a saving factor in this country, as there is much less chance of communication lines running parallel with power lines for any appreciable distance.

Standard practice with power transmission is to employ a three-phase 3-wire system. With pressures up to 11 000 volts, generators feed directly into the overhead lines. Above that pressure, step-up transformers are employed. Fig. 41 illustrates various arrangements that may be made :—

(*a*) Generator to line.
(*b*) Transformers delta-delta.
(*c*) Transformers delta-star.
(*d*) Transformers star-delta.
(*e*) Transformers star-star.

The method employed for connections has a very important bearing on the possibility of producing interference owing to the development of the third harmonic or multiples thereof.

In the case of star-connected three-phase systems with the neutral point earthed, the third harmonic in each of the conductors is in phase and this causes an alternating voltage to appear between conductors and earth of a frequency three times that of the fundamental. With only one earth on the system, i.e. at the neutral point of the star winding, the three wires are raised or lowered in voltage simultaneously in respect to the earth, and the effect on neighbouring communication circuits is wholly electrostatic and, generally, telephone circuits only are affected. If the power system is extensive, however, and other conditions are favourable, telegraph circuits may also be interfered with, as the charging current may be of considerable magnitude. If there be a second earth on such a system, a single-phase current will circulate between the two points over the three conductors in parallel, with the earth as return. This arrangement may be particularly undesirable from the point of view of interference.

(*a*) Generators supplying three-phase current and having the neutral point earthed are very prone to produce third harmonics and multiples thereof, and if such a generator be connected directly to an overhead line inductive troubles may be experienced on neighbouring communication circuits. The removal of the earth connection will remove the inductive interference. Modern practice, however, appears to be definitely in favour of working with an earthed neutral and as, in addition, an earth may be required in connection with the operation of protective gear on the power system, this course is usually objectionable and alternatives have to be found, if possible. Machines vary considerably in this matter of producing third harmonics, and it is frequently found that where several alternators are in use at a generating station, there is usually one which either is innocuous in this respect or produces very much less inductive interference; and if the earthing is arranged to be made at that particular machine, interference effects are removed altogether or made inappreciable. In other cases it may be found to have satisfactory results if the earthing be done at the neutral point on a step-down transformer instead of at the neutral point on the generator. Fig. 42 illustrates the arrangement. A transformer with a delta on the secondary side is the most effective, or, alternatively, a zig-zag star-connected transformer would probably be equally effective. The rating of such a transformer would no doubt have to bear some relationship to the capacity of the system and to the characteristics of the protective gear employed. The author has no information as to this. A simpler solution is the employment of a paper resistance in the earth connection. This provides what is practically an isolated neutral during normal conditions, and can be arranged to break down and provide a direct earth on the occurrence of a fault.

Where a generator has the neutral point earthed and supplies power to an overhead line through transformers, the type of connection of the transformers is of great importance from the point of view of inductive interference. The following briefly analyses the position (see Fig. 41).

(*b*) Delta-delta. There is no inductive interference from the third harmonic or its multiples. The third-harmonic magnetizing current circulates in both windings. There is a third-harmonic voltage in the windings but no third harmonic in the voltage or transmission line.

(*c*) Delta-star. The inductive interference effects are usually small. There is a third-harmonic magnetizing current in the primary winding only. A third-harmonic voltage appears between the lines and neutral on the line side and produces a third-harmonic current between the lines and earth.

(*d*) Star-delta. The inductive effects are only on the primary side. The third-harmonic magnetizing current circulates in the secondary winding only. The third-harmonic voltage appears between the line and neutral on the primary side. There is no third-harmonic voltage or current in the transmission line.

(*e*) Star-star. This is the worst condition for inductive interference. There is no third-harmonic magnetizing current. A third-harmonic voltage appears between the lines and neutral on both primary and

secondary sides, and the third harmonic current flows between the lines and earth if the neutral is earthed.

It will be seen that (b), delta-delta, is the best arrangement, and (e), star-star, the worst. A tertiary winding in the latter case will reduce the inductive effects.

The usual arrangement in this country is delta-star with the neutral point earthed.

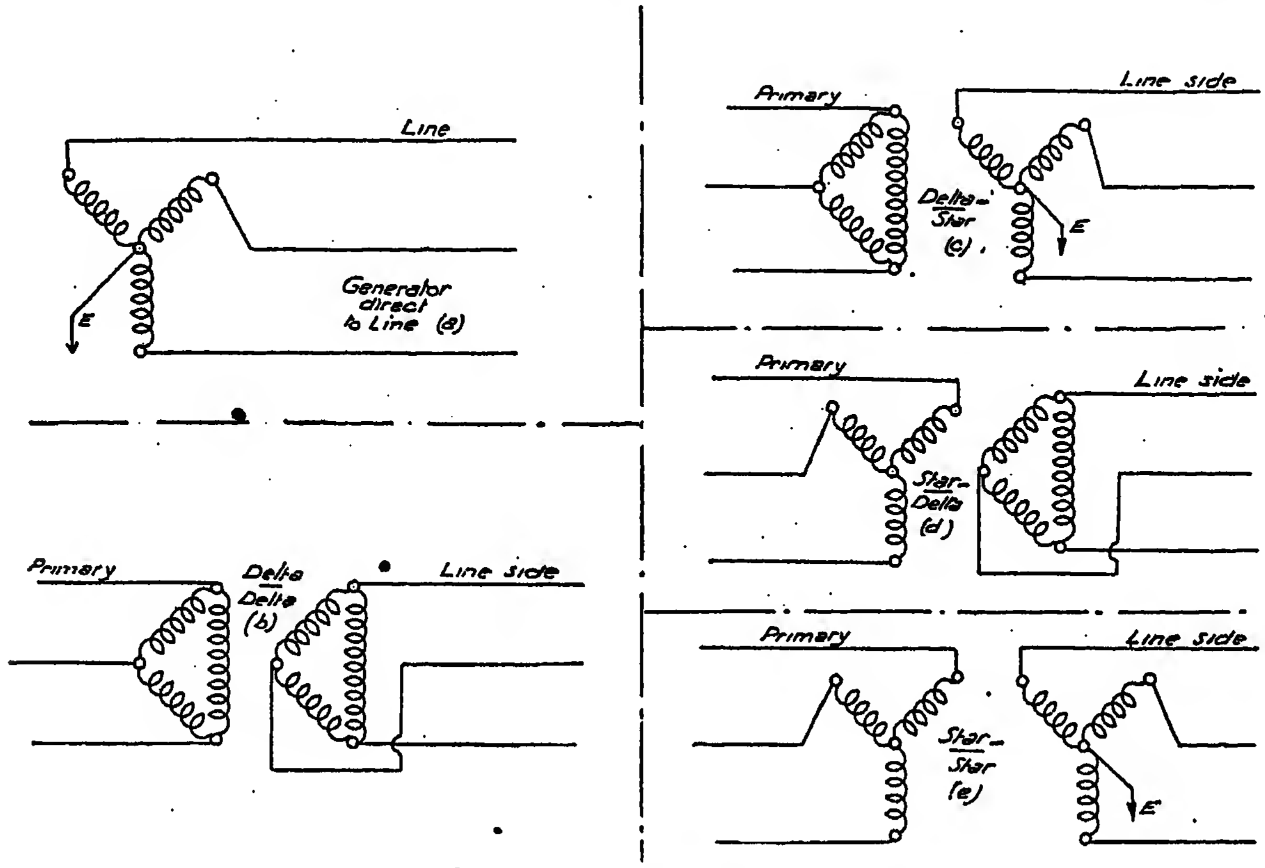

Fig. 41.—Generator and various transformer connections.

Interference from balanced voltages and currents on the power lines is not usual in this country. These effects depend upon the formation of the power lines, separation between the conductors and, as in all cases of interference, the distance between the power line and the communication circuit. It can be taken that the greater the spacing of the power conductors, the greater will be the magnitude of the inductive effects from these causes. Power wires have, however, to be given ample spacing in order to avoid short-circuits from wind, birds, etc. The avoidance of short-circuits is of importance from an interference point of view, as well as from the operating standpoint, as transient disturbances of a serious character may be caused by them. The power wires on supports either form an equilateral triangle, are horizontally in the same plane, or are arranged vertically one above the other. The last is the best arrangement, taking into account the effects of balanced voltages and currents. As pointed out in the relevant section, interference from balanced voltages and currents can be overcome by transposition of the power wires in the exposed section, so that each power wire occupies each of the conductor positions for equal distances in relationship to the communication circuits.

Multiple earthing on power systems.—Power systems may be connected with earth in accordance with Regulations made by the Electricity Commissioners for securing the safety of the public and ensuring a sufficient supply of electricity. Earth connections made for other purposes may be approved by the Electricity Commissioners subject to the concurrence of the Postmaster-General. The general practice in this country has been to allow only one earth connection on each distinct circuit. There have been exceptions; for instance, in the case of the constant-current series system of the Metropolitan Electric Supply Co., where an earth return on sections between substations is permitted in the event of repairs being required. It will be remembered that on this system the direct current is maintained constant at 100 amperes, the voltage varying with the load. The Electricity Commissioners' earthing approval stipulates generally that the earth connection shall be made at a neutral point on the system, the exception being in the case of a single-phase supply with a concentric cable having the outer earthed. The limitation of one earth connection is made primarily in the interests of the owners of communication circuits

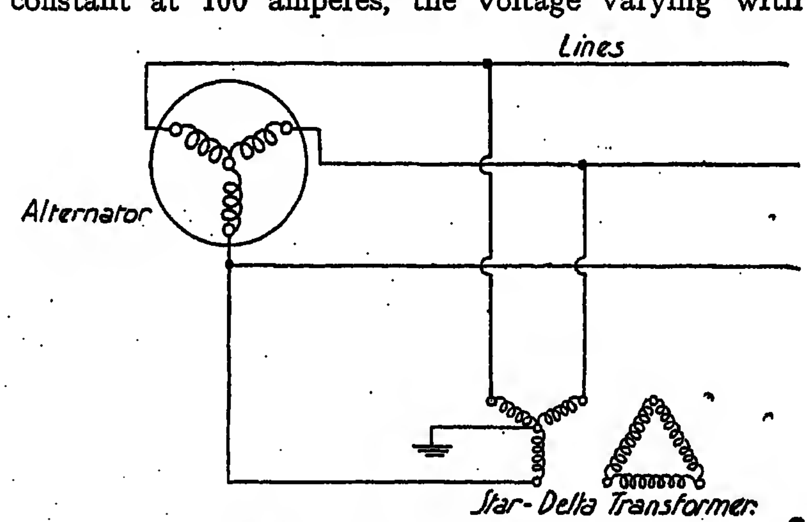

Fig. 42.—Earthing transformer.

(Post Office, railways, etc.) whose services might otherwise be injuriously affected. As pointed out earlier, interference may be produced by the residual voltages and currents with one connection only on a three-phase system; and, theoretically, two connections on such systems have always been considered to be particularly undesirable, as charging currents in such circumstances become circulating currents through the two earth connections. Practical experience has confirmed this in many cases, as the earthing of power circuits at more than one point has caused serious interference, especially in those cases where three-phase generators with the neutral point earthed have been feeding directly into a system and a second earth has unwittingly been made at a transformer or auto-transformer in the network. In 1920 it was found that the telegraph circuits between Newcastle and Sweden could not be worked at speeds high enough to carry the traffic, and the laying of another submarine cable was being seriously considered. No reason could be assigned for the failure to attain the proper speed of working, and power circuit interference was suspected. With the co-operation of the power company the cause of the trouble was traced to a second earth connection having been inadvertently made permanent following a fault. The removal of this second earth resulted in the speed of working on the submarine cable being raised by 12 per cent, and with it the need for another submarine cable disappeared. A very large sum of money was involved, as, the author understands, an expenditure of over £100 000 would have been required for the provision of such a cable.

The great growth of the power systems of the North-East Coast has brought into prominence difficulties in connection with the operation of protective gear where there is interconnection of networks and only one earth connection. The continuance of faults on this system in some cases resulted in serious disturbance to telegraph and telephone circuits. In one instance a fire was started in a terminal hut by the induced voltages in the communication circuits. The power company pointed out that whilst the provision of more than one earth connection might increase the interference from normal working of the power system, it would certainly decrease the possibility of serious trouble arising out of momentary disturbances of larger magnitude, and would reduce the risk of these latter continuing for any appreciable time. It was agreed that it would not be wise to have more than one earth on a circuit directly connected with a generator the neutral point of which was earthed, but it was contended that with delta-star

SCHEDULE OF TESTS.

Time	Neutral earthed at	Time	Neutral earthed at
11 a.m.	Philadelphia (instrument damaged).	2.45 p.m.	Philadelphia, North Tees, Bowden Close, Dunston.
11.15	Philadelphia, Dunston.	3.0	Philadelphia, North Tees, Bowden Close, Dunston, Carville.
11.30	Philadelphia, Dunston, Carville.	3.15	Philadelphia, Dunston, North Tees.
11.45	Philadelphia, Dunston, Carville.	3.25	Philadelphia, Dunston, North Tees, Carville.
1.45 p.m.	Philadelphia.	3.35	Philadelphia, Dunston.
2.0	Philadelphia, North Tees.	3.45	Philadelphia, Dunston.
2.15	Philadelphia, Bowden Close.	4.5	Philadelphia, Dunston, Carville.
2.30	Philadelphia, North Tees, Bowden Close.	4.15	Dunston, Carville.

In the tests at 11.15 and 11.30, Philadelphia was solid to earth. At 11.45 Philadelphia earthed through the resistance. In all the other tests in which Philadelphia enters, the earth is through a resistance. At 3.15 and 3.25 North Tees should have been clear but was not, and no readings were taken there over this period.

Vertical lines having no curve continuation mean that places were earthed but no readings were taken. Small barbs above and below the North Tees curve represent maximum and minimum readings.

transformers feeding a system, the triple-frequency currents would be small and would not be likely to increase to any extent the normal interference. Sir John Snell suggested that the matter should be put to the test by co-operation between the Post Office and the companies concerned, and a series of observations was arranged to be made with various conditions. The currents in the earth connections were measured with the different combinations, and arrangements were made to note the effects on telegraph circuits with various types of apparatus, and also on telephone circuits.

The currents in the earth connections at the various points are shown diagrammatically in Fig. 43. It will be noticed that the 0·6 ampere on one earth connection increased to 3·6 amperes with all the earths in use.

The telegraph circuits under observation were not affected, and although there was an increase in telephone interference this was inappreciable. It should be pointed out, however, that the routes of the communication circuits under observation were not very favourable for interference. As the result of these tests, multiple earthing on the North-East Coast systems has been agreed to, subject to certain qualifications, which include an embargo on generators feeding directly into a circuit. The matter of interconnection of this latter type of system was dealt with in a paper* on "The Parallel Operation of Electric Power Stations," read by J. S. Peck before the Institution.

Transient effects from abnormal conditions.—The earthing of power lines by means of a Petersen coil has found favour in some countries. The purpose of the coil, which is a reactor, is to limit the severity of accidental faults which might otherwise interrupt service or endanger equipment. In this method, the neutral of the system is earthed through an inductance which is in resonance at the fundamental frequency with the total direct capacity of the system to earth. The arrangement has the effect of suppressing arcing faults to earth, tending to extinguish the arc and prevent it from re-striking. The effect of this on the interference problem was not apparently mentioned in Petersen's original description in the *Elektrotechnische Zeitschrift* of the 2nd and 9th January, 1919, but it is clear that, if effective, it will reduce the chances of inductive interference during abnormal conditions on a power system. The effect of the reactor in modifying the conditions as regards inductive interference during normal operations has been analysed by H. M. Trueblood in an important article in the *Bell System Technical Journal*, July 1922. For the reduction of the effects of triple-frequency residual currents and voltages, the reactor appears to be preferable to earthing through a resistance, but, on the other hand, it will accentuate the effects of fundamental frequency if the power-line is unbalanced. It is possible, however, that the Petersen coil will not combine with any of the standard protective systems.

A paper by S. Kudo and S. Bekku in the *Journal* of the Japanese Institution, May 1923, deals with the placing of a high resistance in the neutral earth connection, and states that this suppresses normal interference, but it is not known whether transient effects are reduced.

* *Journal I.E.E.*, 1917, vol. 55, p. 61.

Conclusions.

It will no doubt be agreed that the problem of inductive interference is not simple, and, although the troubles cannot be said to be serious in this country, one can foresee that they may become so if due consideration is not given to the possibilities. Many interests are concerned and the author would place responsibility for solving the problems in the following order:—

First, the designer, who by producing machines free from harmonics can practically eliminate the whole trouble with telephone circuits.

Secondly, the power engineer, who can plan his system to be balanced as regards loads and lines, employ transformers with connections least likely to cause trouble and worked at a low magnetic density, and by proper precautions and maintenance reduce faults on his circuits.

Thirdly, the telephone engineer, who, by designing his circuits and apparatus in such a way as to reduce the possibilities of out-of-balance and by the proper maintenance of his lines, can do much to avoid interference.

Fourthly, the protective-gear engineer, who, last but not least, will prevent those breakdowns which result in very serious trouble due to abnormal happenings in the power system. These may be transients but he must endeavour to make them micro-transients.

It is perhaps impossible to produce rotating electric machines free from harmonics, and similarly it must be expected that there will be some distortion of wave-form in power transformers owing to the employment of iron in the magnetic circuit, but the author suggests that if those responsible are made aware of the significance of these features in connection with the interference problem, they will be kept within reasonable limits.

APPENDIX.

METHOD OF GETTING RID OF TELEPHONE INTERFERENCE FROM A MERCURY-ARC RECTIFIER.

By Professor E. W. MARCHANT, Member.

A method has been devised by which the voltage ripple found in some types of converting machinery can be almost entirely got rid of. The particular case dealt with was a mercury-arc rectifier, and the oscillograph record of the voltage wave is shown in Fig. 44. The

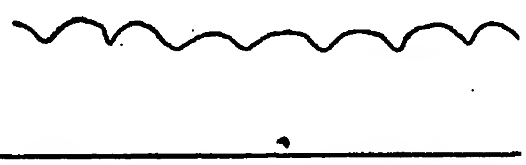

FIG. 44.—Rectifier d.c. voltage: 470 V.

voltage variation amounted to $\pm 9 \cdot 5$ per cent of the average steady P.D., and when current was supplied for lighting purposes from the circuit it gave rise to considerable disturbance in neighbouring telephone lines. An analysis of the voltage showed that it consisted of a ripple of about 300-cycle frequency, but that there was also present a component of 600 cycles. The analysis also showed that the higher harmonics of the voltage wave were relatively small. The actual figures obtained in the analysis of the first, second, third, fourth and fifth harmonics were as follows:—(1) 9·5 per cent; (2) 2·5 per cent; (3) 0·8 per cent; (4) 0·83 per cent; and (5) 0·42 per cent. It was thought that if the first two ripples could be eliminated, the remaining higher-frequency harmonics would not cause any serious trouble, and this actually proved to be the case.

A method which suggests itself for a single-phase rectifier is to use a shunt consisting of an inductance and capacity in series, and to adjust the inductances and capacities to be of zero reactance for the ripple frequency and so practically to short-circuit the rectifier for currents of ripple frequency. Instead of applying such a circuit to each arc circuit of the rectifier, it was decided to use a single circuit, tuned to the frequency of the resultant ripple of which the analysis is given. This arrangement (Fig. 45) was found to be quite successful in dealing with the "6 arc" circuit, the ripple current through the shunt distributing itself along the different arc circuits in succession. If, however, this shunt circuit is used alone, a relatively large current of several hundred amperes will pass through it and through the different arcs, and the reduction in voltage variation will not be very marked.

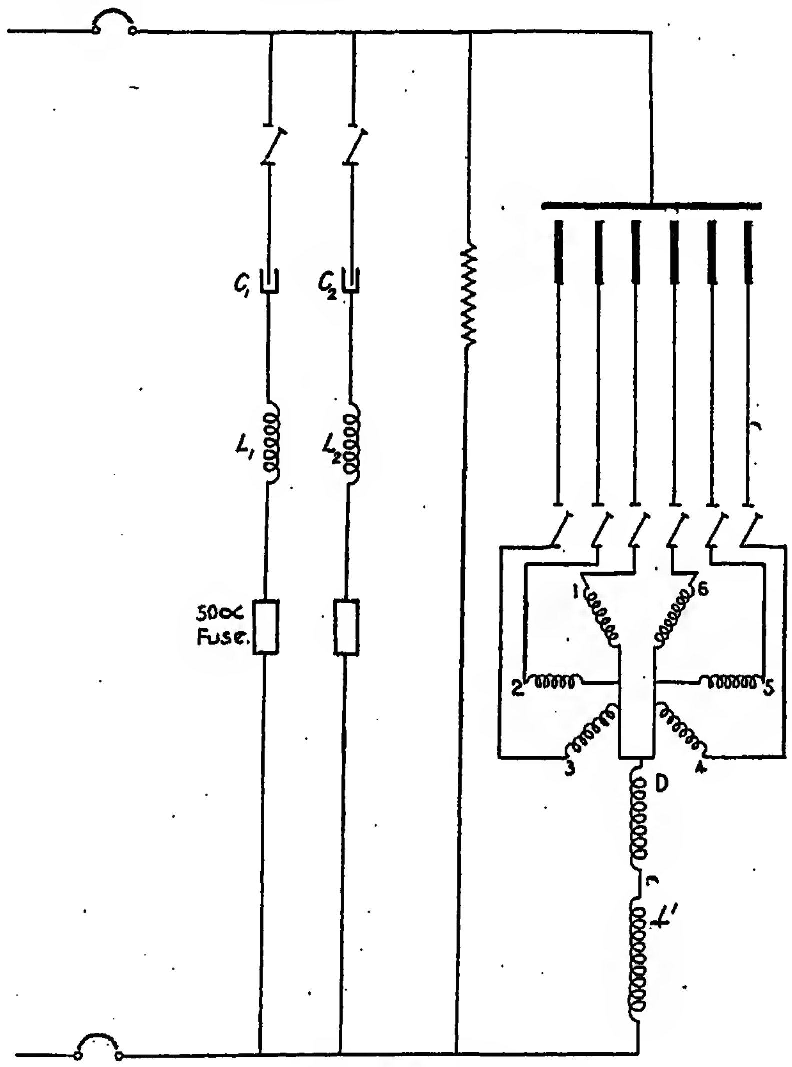

FIG. 45.—Diagram of circuit.

In order to limit the current, an additional single inductance coil L′ is placed in the main circuit of the rectifier, the currents through the various branches of the rectifier combining to flow through this inductance and being reduced to as small values as may be considered necessary. The effective impedance of the shunt, for the ripple which it is desired to get rid of, is equal to its effective resistance only. The value of the effective resistance, however, is not simply the ohmic resistance, but includes the effective resistance due to iron loss in the choking coil (if iron is used) and also the effective resistance due to the dielectric loss in the condenser. This latter, however, is as a rule very small. The R.M.S. current, i, flowing through the shunt is determined by the magnitude of the voltage ripple and is equal to $v\sqrt{/[R^2 + (L'\omega)^2]}$, where v is the R.M.S. value of the voltage ripple, R is the effective resistance of the limiting inductance and the shunt, L' is

the value of the limiting inductance and $\omega = 2\pi \times$ (frequency of ripple). The voltage across the shunt when this current is passing is equal to iR, and the ratio of the voltage ripple before and after introducing this arrangement is, therefore, given by $\sqrt{[R^2 + (L'\omega)^2]}/R$. By increasing the value of L' in comparison with R, it is therefore possible to reduce the voltage ripple on the main supply to negligible dimensions. In designing the shunt circuit the consideration which is of most importance is the maximum voltage which will be produced on the condenser; approximately this equals $i/C\omega$ and, therefore, if the voltage is to be reduced, the value of the capacity used must be increased. At the same time, the value of $L_1\omega$ must be kept equal to $i/C_1\omega$, where $\omega = 2\pi \times$ (frequency of the ripple). The condenser C_1 of course prevents any direct current passing through the shunt circuit, and the current flowing through the shunt due to ripples other than that for which the inductance and capacity balance, is relatively small.

Owing to the high frequency of the ripple current, it is advisable to use an air-core inductance at L_1, and in some cases stranded wire, in order to reduce eddy currents in the windings. In the actual shunts used, the power condenser was insulated for 600 volts (maximum). It was decided to design the shunt so as to reduce the voltage variation from $\pm$ 44 volts to $\pm$ 1 volt. The shunt was designed to carry a current of 10 amperes. The R.M.S. value of the voltage ripple was about 31 volts and the reactance of the limiting inductance ($L'\omega$) was approximately 3 ohms. The iron-cored inductive coil L′ was made with approximately this reactance and was arranged as shown in the diagram. There is a steady voltage of 460 on the condenser and therefore only 140 is available for the ripple, if one is to keep within the safe working limit of the condenser. The value of the capacity used was 100 μF, which gave a voltage variation on the condenser of 53 volts (75 volts max.). A rather smaller capacity might have been used, but it was thought better to provide an ample margin of safety against breakdown, as the maximum voltage due to the ripple may be twice the normal maximum voltage (i.e. 150 volts) at the instant at which the condenser is switched on. The power factor of the condenser is 0·0016 and the effective resistance is therefore 0·0085 ohm. The value of the reactance

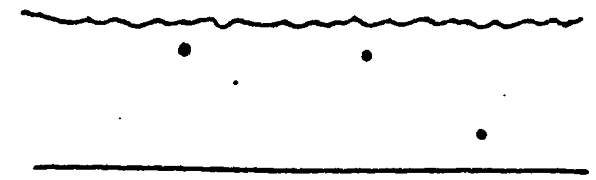

FIG. 46.—B rectifier voltage; 1st circuit connected.

$L_1\omega$ in the shunt was 5·3 ohms, ω being equal to 600 π. This gave $L_1 = 0{\cdot}00282$ henry. A similar shunt was designed for the second harmonic for which the frequency is 600 cycles per second, and the maximum amplitude of the voltage was 11·5 volts. In this case a capacity of 50 μF was used and an inductance of 0·00141 henry. The current flowing through this shunt was estimated to be about 2 amperes, and the resistance corresponding to this current, in order to reduce the voltage variation to 1 volt, would therefore be about

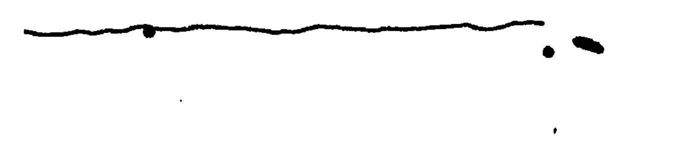

FIG. 47.—C rectifier voltage; two circuits connected; no load except auxiliary resistance.

0·5 ohm. The shunts were adjusted by experiment before being installed, but, when being fitted, a coil connected to a valve amplifier was hung near the busbars and the shunts were adjusted until the noise heard in the telephone connected to the amplifier was a minimum. The effect of using these shunts is shown in Figs. 46 and 47. It will be seen that the ripple is very much reduced by using the first shunt only, and when both shunts are connected the voltage ripple shown on the curve (Fig. 47) is almost negligible.

DISCUSSION BEFORE THE INSTITUTION, 10 APRIL, 1924.

Mr. A. J. Stubbs: We probably all recognize that the path of progress is to be looked for most advantageously in the way of co-operation. Some problems are awaiting solution, and others, which we fail to recognize for want of co-operation, can only be solved in that way. One instance of the benefit of co-operation is the cable relay of S. G. Brown. I think it is right to say that that relay could not have been designed by a telegraph engineer as such, neither could it have been conceived by a power engineer as such. It is due to the adventitious combination of the two qualities in one individual that we own that very useful invention. I have found that power engineers are very interested in the illustration on page 839. Given a power circuit in close proximity to a theoretically perfect telephone circuit, when, in the ordinary course of business, that perfect telephone circuit is put through to another less perfect circuit, it may very well be that, although both the original telephone circuits are good and useful by themselves, in combination they may possibly become unworkable. It is reasonable to suggest that no power engineer in the course of his ordinary experience would imagine that such a result would occur. Again, it is difficult for the power engineer to realize the magnitude of the interests that are jeopardized by the minute details which the communications engineer has to press upon his notice. The conductors themselves are smaller than the difference between two adjacent sizes of conductors which the power engineer uses; but the author shows on page 854 that inadvertently allowing a temporary second earth to remain on the power circuit in the short distance between Newcastle and the English coast nearly involved the laying of a new submarine cable at a cost of over £100 000. The author includes in the bibliography Prof. Hughes's researches on induction, but does not mention his

name on pages 831 to 869, and this omission seems to give countenance to the idea that the cross-over system is American. It is not. When the application in practice of Hughes's researches was first introduced by Preece at the Post Office, the cross-over system was fully considered, but the fact that the sections of uniform routes in England were so short forced us to the conclusion that a complete transposition of the circuits at every fourth pole was best calculated to meet our requirements. I doubt whether, if it were possible to produce the plans of the cross-over system that I evolved by Preece's instructions at that time, there would be found to be any material difference between them and Fig. 19 of the paper.

Prof. E. W. Marchant: As the author says, the greater part of the trouble due to interference is caused by the higher harmonics which occur in power distribution systems. A frequency of 25 periods gives an unpleasant hum in a telephone, but does not seriously interfere with speech. Mr. Osborne gives the relative effects of current at 1 000 frequency and 25 frequency as 60 000 to 1. That seems to be a very big figure, and I should imagine that it would depend to a very considerable extent on the observer. I should be glad if the author would state whether any other figures are available in this connection. One matter which we have investigated to a considerable extent in Liverpool is referred to on page 841, viz. the presence of higher harmonics of current in the neutral return of a power distribution system. It is, of course, well known that, when there are a number of alternators in parallel (the neutrals being coupled together), unless the alternators are exactly similar to one another, very large currents, of three times the fundamental frequency, will flow between the neutrals. I do not think, however, that it is so generally known that if there is an earth on only one of the alternators, and these are connected to a three-phase cable network with earthed sheath, a very considerable current flows from the generators through the capacity between the lines and the sheath to earth, and so back to the generators. The currents that will flow from the conductors to the sheath will be of either three times or a multiple of three times the fundamental frequency. I do not think that these currents are likely to cause any very serious interference between power circuits and telephone circuits if suitable precautions are taken, but it is well to realize that these currents flow, even when only one alternator neutral is earthed, provided that the cable system is earthed also. They only flow between the earthed neutral point of the alternator and the earth of the cable system. It is, of course, comparatively easy to avoid harmonics in the voltage waves of alternators. An alternator which is designed to give a pure sine wave is certainly the best solution; but there are also other methods. The author says that he regards the earth connection as being an essential part of the telephone system. It seems to me that if main-line railways are electrified, the prevention of interference with telephone systems if there is an earth connection on the telephones will be a matter of very great difficulty. I should think that the best way of getting rid of interference would be to use metallic circuits only on telephone systems and to avoid earth circuits, except in certain special cases. I should like to refer to the method invented by Mr. Turney and myself for getting rid of harmonics. The reason I do so is that Fig. 9 in the paper is not quite correct. The object of the method described was to get rid of components in the pressure curve between the neutral point and any phase, which were three times, or a multiple of three times, the fundamental frequency. If there are such harmonics present in an alternator there is no component of the triple frequency or multiple of the triple-frequency component in the voltage between the lines. The pressures in the three phases due to the triple-frequency components are in phase, and therefore there is no triple-frequency component in the line pressure. The only place where the triple-frequency component has to be eliminated is between the line and the neutral. The essential feature of the method is a connection, such as is shown in Fig. A, of shunts

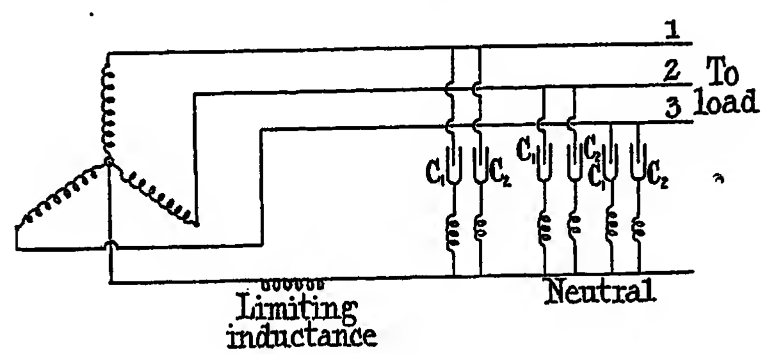

FIG. A.

between the lines and the neutral with a view to getting rid of the triple-frequency component between those two points. The double set of shunts, C_1 and C_2, shown in the figure can be used for getting rid of two of the high-frequency components of the pressure. The advantage of this arrangement is that a single limiting inductance can be used, which only carries the triple-frequency (or multiple of triple-frequency) shunt currents, and which, therefore, need not be of such large dimensions as if it were carrying the whole load current.

Mr. E. Parry: The author refers on page 835 to some theoretical investigations of my own into the phenomena of electrostatic and electromagnetic induction between power circuits and telegraph and telephone circuits. He also refers to some confirmatory experiments conducted by Messrs. Marsden and Caldwell. Those investigations were instituted with the object of establishing a method of predetermining the induction for any given combination of circuits and disposition of conductors, and the results went a long way towards achieving that object. Amongst other results it was discovered that no correction is necessary to bring the equations into harmony with facts, in the simple case of a single power circuit acting upon a well-insulated parallel conductor. Neither is any correction necessary on account of the proximity of other conductors, so long as they also are insulated. A considerable disparity was, however, disclosed between theory and experiment in the case of electrostatic induction between a 66 000-volt power circuit and a pair of telephone con-

ductors carried on the same poles and distant only 6 ft. 6 in. from the plane of the two lower conductors. The value of the impressed voltage was observed to be 1 730 volts, as compared with 3 565 volts calculated. The disparity is evidently due to the fact that the insulators supporting the telephone line were incapable of sustaining such a high voltage, and were draining the charge to earth. A much more interesting case than the one referred to, and one of more practical importance, is the case where a pair of three-phase 11 000-volt power circuits occupy one side of a road, and telegraph and telephone circuits occupy the other side. Such a combination is of frequent occurrence in other countries, though rather an exception in Great Britain, and the question arises how far the two services can be run in parallel under given conditions. I now submit a contribution to the solution of the problem, which may be of particular interest to some members of the Institution. The power circuits are three-phase and each circuit consists of 19/14 conductors triangularly spaced 2 ft. apart. The plane of the two lower conductors is 27 ft. 4 in. above the ground, and a distance of 5 ft. 4 in. separates the upper conductors of the two circuits. The telephone or telegraph wire acted upon is assumed to be No. 11 S.W.G. and the frequency is 50 cycles per second. The pressure between phases is 11 000 volts, and the current is assumed to be 100 amperes per phase. Fig. B shows the variation of the electrostatic induction with the distance measured from the centre line of the pole carrying the two power circuits to the vertical line through the telephone or telegraph wire, and the

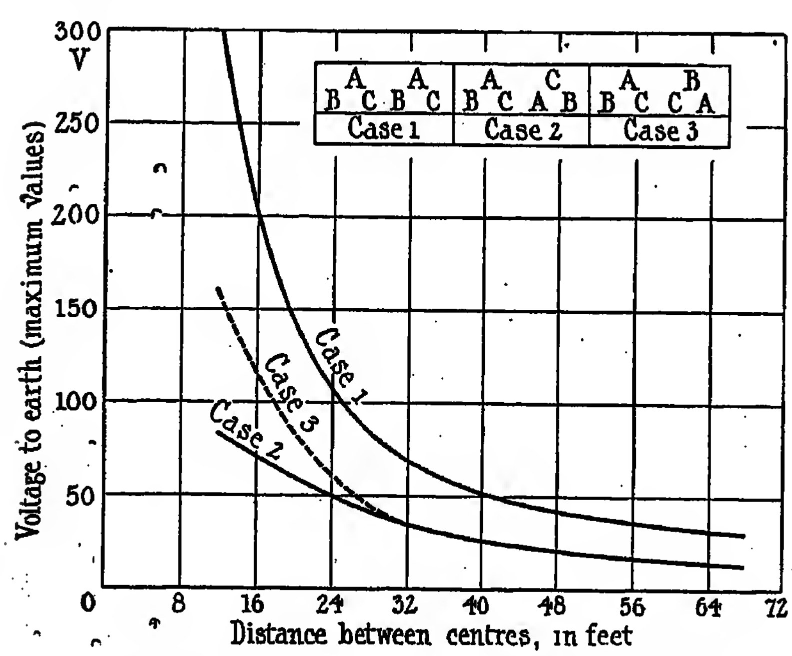

FIG. B.—Electrostatic induction between power and telephone circuits.

Power circuits: 19/14 at 2 ft. spacing, 11 000 volts, 50 periods, three-phase. Telephone circuit: No. 11 S.W.G.

impressed voltage is given for three conditions of phase. In the first case the two power circuits are symmetrical, in the second case the phase of one circuit is rotated in space through 120° with respect to the other circuits, and in the third case the phase of one circuit is rotated through 240° in respect to the other circuits. It will be seen from the figure that the lowest induced voltage is obtained under conditions specified in case 2 above, also that the induced voltage at a distance of about 66 ft. is of the order of 10 volts. Fig. C shows the electromagnetic induction in volts per mile at different distances between the circuits and for the three different conditions already specified in the case of the electrostatic induction. It will be noted that

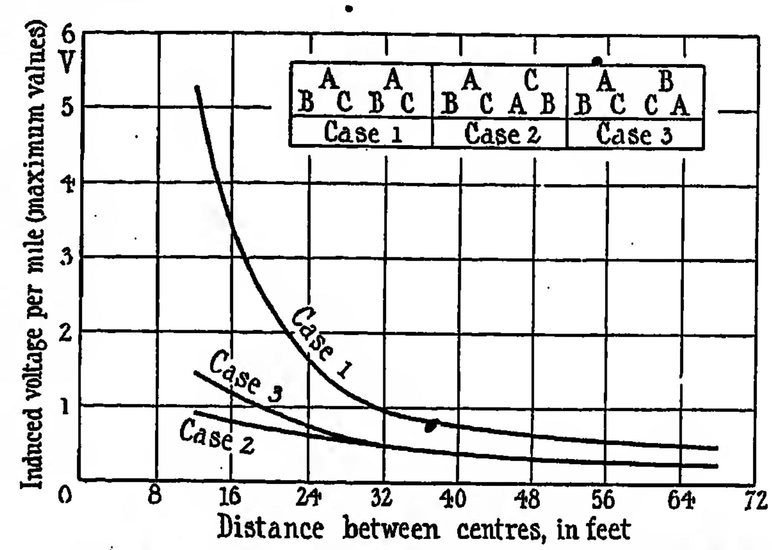

FIG. C.—Electromagnetic induction between power and telephone circuits (100 amperes, max. value, in each power circuit).

Power circuits: 19/14 at 2 ft. spacing. Telephone circuit: No. 11 S.W.G.

the curves for cases 2 and 3 merge at a distance of about 32 ft. and that the values of the induced voltage for distances in excess of 32 ft. are one-half that in case 1, the value in cases 2 and 3 at a distance of 66 ft. being 0·25 volt per mile per 100 amperes. The figures do not, of course, represent the whole of the circumstances, but they form a basis of discussion and of an arrangement between the two conflicting interests.

Mr. W. J. Thorrowgood: At the time when the City and South London Railway was first brought into operation the London and South-Western Railway had a telegraph circuit between Nine Elms and the City in Arthur-street, just near London Bridge, and after the trains had started we were surprised to find that a stray current flowed which interfered with the working of the telegraph. We found that the addition of a resistance to the circuit reduced the stray currents from the electric railway so that it did not interfere with the telegraph. The voltage of the working battery was increased to compensate for the added resistance. We generally find that there are two sorts of interferences, for short distances and for long distances. I am more interested in short distances because of the signalling and block circuits on the line which are, of course, very much more important than telegraph circuits. We find that for all these short circuits the only remedy for stray currents is to provide insulated metallic circuits. In the electrified area and in the neighbourhood of London, and also many places in the vicinity of tramways, we have to provide metallic circuits throughout for both telegraphs and signals for short distances. Short-circuits on electric lighting systems are sometimes very serious in their effects. For instance, a short time ago the main switch of an electric motor in a saw-mill was put to earth, with the

result that all the earth circuits for three miles around were affected. On one of our telegraph circuits between London and Shepperton we have to add a resistance of 900 ohms in order to reduce the stray currents sufficiently. As a matter of fact the earth all over the country has a difference of potential from one spot to all others, and this potential varies continuously. Table A gives some of the measurements which I have taken. Although telegraph engineers have asked power engineers to give them consideration, I think that they themselves have to give consideration and readjust their apparatus so as to come into line. On the South-Western section of the Southern Railway we have numerous telephones over the electrified area and there is no interference at all. As to the proximity of the telegraph wires and telephone wires to the power line, with a railway it is rather a serious question to separate them widely; as a matter of fact it can hardly be done without widening the railway. In some cases where the Brighton and South-Western sections run parallel with the Brighton section electrification we thought that there might be some trouble, but on the telegraph lines on the South-Western section, running parallel with the Brighton electrification at Clapham Junction, no effect whatever was found.

TABLE A.

Difference of Potential between Towns, as measured by Stray Earth Currents.

Circuit	Distance	Resistance of circuits tested	Average current varying in direction	Occasional momentary value of current	Difference of Potential
	miles	ohms	mA	mA	volts
Waterloo–Woking	24·5	312	2 to 6	20	0·624 to 1·872 and 6·2
Waterloo–Guildford	30·0	202	4 to 10	20	0·81 to 2·025 and 4·05
Waterloo–Portsmouth	73·25	803·75	0 to 10	15	0 to 8·03 and 12·02
Waterloo–Salisbury	83·75	3 247·5	0 to 3	—	0 to 9·74
Waterloo–Exeter	171·5	7 000·0	0·1 to 0·4	—	0·7 to 2·8
Exeter–Waterloo	171·5	7 000·0	0·2 to 1·0	—	1·4 to 7·0
Waterloo–Exeter	171·5	6 675·0	0·16 to 0·4	—	1·068 to 2·67
Waterloo–Exeter	171·5	3 524.0	0·2	—	0·7048
Waterloo–Southampton ..	78·5	2 285·25	0·1 to 1	—	0·2285 to 2·285
Waterloo–Dartford	19·0	2 634	nil	—	—
Waterloo–London Bridge ..	1·25	1 500 ohms added to circuit which was dispensed with when circuit put through to Dartford.			

Tests were made on different days. The stray currents varied in strength and direction continuously during each of the tests.

Mr. R. A. Mack: The subject of interference has grown during the past 10 or 20 years from one of interest to one of very great importance. I do not think that it is an exaggeration to say that from the points of view of both power and communication engineers it is one of the big problems which demand careful consideration and which justify considerable expense and investigation. The paper deals almost exclusively with communication circuits over open wires. It is hard to understand the reason for this, seeing that the majority of telephone lines now being put down in this country, in Sweden, in Switzerland, in France, in Italy, and in practically every country in Europe, are not open-wire lines but cable circuits. The author may reply that with cable circuits one can neglect interference; in fact, on page 820, in one of the few references that he makes to cable circuits, he says, after referring to certain disabilities present in the case of open-wire lines: "Circuits in underground cables are, of course, not included in the above list of disabilities." With telephone or telegraph cables, provided the sheaths are earthed, electrostatic induction is, of course, eliminated and the standard of precision in the manufacture and installation of good modern telephone cables is so high that the effects of electromagnetic induction are very materially reduced. Cables, however, are not a certain cure. The author refers on pages 846 and 847 to two good examples which show very clearly that one cannot regard cables as a means for completely avoiding inductive interference. On page 822 circuits for noise measurement are given, but that illustrated in Fig. 3 dates back, I believe, to 1913. There is an instrument using a later circuit, now widely employed in America and in Europe, which is more portable and with which very good work has been done. In spite of the inherent difficulties in obtaining precision with noise measurement, this instrument in the hands of the Bell System engineers has enabled a fairly complete technique in noise measurement to be developed. It is now possible to predict with fair accuracy the influence upon intelligibility of a given amount of noise. The circuit of this instrument was described in a recent paper* on "Transmission Maintenance of Telephone Systems" before this Institution. It is important to remember that the "noise unit" in which this instrument is cali-

* *Journal I.E.E.*, 1924, vol. 62, p. 658.

brated is but one-twelfth that for the circuit described by the author. On page 845 the author touches on the question of the relative advantages, from the inductive-interference standpoint, of d.c. and single-phase a.c. systems. I am not sure that it is altogether fair to refer to this question in a paper which does not mention electrolysis, although the title may perhaps give just cause for expecting reference to electrolysis. But whether or not his remarks are correct regarding the single-phase system having given more trouble than the d.c. system, it is, I think, quite fair to say that, if such be the case, the single-phase system or the communication systems which he has in mind are badly designed. There are examples in Europe which indicate definitely that the single-phase traction system can be run parallel with and in close proximity to a communication system without causing difficulty. The first lantern slide shown by the author indicated a typical condition in Switzerland where the routes of the power system and the telephone system cannot be separated. In Switzerland there are cases of single-phase traction working over routes with very steep gradients and in close parallelism with communication circuits, where noise causes no difficulty whatever. In some cases it has been necessary to install high-grade telephone cable to ensure this immunity. The same point is indicated by the recent decision in Sweden to employ the single-phase traction system on the railways, notably the line from Stockholm to Gothenberg. It is of interest to remark that in this case the Administration have decided to use a cable laid actually alongside the rails from Stockholm to Gothenberg, a distance of approximately 300 miles. Provided that proper care is taken with the power or traction system, whether a.c. or d.c., and provided also that proper care is exercised in selecting the right telephone system and material, there is no reason why adequate protection from, or avoidance of, these difficulties cannot be obtained. I am not sure to what extent British manufacturers of power machinery have given close attention to this matter, but I suspect that some of the Continental manufacturers are ahead of them. Some Swiss companies in particular have considerable experience in the design of machines which are free from interfering effects. On page 839 the author states that "a properly balanced circuit for commercial purposes is taken as one which would be undisturbed by other telephone or telegraph circuits working on the same route." This remark might give the power engineer the impression that the telephone engineer is content with his circuits so long as they do not interfere one with the other. If a power engineer does get that impression, he is certainly getting the wrong impression, as modern telephone plant provides numerous examples of features in which the telephone engineer is providing something to take care of the liability of power interference. The precision methods now employed in the manufacture and installation of modern long-distance cable systems are to some extent the outcome of the necessity for reducing this liability. Numerous cases could be quoted where the balance upon communication circuits is to a considerably higher standard than is necessary from considerations of interference between communication circuits. Two further examples which might be cited are the use of the three-coil system for loading phantomed circuits, and the utilization of dust cores in loading coils. The three-coil system ensures that any current which may be induced from a power system influences both sides of the phantom circuits equally and so avoids a condition of unbalance which would result in serious power interference upon the phantom circuits. With alternative systems, notably the four-coil system, this condition does not exist, and a telephone system using this type of loading is liable to serious interference. The use in loading coils of cores made from very fine, insulated particles of iron dust ensures that the risks of core magnetization from induced currents are reduced to a minimum. There is, of course, a great deal of information yet to be gathered upon the general subject of power interference before the best economic solution for its prevention in any given case can be determined; and in this work much investigation by both power and telephone engineers will be necessary. The greatest factor towards the satisfactory solution of the outstanding problems will be a spirit of helpful co-operation between these two bodies of engineers.

Mr. G. V. Twiss: The author deals with the matter of single-phase systems where uninsulated earth returns are used, and shows that such systems are particularly disadvantageous from the point of view of communication circuits. It is sometimes thought that single-phase systems using uninsulated earth returns may present advantages in the matter of giving supplies to small villages and outlying rural districts, but I think that that is rather a short-sighted view, as such a system can only be economically justified so long as the transmission lines are less than fully loaded. When full electrical development does come—and I imagine that it must come to this country—I think that it will be found that the more normal three-phase systems will be far more suitable. Therefore, although I think it is sometimes held that the Postmaster-General is at issue with the industry on this point, nevertheless in my opinion his view does not conflict with the interests of the electric supply industry. Then, as regards the use of the more normal three-phase systems, the author shows that inductive interference is largely due to earthing, but then apparently only due to residuals in the three-phase circuit, which residuals in turn are chiefly due to the presence of harmonics, when the connections of the transformers are such as to permit the propagation of such harmonics in the line. From that may be deduced the attitude of the Postmaster-General in respect to the matter of earthing. There are so many advantages to be obtained from earthing that it seems to me that the first thing to do is to make provision for earthing, and then to find means whereby earthing will not lead to results harmful to communication circuits. That seems to me to be the correct method of attacking the problem. The recent 220 000-volt systems in California could not run unless they were earthed. Turning to the legislative side, it would seem that permission to earth is something which the Electricity Commissioners themselves can give, subject, however, to the concurrence of the Post-

master-General, which is liable to be withdrawn at any time. It would be extremely unfortunate if the Postmaster-General were ever to exercise such right. In view of the fact that such interference as already indicated is due to other things than earthing, I am surprised that the Postmaster-General should pick out that one thing and disregard the other questions of harmonics and transformer connections, particularly in view of the fact that in Section 69 of the 1899 Act it is made incumbent upon undertakers to see to it that their lines and works—which presumably include such things as transformers, etc.—shall not harmfully affect the communication circuits of the Postmaster-General. That would seem to be an umbrella under which the Postmaster-General can always shelter, and it is difficult to know why he wants another and smaller umbrella, as it were, to catch the drops that might fall off the larger one. There is still another aspect of the case. The Commissioners, if they think fit, in cases where they deem earthing to be necessary for the safety of the public, can give authority therefor without any reference to the Postmaster-General. I do not think I am alone in the view that earthing is in all cases a matter which affects the safety of the public. It is a concomitant of protective systems, and as regards overhead lines it gives a more certain method of causing the line to be shut down in emergency. It would seem, therefore, that the whole matter of earthing could stand, as it were, upon the basis of safety of the public. As regards the protection of the lines, the requirements of the Postmaster-General differ from those laid upon undertakers by the Electricity Commissioners. All these things add to the difficulties of the industry, and in my opinion some of them are difficulties which we ought to try to avoid. In that connection the author refers to the development which he thinks will come about in this country. I would supplement what he says in this matter. In my view the development of the electrical industry in this country is a vital matter. It is essential that development shall take place on lines far bigger and broader than we have ever contemplated. In my opinion we shall never achieve the full development of this country, not only electrically but nationally, until we have adequate interconnections, networks and distribution systems generally on the broadest possible lines. It is therefore very apropos that the author should have ventilated the possible effect of development of electric supply upon the Postmaster-General's lines, at a time when such development is still immature, and whilst it is, therefore, not too late to endeavour to apply ameliorative measures.

Mr. A. J. Aldridge (*communicated*): The author has referred to a telephone interference-factor meter

suggested by Mr. H. S. Osborne as a result of investigations carried out in America.* It is an arrangement whereby the disturbance on telephone lines caused by different frequencies in alternator harmonics is measured. Different frequencies produce different effects on telephone lines, and the measuring device "weights" accordingly the different frequencies occurring in the alternator waves. Fig. 1 in the paper shows the curve on which the "weighting" is based. A warning is necessary as to the use of such an instrument. Fig. 1 is practically an average resonance curve for a telephone receiver of the present day. Should this curve change —15 years ago the average resonant frequency of a receiver was about 750 periods instead of 1 100—the "weighting" allotted will be quite wrong. I think that it is a mistake to rely entirely upon a variable factor such as the receiver resonance point to obtain the relative disturbing effect of different alternators. A second test should also be made without this weighting, as mentioned on page 822. On pages 826 and 827 the author refers to the use of resonant shunts to eliminate harmonics. Can he give us any further information as to the construction of these shunts and as to their real effect? In many supply systems the equivalent station load will be a small fraction of an ohm, and to be effective the resistance of the resonant shunt must be much lower than this. One would anticipate some difficulty in building at a reasonable cost an inductance coil having the desired characteristics. What is the attitude of the supply authorities towards this remedy? As showing the magnitude of these high-frequency currents which may be circulating quite unknown to the supply authorities, I should like to draw attention to Fig. D. This shows the current (nominally direct) flowing between the station busbars and two rotary converters supplying them, in a tramway system. Rotary converter No. 4 was supplied from a three-phase transformer, and converter No. 2 from three single-phase transformers, all fed from one alternator. The low-frequency curve is simply a timing wave. Three points should be noticed: (1) The magnitude of the ripple; (2) the difference in the ripple from the two machines; and (3) the difference in the ripples in the positive and negative leads of machine No. 4. The two curves marked 15 were taken simultaneously each from 100 turns of wire wound directly over the respective cable leads, close to the machine. The oscillograph strip showing the smaller curve was very slightly more sensitive than the other. I should be glad to know whether the author has encountered any similar occurrence and can give any explanation of the effect.

* *Proceedings of the American Institute of Electrical Engineers*, 1919, vol. 38, p. 261.

Mr. J. Collard (*communicated*): In discussing the methods of minimizing telephone interference the author points out that none of the remedial measures so far devised for application to the telephone circuit is suitable for use with public telephone systems. The only means at the disposal of the telephone engineer, therefore, apart from those measures applicable to the power system, is an improvement in the balance of the telephone circuit. This necessity for a high state of balance in telephone circuits exposed to induction from power circuits is brought out very clearly on page 839, under the heading "Telephone Circuit Balance." The great importance of telephone circuit balance being recognized, it becomes necessary to devise some method by means of which this balance may be measured, so that, where necessary, definite values may be specified and circuits may be tested to determine whether their balance is above or below the permissible value. A suitable method for accomplishing this on a circuit subject to interference was described in a recent paper * on "Transmission Maintenance of Telephone Systems." Briefly described this method consists in the measurement, by means of apparatus described in the paper, of two values of noise, (*a*) the noise between the two wires of the circuit, and (*b*) the noise between the two wires of the circuit in parallel and earth, a resistance of 100 000 ohms being connected in series with the receiver for the second measurement. Since the latter value of noise is a measure of the total noise-producing power of the disturbing circuit, and the former value is a measure of the actual noise produced in the telephone circuit, the ratio of the noise to earth to the noise between wires is a measure of the freedom of the telephone circuit from interference. In other words, it is a measure of the balance of the circuit. A telephone circuit having a high value of "noise ratio," as this ratio of noise to earth to noise between wires is called, will therefore be one having a high degree of balance, and hence will be subject to only a relatively small amount of interference. A circuit having a small value of "noise ratio," on the other hand, would be one that is poorly balanced, and one, therefore, that would be very liable to interference. As an illustration of the values of "noise ratio" that may be obtained in practice it is of interest to note that for open-wire lines a value of about ½ is usually obtained, although this value may rise to as high as 2 for a well-maintained circuit. In the case of cable circuits higher values are, of course, obtained and values of 20 or more have been measured. These figures show the considerable decrease in the amount of noise disturbances that will result from the use of cable instead of open-wire telephone circuits. In comparing the relative merits of d.c. and a.c. traction systems with respect to their interference with communication circuits, the author states that the a.c. system has been found to give the most trouble. This conclusion is, perhaps, not quite fair, as no mention is made of the d.c. system supplied with power from mercury-arc rectifiers, although a method for reducing the harmonics in such a system is given in an appendix to the paper. This type of d.c. system may give rise to very serious interference with neighbouring telephone circuits, and, as its use appears to be increasing, there is a probability that some trouble due to this type of system may be experienced in the future. As an example of the noise that may be produced in a telephone circuit in close proximity to a d.c. traction system supplied from a mercury-arc rectifier, the case of a mountain railway of this type, for which measurements were made, may be quoted. The telephone line used for communication between the different stations along

* *Journal I.E.E.*, 1924, vol. 62, p. 653.

the route was carried on the same poles as the trolley conductors. When power was supplied from a d.c. generator, communication over this line was satisfactory. When, however, a mercury-arc rectifier was used for supplying the power the noise induced in the telephone circuit was so great as to make communication difficult even between adjacent stations. The noise measured on this circuit by means of the 1-A noise-measuring set described in the paper already mentioned rose at times, when the mercury-arc rectifier was in use, to a value of about 5 000 noise units. This value corresponds to about 400 of the units described by the author on page 823.

Mr. D. M. W. Hutchison (*communicated*): The troubles that may arise due to the presence of third harmonics may in certain cases be very serious, affecting not only the communication lines but also the power lines and apparatus connected thereto. I have just had experience of such a case, the circumstances being as follows: Three-phase current at 2 200 volts supplied by a turbo-alternator was stepped up to 11 000 volts in a bank of three single-phase shell-type transformers connected star-star with the neutral on the e.h.t. side earthed direct. The transmission line consisted of three miles of overhead line coupled to one mile of underground cable which ended on the busbars of a substation. On the first trial run, when the voltage reached 8 000, the isolating switches in the substation cubicles flashed over their wooden operating links to earth. These were removed and boiled in paraffin wax, and on running up again the oil-switch rods caught fire at about the same voltage and two cable joints broke down. It was observed during this time that the filament of a test lamp supplied from a potential transformer and near a bare e.h.t. conductor was vibrating violently all the time current was on and it was therefore thought likely that the trouble was due to third-harmonic over-pressures not apparent on the voltmeters connected to the busbars. The greater part of this trouble was removed by connecting the neutral of the alternator to the neutral of the transformer bank, but this has not entirely eliminated the triple harmonics on the 11 000-volt side, potential transformers being burnt out after a few hours' run, and there is a perpetual brush discharge between the porcelain insulators of the current transformers and their frames. The note from the third harmonics is audible on the telephone lines, which run for three miles parallel to and 70 feet away from the transmission lines. It is probable in this case that the trouble, which appears to be due to electrostatic charges induced by third-harmonic over-pressures, can only be eliminated by supplying the step-up transformers with a tertiary winding on the e.h.t. side or perhaps a three-phase choke coil with an earthed neutral external to the transformer bank but in the substation to act as a by-pass for the third-harmonic currents.

Mr. R. G. Jakeman (*communicated*): As a machine designer I am particularly interested in the harmonics in the power circuits. The slot harmonics in large modern alternators are very small. In turbo-alternators the pressure wave is practically a pure sine wave, owing chiefly to the large air-gap and the large number of slots per pole. In low-speed alternators the slot harmonic can be suppressed by providing suitably-spaced extra slots, which are not used for the winding. In rotary converters there are two chief causes of a ripple in the d.c. pressure; one is the slot ripple and the other a ripple with 6 times the fundamental frequency, caused by the variation of the armature M.M.F. during a cycle. By careful design the slot ripple may be made quite small, but it can never be

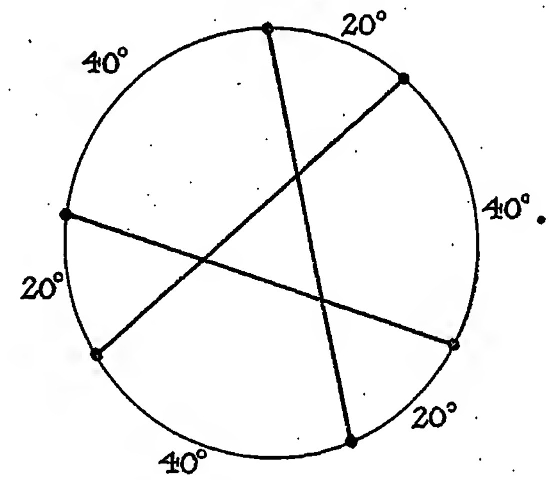

FIG. E.

wholly suppressed in an ordinary 6-ring rotary converter. The reason for this is that the slots per pole-pair must be a multiple of 6 in order that adjacent tapping points may be at 60 degrees to each other, so that the slots per pole must be divisible by 3 and therefore a whole number. By spacing the 6 rings as shown in Fig. E,* the slots per pole-pair are a multiple

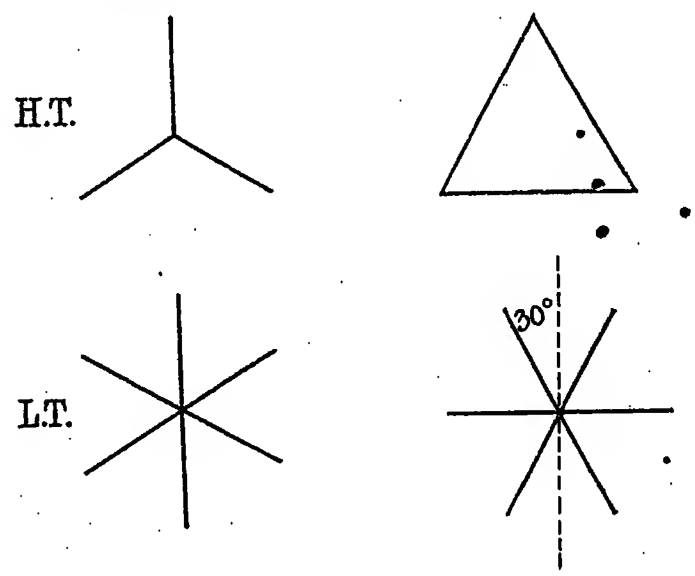

FIG. F.

of 9. Hence, the slots per pole are a multiple of $4\frac{1}{2}$ and may be fractional. This has the effect of suppressing the slot ripple. It will be noted that the three phases are at exactly 120 degrees to each other. This arrangement of the tapping points also reduces the sixth-frequency ripple. The method does not give a neutral point for three-wire balancing, but this is not usually necessary in a traction supply. With a 50-period rotary converter, the sixth-frequency ripple corresponds to 300 periods, which is within the range of speech frequencies. It is impossible to suppress it in a single rotary converter, although it may be consider-

* Provisionally protected.

ably reduced by correct design. In the case of two rotary converters connected in series on the d.c. side, this ripple may be practically eliminated by the arrangement shown in Fig. F.* Each converter is supplied by its own transformer, the primary of one transformer being star-connected and the other delta. As is well known, this provides a difference in phase of 30 degrees between the secondary pressures of the two transformers. The result is that the sixth-frequency ripples of the two converters are displaced by 30 degrees, so that they oppose one another and counterbalance (Fig. G). Since the two armatures are displaced by 30 degrees, the slot ripple can also be eliminated if 30 degrees corresponds to a fractional number of slots, i.e. if 60 degrees corresponds to an odd number of slots. The same effect can be produced by using one transformer only, having two secondaries, one connected "diametral star" and the other "double delta." Further, the ripples will be eliminated from the line if the converters are connected in parallel on the d.c. side. In this case the ripples will circulate between the two machines. A similar effect may be produced with two mercury rectifiers by connecting the primary

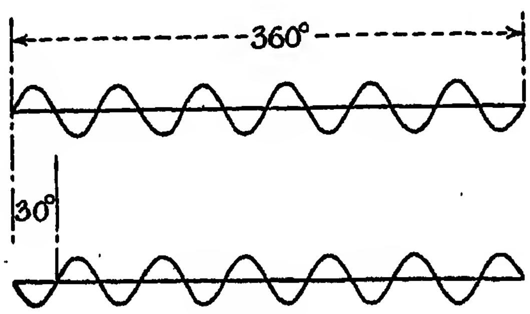

FIG. G.

of one transformer star and of the other delta. In this case two curves like that in Fig. 44 will be displaced by 30 degrees and added, the result being a very much smoother curve.

Mr. S. A. Stigant (*communicated*): The paper seems to indicate that the chief offenders in respect of harmonic interference with communication circuits are rotating machines, particularly main generators. It is perhaps in the nature of things that this should be the case, and so far as one can see at present those features of design which cause harmonic trouble must unavoidably be present in some degree, although by skilful design their effects can be greatly minimized. With transformers, however, the case is different in so far that all harmonic phenomena can be avoided by the simple expedient of reducing the induction density in the magnetic circuit, or, as the author phrases it, by reducing the impressed volts per turn. This procedure would effect the desired result without any reference whatever to the type of magnetic circuit or the connections of the windings. It would, however, naturally increase the dimensions and weights and consequently the costs of the transformers. Actually, there is no need to reduce the induction density below the figures which are now in common use, as harmonic phenomena may also be reduced practically to the point of elimination by suitable connections of the windings. The author on page 852 briefly outlines the influence of transformer connections upon third harmonics, and points out that a delta winding short-circuits third-harmonic pressures, thereby allowing the circulation therein of third-harmonic currents, and that the three-wire star connection may possess third-harmonic pressures either from the neutral to earth or from each line to earth according to whether the neutral point is insulated or earthed. The author also states that there are small residual third-harmonic pressures present on the star side with both the star-delta and delta-star connections. While this is correct from the rigidly theoretical standpoint, I should have thought that inductive-interference effects from these residuals were not only "unusually small," but absent. Can the author give some figures bearing upon this as a result of his own experience, at the same time stating the types of transformer (i.e. core or shell) and whether three-phase transformers or three-phase groups of single-phase transformers were used? Transformer designers have always considered that for all practical purposes a delta winding on either side or a tertiary delta winding short-circuits the third-harmonic pressures so effectively as to leave no residuals worth mentioning. A four-wire star connection similarly considerably reduces third-harmonic pressures, as the fourth wire from the neutral point permits a circulation of third-harmonic currents. In this case, however, there will be larger residual third-harmonic pressures corresponding to the additional impedance between the transformer terminals and the rest of the four-wire circuit. This applies whether the four-wire star-connected circuit is on the primary or the secondary side. With a star-star-connected three-wire circuit considerable third-harmonic pressures may be present, depending upon the form of the magnetic core. With a three-phase shell-type transformer or with three-phase groups of single-phase transformers, third-harmonic pressures having amplitudes of as much as 60 per cent of that of the fundamental may be found when the windings are star-star connected for three-wire service. This is so, as in both these cases the magnetic circuit of each phase is closed upon itself and independent of the other two, so that the flux and, therefore, the induced pressures provide the third-harmonic component necessary for the complete magnetization. In this connection it is worth emphasizing that harmonic phenomena in transformers are due almost entirely to the varying permeability of the sheet-iron used, and very little, if at all, to the hysteresis of the iron. With three-phase core-type transformers, however, third-harmonic phenomena are certainly negligible and in many instances practically absent on account of the magnetic interaction between the cores through the common yokes. Therefore the star-star connection of three-phase core-type transformers should prove perfectly satisfactory in service under any normal earthing conditions. From Fig. 1 it would appear that the relative interference effect at the triple frequencies which are likely to occur on systems in this country are almost negligible, so that transformers are by no means the principal offenders in causing harmonic interference. It is to be expected, therefore, that the earthing of generator neutral points

* Provisionally protected.

is most conducive to trouble, and this appears to have been the author's experience. This aspect should, therefore, have an important bearing upon the question of multiple earthing. If multiple earthing could be effected at transformers alone there seems to be no doubt whatever that the resulting harmonic phenomena causing interference would be restricted to innocuous magnitudes. On the other hand, the requirements of the different protective systems sometimes make it imperative that the neutral point of at least one of the generators actually in commission should be earthed, and therefore the earthing arrangements must necessarily be of the nature of a compromise. If, however, multiple earthing can effectively be adopted without earthing generator neutral points, as appears to have been done in the very home of automatic discriminative protective-gear systems, then the outlook for a wider application of this most desirable procedure is very bright indeed. It would appear that multiple earthing is bound to become more prevalent in this country on account of the increasing interconnection of power stations and networks and the consequent increase in transmission pressures, and it is hoped that the lead given by the North-East Coast power companies will be followed in other places. I am under the impression that interference with communication circuits becomes most severe and at times possibly dangerous when a fault occurs on the power system. Multiple earthing should therefore be very helpful in this respect, as it would enable the fault to be disconnected more rapidly and surely, while the fault currents would probably be weaker (and so less dangerous) on account of the diffusion of the currents through the different multiple paths. While the author gives some interesting data upon the increase of earth currents with multiple earthing, he only gives the current values at the power stations. I do not think that the earth currents are of very much importance at such places, and the vital issue really is to what extent the earth currents diffuse. Can the author give any precise information upon this point? Certainly we are told that under the conditions existing on the North-East Coast, interference to the telegraph circuits under observation was absent and to the telephone circuits inappreciable, but apparently this only indicates the non-proximity of power and communication circuits. The resonant-shunt method of eliminating generator harmonic pressures shown in Fig. 9 appears to me to be somewhat unnecessary. It is clear that this combination will act efficiently only upon the harmonic for which it is designed, and equivalent results can be attained with equal effectiveness if the resonant shunts are replaced by a three-phase interconnected-star neutral earthing compensator, the neutrals of the generator and compensator being connected together and, if desired, earthed. Although I have had no experience of the apparatus shown graphically in Fig. 9, it would appear that the interconnected-star compensator would be cheaper, and it is certainly a piece of apparatus which to my knowledge has already proved its worth. The author is evidently familiar with this type of apparatus, which he refers to on page 852. In reply to his query concerning its rating, while normally it would carry currents corresponding to the excitation of the system and the circulating harmonic currents, it would have to be designed to withstand the short-circuit currents and stresses which may be imposed upon it under the conditions of a short-circuit at its terminals. The duration of this short-circuit would, of course, be fixed by the setting of the protective gear. If neither of these conditions permitted the manufacture of robust windings the mechanical design of these would be the limiting feature. It may be taken for granted that generator and transformer designers are fully aware of those design features which are likely to cause harmonic troubles, and usually the requisite amount of care is taken with the design in order to minimize these effects. Often, however, the designer is left in ignorance of the operating conditions, and he cannot always be held responsible for any abnormality that may occur due to circumstances of which he had no cognizance.

Mr. G. Wüthrich (*communicated*): The author, no doubt on the basis of the evidence accessible to him, considers the single-phase railway system to be a worse offender than the direct-current system. It is rather unfortunate that the only reference to the biggest single-phase electric traction system in the world, namely that operating in Switzerland, represents a no doubt unintended contradiction to this reproach, in so far as the system in Switzerland is disposed of in a single sentence on page 845 by the unqualified testimony to the effect that it "is very successfully used." Quite independent of the present paper, a few days ago I received from Dr. Behn-Eschenburg and Mr. Kristen a summary of their views on this rather controversial subject, and as these views may be of general interest I give them herewith :—

"In our opinion, the disturbances which are most difficult to contend with, from a technical point of view, are those produced in electric circuits by transient phenomena. The rate of increase or decrease of current, which is a determining factor for the inductive effect in the neighbouring conductors, is in the case of short-circuits and interruptions in circuits occurring in d.c. installations a multiple of that for a.c. installations, if we assume that the generating plant is of usual design and the working pressures 3 000 volts and 15 000 volts respectively. The maximum induced pressures are not reduced by the quick-acting switches; the advantage secured resides in the fact that the duration of action of the phenomena is reduced and the disturbances thus rendered less harmful. The conditions are still more unfavourable in the case of rotary-converter operation and a working pressure of 1 500 volts. When carrying out electrification on a large scale it will, in any case, be hardly possible to provide a service affording entire security so long as communication circuits have to be kept above ground near railways operated with single-phase current, three-phase current, or high-tension direct current. The displacement of these communication circuits overhead, on extensive lines, or the adoption of cables cannot, therefore, be avoided (see also the report of M. Mauduit of the French Commission for Electrification). In view of these circumstances, the question of disturbances in communication circuits cannot be regarded as a determining factor for

the choice of the current system, as it is nothing more than a matter of economical importance for all systems. For large railway installations, data are only available up to the present for the single-phase system, in the case of which the use of cables has been resorted to both in Italy and Switzerland for the most important sections; on the other hand, in Sweden a mixed solution has been adopted in view of certain economical considerations (displacement of lines and booster transformer or cables). For direct-current installations of similar size no such data are available; it may also be added that most of the small installations adapt themselves to the plan of the towns where long parallel lines seldom occur. There is an additional difficulty in the case of direct-current installations, namely, electrolysis, which itself necessitates the displacement of the communication cables away from the track. We would further mention that cases have occurred where the Swiss telephone authorities have prohibited the use of mercury rectifiers for suburban lines, owing to disturbance arising from oscillating direct current. In our opinion, the data so far obtained from tests seem to confirm our views regarding the question of system and communication-circuit disturbances."

It would appear that the transposing of communication circuits into cables represents the only radical protection against the troubles experienced, both with d.c. and single-phase traction systems. The experience in connection with single-phase traction is already vast and fairly conclusive. As regards d.c. traction, certainly with pressures above 3 000 volts, the field has yet to be explored, especially in connection with the subject of the present paper, and also in connection with other phenomena of undesirable nature.

[The author's reply to this discussion will be found on page 872.]

Mersey and North Wales (Liverpool) Centre, at Liverpool, 28 April, 1924.

Mr. A. J. Eames: The chief responsibility for preventing interference with communication circuits must necessarily rest with power engineers and designers, whose efforts in that direction should be supported by the application of such remedies as are within the means of telegraph and telephone engineers. The successful elimination of power interference depends largely upon effective co-operation and goodwill. The difficulties can be readily overcome if cordial relations are established between all the parties concerned. There is not a very great deal that communication engineers can effect, apart from seeing that their plant is well constructed and maintained and that telephone circuits are satisfactorily balanced, and assisting in keeping communication and power circuits as far apart as practicable. An accurately-balanced aerial telephone loop is not easily achieved, and it is still more difficult in practice to prevent interference between telegraph and telephone circuits that are carried on the same poles for an appreciable distance. Attention to these points is essential for ensuring efficient transmission, besides tending to circumvent the troublesome effects of power interference. Similar considerations will apply equally to power plant, and, if given proper attention, the additional advantage of the repression of interference troubles at the source will be secured. The most effective method for eliminating the effects of induction is to adopt the best construction and maintenance standards. There appears to be some tendency to use the word "minimizing" rather too freely, with reference to this subject, as there is no doubt that public telephone circuits, particularly trunks and junctions, cannot be regarded as really satisfactory unless they are absolutely free from extraneous inductive disturbances. The considerable development of the telephone service that is expected to take place in the congested South Lancashire district during the next few years can only be met by the liberal provision of suitably designed telephone cables, or by what will be practically an all-underground service. This will materially help to solve the inductive problem, at least locally. The degree of perfection which has been reached in the design and manufacture of telephone cables, and in their maintenance after being laid, is exemplified by the fact that there is no perceptible overhearing between the circuits in the cables, although there may be hundreds of wires running together for scores of miles, contained in a small circular space 2 to 3 inches in diameter. The achievement of such remarkable results in the balancing of telephone circuits surely renders leakages and disturbances from distant power circuits matters which should be remedied at the source of the trouble. In other words the disturbing harmonic frequencies ought to be eliminated as the result of improvements in the design of power plant. It is noticeable that America is the chief source of the information given in the paper, especially as regards the disturbing influences associated with extra-high-pressure power systems. British authorities are in no small measure entitled to claim credit for the great foresight exercised in establishing important safeguards. In fact, it should be recognized that the regulations ensure protection for the plants of all properly constituted power and communication engineering authorities alike, in preventing chaotic conditions arising. The comparative immunity from danger, and freedom from the worst effects of induction experienced in this country, possibly accounts for the fact that British contributions to the literature on this subject are relatively meagre. This is really an indication that difficulties in this connection are being satisfactorily surmounted. It is significant that specialists generally commence by expressing the view that the greatest possible separating distances should be provided between power and communication circuits, particularly where comparatively long lengths of aerial parallelism exist. All responsible engineers will admit that this ideal is sound. In the majority of cases the older services, telegraphs and telephones, were first in the field. Naturally, when traction schemes mature, the question arises whether the undertakers are

prepared to pay the high costs that may be involved in providing the maximum clearance. The matter resolves itself into questions of economics and expediency, and consequently other measures are preferred, unless the policy finds favour of waiting to see how much power interference with telephones the communication engineer will stand. Apart from this aspect the public highways, if used conjointly, do not usually admit of entirely satisfactory clearances being readily obtained, and it is then a case of adapting measures to the conditions which arise. The method for overcoming interference described by Prof. Marchant in the appendix, was used with marked success at Liverpool. A considerable number of exchange subscribers' lines in one of the Liverpool exchange areas were adversely affected by the harmonic frequencies produced by the mercury-arc rectifier, both when in use for lighting and for traction services. Such troubles may be accentuated where electric lighting services are installed in the same buildings, and where there may be damp walls. With regard to the transposition system for telephone wires, would it not be advantageous where there is parallelism with a traction system to revert to the continuous transposition (or twist) system, in which the wires make a complete revolution every four spans? According to the diagrams there are intervals of from $\frac{1}{4}$ mile to 2 miles between the transpositions. In the first two paragraphs in the section headed "Noise in Telephone Circuits," it is not clear how the assertion that the mean frequency is 800 per second can be reconciled with that further on, viz. that the maximum sensitivity of the human ear is not less than 1 024 per second. The latter is no doubt correct if this sensitivity be also associated with that of the normal telephone receiver. Serviceable frequencies for music range from 16 to 4 500 (7 octaves), and I have seen a statement to the effect, although I do not credit it, that the extreme range for audibility is 38 000 vibrations (11 octaves). Frequencies of 10 000 to 12 000 have been mentioned as being within the powers of an expert. Wireless amateurs would be interested to know to what extent power circuits may interfere with the reception of wireless broadcasting programmes. The use of a search coil is described in the paper. Does the author think that this could be usefully employed in connection with laying ducts with the aid of a thrust boring machine? (The latter is used for boring a way under the ground ready for pushing pipes through without breaking down the surface.) Perhaps the use of a search coil would be a useful precautionary measure to avoid piercing high-tension mains, the existence of which is not suspected.

Mr. T. Cornfoot: One of the most serious disturbances on telephone or telegraph circuits is that of electrolytic action due to leakage from tramway and railway earth-returns. This disturbance or interference is not referred to in the paper. It is exceedingly difficult to counteract and locate because, while the other disturbances described make themselves felt at once on telegraph circuits or can be heard on telephone circuits, electrolytic action is silent and does not make itself manifest until very material and irreparable damage is done, resulting in grave interruption to communications. With the growth of underground systems using lead-covered cables, which are liable to damage from leakage, it would be of interest to learn whether the author regards the disturbance as being serious. Telephone systems are metallic, but with the development of automatic telephony extensive use is made of earth circuits for signalling and dialling purposes. Would any serious difference of potential between two signalling earths, due to power leakages, cause mutilation of the dialling impulses? The author mentions several electric railway systems which have given rise to inductive trouble. In Liverpool we have an electrified section of line between Liverpool and Southport and also between Liverpool and Ormskirk. This system supplies alternating current at 7 500 volts on the feeders at 25 periods, with 650 volts (d.c.) on the live rail, and there has been no appreciable disturbance on the telephone or telegraph circuits in the vicinity. On page 826 there is a reference to a charging current which alternates between the neutral point through the winding of the machine and through the capacity of the lines to earth. It is further stated that in some cases in this country this current is as much as 90 amperes. I am under the impression that a current of this magnitude at such a point is prohibited by the Regulations of the Electricity Commissioners. I should be glad if the author would confirm this view, and state whether there is any method of overcoming the difficulty.

Prof. E. W. Marchant: One of the most interesting parts of the paper is Mr. Gill's curve, Fig. 1, showing the audible effect of different frequences of current. The enormous difference between the effect produced by a sound due to a current at 50 periods and that due to a current at 1 000 or 1 100 periods is very remarkable. The figures quoted (on page 821) as given by Osborne would, I think, be subject to variation in different individuals, and I suggest that it would be valuable if some such records could be obtained for a number of different people. As a rule, older people can hear high-pitched sounds less clearly than younger people can. In some experiments made in the laboratory a few months ago, I found that one of my students was able to hear a sound of over 12 000 frequency which was entirely inaudible to me. With regard to the question of the transposition of lines, I noticed many years ago, in connection with long-distance transmission in America, that it was found necessary to transpose both the telephone and the power lines for reasons which have been clearly explained in the present paper. I am sure that if power station and telegraph engineers consult together with a view to reducing disturbance, a great deal of trouble in the future will be avoided.

Mr. W. Fennell: I am interested in the running of a number of miles of e.h.t. transmission and distribution lines and my experiences so far indicate that eventually a slightly different, and more reasonable, attitude will be taken up by the Post Office in regard to this matter. One can imagine the case of a projected line which can best be run along a route near to that of a few subscribers' branch lines. In a case like that it would appear that the Post Office should give way, but at present the Post Office will try to prevent that line being erected. The present attitude of the Post Office is that they not only claim that all the expenses of such precautions as the Post Office consider to be necessary to protect their

existing lines from danger or interference shall fall on the power undertaking if a second-comer, but they even put forward the claim that if the Post Office, as second-comer, put a line near to an existing power line they can still throw on to the power undertaking all the expense of protection of the new Post Office line. This is considered to be too unjust even for the Post Office, so it is stated that when the Post Office lines are second-comers the authorities will usually, as " an act of grace," charge half the cost. In this connection there is a statement on page 839 to the effect that if the telephone lines were perfect as to design and maintenance they would not be affected by induction from power or other lines. I would suggest that as neighbouring power lines, etc., will have a very much greater disturbing effect on imperfect lines than on good ones, the Post Office are asking others to pay for Post Office deficiencies. The Post Office, of course, have in general erected their lines first and have covered the country with absolutely unprotected overhead circuits, so that if the power engineer is asked to supply power to the inhabitants, say, of an area like the Wirral Peninsula—which can be dealt with economically only by means of overhead electric lines—he will be put to very considerable trouble and expense, involving high charges for electricity if the Post Office are not accommodating. The public interest, in fact, should come before departmental interests. I consider that electric power lines in this country, and especially electric railway lines, are, in general, more important than telephones and are certainly more fixed as to route than are overhead Post Office lines. The Post Office cannot fairly claim to continue to follow railway routes when by so doing they impede or even prevent railway electrification. The same applies to some extent to public roads in relation to electric power and light. The case referred to by the author, of leakages in power circuits upsetting exchange indicators, reminds me of a case which occurred in Cheshire. There was a 50-period overhead distribution system for an outlying residential district. Some consumers in that district insisted that the service lines should go underground from the nearest pole into the residences. These underground services were not properly sealed at the pole and moisture entered the cables, causing rapid deterioration. When these faults occurred the local exchange indicators dropped. Investigation showed that the reason was that neither the supply company nor the Post Office had efficient earth connections, due to the sandy nature of the soil in the locality. I would call special attention to a matter referred to in this paper, viz. the very great effect which an earthed guard wire has in this matter of shielding. Some figures are given in the paper as to the efficiency of one earthed wire running along the side of an electric railway between the power line and the telephone lines. I submit that most cases of static interference due to proximity would be dealt with economically by this method, and no dangerous charging of message wires would be possible if an earthed wire were fixed to each telephone or telegraph cross-arm on the side facing the power line or tramway. This method has its parallel in the armouring of electric cables and the provision of marker boards—to ward off the picks of excavators employed by gas or water authorities—and in the provision of bitumen or other overall coverings of lead-covered cables to prevent electrolysis. The guard wires can be looked upon as the equivalent of armouring and outside insulation. Electric power undertakers do not ask the other road users to pay for these means of preventing interference and it would be well if the Post Office followed the principle of each authority providing at its own cost such means as it thinks fit to protect its own plant.

Mr. C. J. Mercer: To the power engineer the intimation that he is causing interference with telegraphs or telephones not infrequently comes as a surprise and he is inclined to resent any suggestion that he should alter his plant to overcome the difficulty. The paper will have served a most useful purpose if it results in co-operation between power and telegraph and telephone engineers to prevent interference at the source. The author refers to the fact that interference is sometimes carried over a wide area. Such a case came under my notice some time ago. A 7 000-volt three-phase system with overhead transmission was erected parallel with telegraph wires carried on railway poles. The working of the telegraphs was not adversely affected, but the telegraph wires diverged to other routes, and the interference was transmitted by tertiary induction to telephone lines which did not themselves approach the power lines. I have heard the distinctive note of this interference more than 100 miles from the power lines. The trouble was clearly due to harmonics.

Mr. L. Breach: It is not clear from Fig. 43, which refers to the neutral currents on the Newcastle Electric Supply Co.'s system, where the system was earthed when the tests were made. As the figure refers to the 20 000-volt system, it would appear to refer to the leakage on that part of the system only, and not on that part which is coupled to the 6 000-volt supply, and it does not refer in any way to the leakage at the neutral point of the alternators. If a diagram were included showing these earthing points, the figure would be more easy to follow. On page 852 the author refers to the earthed neutral as an accomplished fact, and states that "in addition an earth may be required in connection with the operation of protective gear on the power system." It is not quite clear what is meant by this second earth, as of course one earth at the generating station is all that is required for the protective gear, unless the author refers to the earth on the secondary side of the protective gear, which would not appear to enter into the discussion. Referring to the appendix on page 857, I would add that the rectifier caused disturbances on the telephone circuits both when operating on the traction system and when on the lighting system. The disturbance has, however, been entirely eliminated by the methods shown in Fig. 45, but the diagram needs some further explanation. The piece of apparatus D is a choker in the cathode and is of the air-core pattern; this was in circuit originally, as were also the chokers in the anode. The latter were, however, iron-cored, so that some attempt was made by the designers to obviate the possible trouble. The coil with no denotation is of course the auxiliary resistance which is required to supply a load on the rectifier at times of light load on the system. A lantern slide ex-

hibited by Prof. Marchant showed a reactance in the neutral of the alternators and resonant circuits on the phases instead of a resistance in the neutral. This reactance would form a very large piece of apparatus in a modern power station where the current to earth for alternator protective purposes must be equal to the current of the largest alternator installed in the station, and this may be over 3 000 amperes. I should be glad if Prof. Marchant would give us some idea of the size of such apparatus.

Mr. J. A. Morton: It is stated in the paper that, the usual three-phase power lines in this country having balanced currents and voltages and being mostly untapped lines, the interference with open communication wires is at present very small; but in the future the situation may alter. There are likely to be many high-tension supply lines erected in sparsely populated and agricultural districts where nothing but an overhead line would pay and where the loads taken off are at irregular intervals and of quite small amounts, these small loads being almost certainly single-phase loads. This being the case, the currents and voltages in the three-phase transmission line will be unbalanced in different parts of the lines, and the possibilities of interference will consequently be increased, unless the Post Office have by that time put their circuits where they should be, i.e. underground. In the case of bare telephone wires carried on the same poles with, and underneath, power lines, it is quite possible to get good speaking through such wires, provided they are continuously revolved and the insulation is maintained in a satisfactory state. Such telephone lines are, however, likely to be of little use when most wanted, that is to say, when something has happened to the power line itself. At such times the open telephone line is likely to be out of commission also. The best practice is to put the telephone wires in a lead-covered cable, the wires being paired and paper-insulated in the ordinary way, and the lead covering of the cable being earthed. The telephone cable is usually suspended from the longitudinal steel earth wire which is also earthed and which itself acts as an efficient earthed screen between the telephone cable and the power wires. I have never heard of dangerous voltages being induced in a telephone cable carried in this way. The suggestion, on page 843, for a change in earth connections is a useful one. This has been discovered by possessors of wireless receiving sets, who in some cases have reduced the buzzing in their receivers by taking the earth off the water system, which acts as a sort of collector of stray currents, and sinking an old bucket as a separate earth in the garden. On page 851 a case is mentioned in which interference with overhead telephone circuits occurred because the outer conductor of a single-phase concentric cable was leaking to earth at several places. Would the author expect such a state of affairs to cause interference on *underground* telephone circuits, i.e. on paired circuits in underground lead-covered telephone cables? The author mentions that the earth required in connection with the operation of protective gear on some power systems is objectionable, but I fail to see why this should be so. Prof. Marchant showed in his first lantern slide how the capacity current in a power system might cause interference even with only one definite earth on the system, but the protective-gear pilot circuit is usually physically separate from the power circuit, and the capacity current in a protective pilot cable must surely be too small to cause interference. There is, however, one form of protective system in which each pilot conductor used in connection with the protective gear has an insulated copper earth-sheath round it which carries the capacity current back to the station, so that in this case it never gets to the earth at all and could not cause interference. The necessity on both power lines and telephone lines of having the insulation as perfect as possible is very apparent. There are high-tension lines which, although they are the most exposed portion of the electrical plant and work under the most onerous conditions, are never examined until they fall down. Some engineers who keep their station plant perfectly clean and well-maintained seem to forget the power line, presumably because it is not directly in front of them. The consequence is that insulators get covered with soot or salt and that the line insulation is not properly maintained. Leakage caused in this way will affect the communication circuits in the neighbourhood. Having said this, I wish to suggest to the author that possibly the Post Office themselves would get less interference if the insulation of their own lines and instruments were better maintained.

Mr. F. J. Teago: Fig. 1 is, in my opinion, the most interesting part of the paper. Further research along these lines might well be carried out in order to ascertain whether the interference curves for other types of receiving apparatus differ materially from that of Fig. 1. Having a set of typical interference curves, one could endeavour, in the design of electric generating machinery, to avoid those harmonics which produce peak values of interference. Fig. 1 appears to suggest that the reason why d.c. machinery does not interfere to the same extent as a.c. machinery is that the harmonics in the d.c. case are of high order and lie beyond the peak, whilst in the a.c. case they are of low order and lie between zero and the peak. I should like to point out that to eliminate harmonics from electrical machinery to the extent desired by the author would be a difficult and expensive matter, and that self-help is usually the most effective form of assistance.

Mr. C. Rettie: I should like to ask the author whether more trouble is experienced with three-phase lines than with single-phase lines. I should imagine that a partial earth on a three-phase system with an unearthed neutral would cause a great deal of trouble. The late Prof. Steinmetz referred in one of his books to the great destructive oscillations that would occur on a 50-mile length if a neutral wire on a three-phase 44 000-volt system fell to within 2 inches of the ground. An arc would be formed and the voltage would drop to 25 000, the arc would go out, the voltage would again rise to 44 000, and this would go on intermittently for hours until the fault was cleared. I should like to refer to the author's remarks on the question of the design of the machinery. In the Report of the Californian Railroad Commission it was pointed out that with the accurate design and manufacture of the machinery many, if not all, of the troubles with inductive inter-

ference would disappear. Are there any difficulties in the way of obtaining that end? Mr. Teago has partly answered that question, and has referred to the difficulties that would be encountered in the design of dynamos to eliminate indefinitely small leakage currents; but it is to be hoped that the difficulties will soon be overcome. I am pleased to note that interference is caused by direct-current systems as well as by alternating-current systems; the disadvantage, being common to both, cancels out.

Mr. S. C. Bartholomew (*in reply*): Before replying in detail to the discussion in London and Liverpool I should like to express my gratification at the manner in which the paper was received. The discussion will add considerably to the value of the paper, as much new matter has been added and the criticism is helpful.

I have for long held the opinion that co-operation between the various interests concerned, referred to by Mr. Stubbs and others, is the only way of solving the majority of the interference problems. Mr. Stubbs points out that there is no specific reference to the work of Prof. Hughes on induction. The investigation of Prof. Hughes and his work have become merged in the general basic theory and I did not think it necessary to refer specially to him. I agree that it might be thought from the wording that the merit for the introduction of the cross-over system rests with America: I did not intend to imply this. As Mr. Stubbs points out, designs based on that system were prepared many years ago and are given in old Post Office Technical Instructions, which do not differ greatly from those shown in Fig. 19. It was not adopted, for the reasons given, but it has certain maintenance advantages over the twist system. Particular wires can be more readily identified and, in the event of a general breakdown, services can be more readily restored. There is also less risk of contact between wires, as in the twist system the clearance is less at the centre of the span. On the other hand, in the matter of power circuit interference the twist system appears to have an advantage. When power circuits are erected in proximity to telephone circuits run on the cross-over system the crossing points in the latter may require correcting to co-ordinate with the position of the power circuit; this is not necessary where the twist system is in use.

Prof. Marchant refers to the relative interference effects of harmonics of different frequency, and asks whether any figures other than those quoted from Osborne are available. I have not seen the results of other investigations. The frequency weighting curve used for the interference-factor measuring set referred to by Osborne is reproduced in Messrs. Erikson and Mack's paper on "Transmission Maintenance of Telephone Systems."*

Mr. Parry calls attention to a disparity between theory and experiment in the case of electrostatic induction produced by the Lake Coleridge–Christchurch 66 000-volt three-phase line on a telephone circuit carried on the same pole line. I had noticed this difference when reading Messrs. Marsden and Caldwell's paper, and the reason for this disparity given by Mr. Parry—that the difference is due to the insulators not being designed to stand a pressure of 3 565 volts—is no doubt the correct one. I wish to thank Mr. Parry for the additional curves given of the induced voltages produced by two 11 000-volt power lines by electric and magnetic induction upon a neighbouring telephone circuit with various separating distances. There are one or two comments which I should like to make on this. The calculations are based upon the effects of balanced voltages and currents, which effects can be greatly reduced by transposing the power wires and the telephone wires. The most frequent causes of trouble are, however, due to the residual voltages and currents, upon which the transposing of the power wires has little effect. Moreover, as 11 000-volt lines are referred to, these would in most cases be fed directly from generators with neutral points earthed, and are thus more likely to be carrying a residual voltage due to the third harmonic or multiples thereof, which would be more objectionable than the balanced voltages and currents, and the values are usually unknown beforehand. As regards the separating distance between the power and telephone lines in this country, the minimum would rarely be less than the 66 ft. referred to, as for safety reasons, i.e. to guard against the possibilities of contact, this separation must not be less than $1\frac{1}{2}$ times the height of the telephone line, and would usually be of that order. It may be of interest to supplement the information on this point by giving some figures which have been published in America for a rough general guidance as to limiting lengths of parallel for different separations and voltages of supply circuits which, experience indicates, usually will not lead to serious inductive interference in paralleling telephone circuits. The table applies to parallels with 25- and 60-cycle supply circuits without earth connections, with the load reasonably well equalized among phases, and which are not unbalanced to an extent greater than would be caused by the differences in the capacities between the line wires and earth in an untransposed three-phase supply circuit.

Separation	Limiting length of parallel for		
	11 000 volts	33 000 volts	100 000 volts
ft.			
40	1 mile	700 feet	—
100	4 miles	3 000 feet	600 feet
200	15 miles	2 miles	2 000 feet
500	60 miles	8 miles	1·5 miles
1 000	—	25 miles	5 miles

It will be noticed that these figures are also not based on the case of earth-connected power circuits and, moreover, do not take into consideration the effects of faults on the power line. This latter question is becoming of

* *Journal I.E.E.*, 1924, vol. 62, p. 653.

as much importance as that of disturbance produced by the normal working of the power lines. I understand that in Germany in certain districts the administration are in difficulties owing to the number of operators who are asking to be pensioned owing to the acoustic shocks received, which, it is claimed, undermine their health. Much greater separating distances than those given by Mr. Parry or in the table will have to be allowed to prevent these shocks. It is gathered that the worst offenders are not the very high-pressure lines but those of between 10 000 and 20 000 volts.

Mr. Thorrowgood's remarks are in the main confined to leakage currents. It is rather surprising to find that there is "no interference at all with telephones on the South Western Section of the Southern Railway." The alterations to the rotary converters after the line was opened made a great improvement, but when speaking to Mr. Thorrowgood's office at Wimbledon I have frequently heard the same note that is picked up on some of our Southampton telephone trunks when they are slightly out of order. These trunks are erected on the railway line for a few miles. Much depends, however, upon the definition of interference. A short telephone line—not a public line—will be satisfactory with a considerable amount of induced noise, as the speech margin is usually ample.

Mr. Mack finds it hard to understand why the paper deals almost exclusively with communication circuits over open wires, and then gives the answer. The very great majority of cases of interference which I have experienced have been with open lines, and the same holds good apparently elsewhere, due mainly, as Mr. Mack points out, to the elimination of electrostatic induction where underground lines are used. The cases of interference with underground circuits by electromagnetic induction are likely to be confined to telegraphs using an earth return. Mr. Mack is correct in assuming that the noise-measuring circuit shown in Fig. 3 dates from 1913. I was not aware of the up-to-date position on this matter until I read the recent paper * by Messrs. Mack and Erikson before the Institution, which appeared after I had prepared this paper. I agree with Mr. Mack that a proper comparison between the single-phase and the direct-current system of electric traction from the interference point of view would have to take into consideration the effects of electrolytic action on lead-covered cables. Electrolytic action could, I think, be logically brought in as "interference," but the paper was already sufficiently lengthy. In the matter of electrolytic action the advantage is of course with the single-phase system. I tried not to be dogmatic in this matter of interference as produced by the two systems of traction, but I cannot help feeling that, judging from the published experiences, the single-phase system is, at the moment, the more to be feared —not perhaps so much as regards interference with speech as from interference with telegraphs and by producing acoustic shock. The last point may be just as important with direct-current systems when high voltages are employed; up to the present there has been no trouble from the medium pressure usually employed. Mr. Mack in a sense rather supports my view where he states "In some cases it has been necessary to install high-grade telephone cable to ensure this immunity." I do not know of a case where it has been necessary to cable open wires adjacent to direct-current systems, although it has been necessary in some instances to alter the d.c. machines supplying the current as described in the paper. On the other hand, in a paper by R. Liljeblad before the Electrotechnical Congress in Gothenburg (1923) it is claimed that a properly designed single-phase motor should not produce more disturbance than a corresponding d.c. motor.* The matter of telegraph interference remains, however, and as this is produced by the fundamental frequency the design of motor does not come in, and its extent depends upon the lay-out of the traction system. I do not wish to labour the point, but I cannot resist quoting the following from Mr. Mack's contribution. "I am not sure to what extent British manufacturers of power machinery have given close attention to this matter, but I suspect that some of the Continental manufacturers are ahead of them. Some Swiss companies in particular have considerable experience in the design of machines which are free from interference effects." Perhaps British manufacturers do not need my help, but the following extract from the report on Swiss economic conditions by O. A. Scott, H.M. Legation, Berne, issued by the Overseas Trade Department, appears to have a bearing on the matter:—"A sum of $22\frac{1}{2}$ million francs will be expended this year in connection with the displacement of a number of telegraph and telephone lines exposed to the inductive effects of the high-pressure overhead equipment of the railways." This sum is considerable, say £900 000. Further, the mercury-arc rectifier which caused the interference dealt with by Prof. Marchant and described in the appendix, was made by a Continental firm. The examples of precision balancing given by Mr. Mack are undoubtedly of the greatest assistance in preventing power circuit interference, but I was under the impression they have not been developed specifically for that purpose but primarily for the prevention of interference between telephone circuits themselves. The methods refer, however, to cables, and my definition of reasonable balance referred particularly to overhead lines, and the degree of balance that can be obtained commercially in overhead open wires can be fairly expressed as one in which the telephone circuit is undisturbed by other telephone or telegraph circuits on the same route.

I am glad that Mr. Twiss can see no advantage from the power suppliers' point of view in the use of a single-phase system with an earth return. In out-of-the-way districts with no telephones in the neighbourhood it would no doubt be unobjectionable, but there should be few places where there is a supply of power and no telephone service. Mr. Twiss treats the earthing of the neutral point of high-pressure three-phase systems as though it is without question the best arrangement. I know that the majority of power engineers in this country do favour that method of working, but it has not always been so, and even at the present time there are a great number of systems in America worked with the unearthed neutral and it would be an easy matter

* *Loc. cit.*

* See *Teknisk Tidskrift*, 6 October, 1923.

to quote European engineers who advocate it. The legal position as regards earthing of power systems is briefly as follows. Certain earth connections are compulsory on low- and medium-pressure systems under the Electricity Commissioners' Regulations for securing the safety of the public. Other earth connections are permitted by the Electricity Commissioners with the concurrence of the Postmaster-General [see Section 10 of the Schedule to the Electric Lighting (Clauses) Act, 1899]. The earthing of the neutral point on three-phase systems worked with high or extra-high pressures falls under this latter category, and permission has never been withheld to such earthing, subject to it being made at one point on each distinct circuit, and subject also to a proviso that the Postmaster-General's concurrence may be withdrawn at any time. I do not think that the industry has found this irksome in any way, and yet it is a valuable power of embargo that I believe the Postmaster-General would not willingly give up. Mr. Twiss points out that the principal inductive effects originate in the machines or transformers, and suggests that Section 69 of the Schedule to the Electric Lighting (Clauses) Act, 1899, should provide sufficient protection for the Postmaster-General's telegraphs, and that any control of the earthing is unnecessary. As the removal of the earth connection will usually remove all inductive effects from residuals, I may perhaps suggest that Mr. Twiss has reversed the umbrella, and that the earth connection is the larger of the two. Section 69 of the Clauses Act requires the intervention of the Electricity Commissioners, and in my view it is better that the two parties concerned should settle matters directly, which is the usual way. As will be seen from the paper, the cure is usually found without it being necessary to alter machines and transformers, which would in general call for greater expense. If, as suggested by Mr. Twiss, earthing of the neutral point is made compulsory by including it as a requirement in the Electricity Commissioners' Regulations for securing the safety of the public, this would seemingly rule out the use of the paper resistances referred to on page 852. I should not like it to be thought that the proper design of generators and transformers is not the first consideration, but at the moment the control of earthing appears to be the easier way of bringing that about, as, if earthing is of importance, the designs will have to be such as to permit of it being done. Should the Commissioners decide that the safety of the public requires that the neutral point of such systems must be earthed, then the Postmaster-General's concurrence would apparently not be required, but such compulsory earthing might in some cases involve somewhat expensive alterations in other directions.

The interference-factor meter referred to by Mr. Aldridge does not appear to be based directly on the curve shown in Fig. 1 of the paper. The curve was given by Osborne in the "Review of Work of Sub-Committee on Wave-shape Standard of Standards Committee," * and was reproduced as Fig. 8 in the paper on "Transmission Maintenance of Telephone Systems." † This curve is obtained by multiplying the sensitiveness of the average receiver to the same current at different frequencies, by frequency, and this indicates the relative amount of sound interference produced by unit voltage of different frequencies present in the harmonics of the power system. Should the characteristics of the average telephone receiver change as suggested by Mr. Aldridge, this weighting curve will presumably have to be altered with it. The interference-factor meter has been used in other countries than America, but on the other hand the design has also been criticized. It is pointed out that the measuring instrument (thermo-galvanometer) sets up the average value from the currents flowing through the resonance connections. This average value could therefore only be regarded as a standard for the interference effects of the noise if the aggregation of the partial notes in the human ear took place in the same way, and it is claimed that a study of the physiological and psychological processes which come into play during listening does not support this view. I regret that I cannot give the details of the construction of the resonant shunts applied to power systems. One would anticipate difficulty in designing such shunts for use on large units, but there are no doubt many cases where they could be provided at little cost and used with advantage. I have tried them experimentally in two cases across d.c. machines, using makeshift material, with fairly good results, but apart from the case dealt with by Prof. Marchant in the appendix I know of no supply undertaking where they are in use in this country. In America there are, I understand, a number of cases where they are employed. I can give no satisfactory explanation of the curious case referred to by Mr. Aldridge in which the harmonics in the positive lead to a rotary converter differed from those in the negative lead; nor have I heard of such a phenomenon coming under notice elsewhere. Cases are known of superimposed return current in a traction system, where current from a section fed by long feeders from one station enters another station by its negative feeders, flows through the generators along its trolley wires and through the distant cars to re-enter the former station by a shorter feeder on another route.* This does not appear to offer a satisfactory explanation, however.

The experiences given by Mr. Hutchison of the employment of shell-type transformers connected star-star, are very illuminating, confirming in every way the unsatisfactory nature of such a combination from the operating point of view, apart from the interference aspect. The severe effects may be due to resonance, and a tertiary winding would probably provide a solution. It would no doubt be difficult to add a third winding to each core to form the delta, and attention can perhaps be drawn to a variation in which some closed turns (copper bands) are placed round each limb. This method is described by H. De Pistoye.† Success is claimed for the method.

I wish to thank Mr. Collard for his full explanation of the noise-measuring arrangements described in the recent paper by Messrs. Erikson and Mack. I am not quite clear, however, how a ratio between the noise

* *Transactions of the American Institute of Electrical Engineers*, 1919, vol. 38, p. 261.

† *Loc. cit.*

* J. G. and R. G. Cunliffe: "Problems in Traction Development," *Journal I.E.E.*, 1913, vol. 50, p. 692.

values as low as ½ could be obtained when measurements are made on open lines. This would imply that the noise on the loop was greater than that between the wires in parallel and earth. If this is correct, then presumably the 100 000 ohms in circuit in the latter case is accountable. In the matter of the relative interference effects of d.c. and single-phase traction, I should point out that communication circuits comprise telegraphs as well as telephones, and it was by giving due weight to the effects on the telegraphs that I was led to the conclusion that, at the moment, the single-phase system is the worse offender. So far as telephone circuits are concerned I should say that in this country more trouble is caused by d.c. systems than by a.c. systems. The further example given of the position of mercury-arc rectifiers in this matter is very interesting, and it is evident that in the early designs sufficient consideration has not been given to this aspect.

Mr. Jakeman's contribution is of particular value as he describes other methods of reducing harmonics in rotary converters and rectifiers than those given in the paper, and these should be of great assistance.

Mr. Stigant suggests that in the case of delta-star and star-delta connections of transformers there should, in practice, be no interference from residuals. I agree that this should usually be negligible. No outstanding cases of such interference have come under my notice, but a characteristic note can be heard in some cases on telephone circuits in the neighbourhood of such systems when the telephone circuits are out of balance. I cannot give particulars of the types of transformers (core or shell) or grouping. I note that Mr. Stigant attributes the harmonic phenomena in transformers almost wholly to permeability and very little to hysteresis. I am not in a position to confirm or challenge this, but I should like to draw attention to the following extract from "Transformer Harmonics," by O. G. D. Dahl, a report dated January, 1923, which was prepared for the Research Sub-Committee of the Committee on Inductive Co-ordination of the National Electric Light Association. "There has been considerable discussion of the causes of the harmonics in the magnetizing current. While opinions on this question have differed a good deal in earlier years, most investigators and engineers now agree that they are caused both by the varying permeability of the iron and by hysteresis, which evidently is the case." The multiple earth connections on the North-East Coast are made at transformers and not at generators. The generators may be earthed, but they are on separate and distinct circuits. I am sorry that I cannot give any information as to the diffusion of the earth currents shown to be circulating when the tests were made. This would no doubt be governed by the make-up of the network in overhead and underground plant, and the type of the latter. Mr. Stigant's comments on the resonant shunt versus the interconnected-star compensator, and on the rating of the latter, are welcome. The last method was tried some years ago at my suggestion in a case where serious interference was being experienced, and proved quite effective. In this particular case there was fortunately available in the generating station a transformer which could be used for the purpose.

In reply to Mr. Wüthrich I should like to point out that the expression "is very successfully used" referred to the operation of the single-phase system as a system of traction on the Swiss Railways, and not to the interference problem. I have unfortunately been unable to obtain much information on the Swiss experience as regards interference, and the summary furnished by Mr. Wüthrich of the views of Dr. Behn-Eschenburg and Mr. Kristen is correspondingly appreciated. It is gathered that transient effects due to short-circuits are the greater difficulty, and that these are just as likely to occur with high-pressure d.c. as with single-phase systems. Further, that placing the overhead communication circuits underground or their removal from positions contiguous to the railways is the only way of neutralizing these effects. This is bad news, although not so bad as it would have been considered a few years ago before the development of the loaded cable and the telephone repeater. Overhead routes for trunk telephone service are not now so essential for providing efficient speaking conditions between all parts of the country, but they are of the greatest value and for some services indispensable, e.g. overhead circuits have to be employed for connections between the stations of the British Broadcasting Company when simultaneous broadcasting is in progress, as lengthy underground cables are not suitable for the transmission of music. Large sums of money were paid by the Post Office for wayleave facilities for communication circuits on a number of railways, and the value of these wayleaves depends upon the facilities offered for the erection of overhead lines. As an example, the old Midland Railway carries what is called the backbone telephone trunk route from London to the North. If, therefore, it were established that the electrification of the main railway routes, whether by the direct-current or single-phase system, meant that all overhead Post Office wires must be removed from the railways, a great deal of work would be involved, and one can foresee the possibility of the clash of interests, which it is not necessary to go into here. I had hopes that solutions would be found to the problems, without resource to such drastic remedies as those suggested.

Mr. Eames asks whether it would not be advantageous, in cases where there is parallelism with a traction system, to revert to the twist system of transposition. If the cross-over points are unsuitably placed in relation to the length of parallelism, a rearrangement of the cross-over points should in most cases provide the more economical solution. As pointed out in the reply to Mr. Stubbs, there is an initial advantage with the twist system in that no subsequent rearrangement is required on the advent of a power line in the neighbourhood. Mr. Eames seems to assume that the mean frequency of speech and the note frequency to which the ear is most sensitive must coincide. The former can be computed by comparison with electrical measurements in which single-frequency currents are employed and which do not involve the use of telephone receivers. Similarly, the frequency at which the ear is most sensitive can be ascertained without the use of telephone

receivers. Lord Rayleigh did not use a telephone receiver in the investigations which led him to the conclusion that a frequency of 1 024 per second was that at which the ear was most sensitive. The possibility of power circuit interference disturbing broadcast programmes has several aspects. There is the local interference which affects receiving sets in the immediate neighbourhood of the power line and which is usually confined to sets near to electric railways. Then there is the more serious interference produced by the high-pressure unidirectional current system used in connection with the electrical treatment (purification) of blast-furnace gases. This electrical process involves the transmission of rectified alternating current at 80 000 volts over a line which is perhaps 300 ft. long, and sets up oscillations at the natural frequency of the line. This may affect wireless reception for many miles around, owing to the natural frequency approaching that of the broadcasting transmission. Next there is the possibility of interference with telephone circuits used for simultaneous broadcasting. The land lines between the broadcasting stations have to be overhead as the transmission of music by long underground circuits is not satisfactory, the reason being that the cut-off frequency on underground lines worked with loading coils and telephone repeaters is between 2 000 and 2 600 per second, which is high enough for speech but not for music. Overhead lines are of course much more liable than underground lines to inductive interference, and any disturbance picked up by the land line will naturally be passed on to the listening public. No doubt many have noticed this on occasion. In one case the transmission of a Paris programme to the London station was virtually spoiled by tramway interference with the land lines. Mr. Eames's suggested use of a search coil to detect the presence of power mains under roadways so that precautions can be taken when using a thrust-boring machine, is timely. I may say that the proposed method had been suggested previously, and coils have been made for the purpose. This is an illustration of the old proverb "It is an ill wind that blows nobody any good," as the unpleasant feature of power transmission which is the subject of the paper is here used as a means of assisting other parties in their road operations. A further use for the search coil would be to show the presence of water and gas pipes, as these are usually carrying current if there are tramways in the neighbourhood.

Mr. Cornfoot notes that electrolytic action has not been referred to in the paper although it is another aspect of the interference problem, and asks whether the disturbance under this heading is serious. I agree that electrolysis is a subject that might properly have been included, but on the other hand it is a matter that lends itself to separate treatment, and in any case to have dealt with it adequately would have lengthened the paper to too great an extent. In answer to the question, I regard the general position of disturbance from that source as serious. The possibility of earth currents interfering with dialling on automatic telephone systems in which earth circuits are employed has not been overlooked, and in connection with the proposed change from manual to automatic working in London an investigation was made to ascertain the extent to which the differences of potential between the "earths" of two exchanges might be caused by electric railways or tramways in the vicinity. Tests made with recording voltmeters showed that potential differences were usually of the order of 1 or 2 volts, but in some cases momentary kicks of the order of 15 volts were registered. There was some doubt as to the true values in these latter cases, as the duration of the impulses was short and the sudden increase in the voltage might cause the needle to swing past the correct point. Apparatus was therefore devised which showed the duration of short impulses and also recorded more accurately their magnitude. During a period of one month a P.D. exceeding 10 volts was recorded twice, and 6 volts was exceeded 13 times in tests between Central and Western Exchanges. It has been estimated that the lost calls due to these earth-potential kicks would not be greater than 1 in 600 000, and that the degree of disturbance would require to be 60 times as great as this before the standard of service would be sensibly affected. Mr. Cornfoot's reference to the Electricity Commissioners' Regulations on the matter of maximum current allowed in the connection to earth of the neutral point is of importance. The regulation in question limits the amount of current to 1/1 000th part of the maximum supply current and was evidently intended to ensure that the insulation should be maintained at a high standard, as if that amount is exceeded it is laid down that steps must be taken to improve the insulation. The regulation was evidently drawn up at a time when the effect of the third harmonic in producing heavy charging currents in high-pressure lines was not known. The 90 amperes referred to has nothing to do with insulation failure, and yet according to the regulations the insulation should be overhauled because of its presence. The regulation in its present form is not up-to-date and will no doubt be recast when the regulations are revised by the Commissioners.

The point raised by Prof. Marchant, that the great difference in sound effects by currents of different frequencies as illustrated in Fig. 1 and by the figures given by Osborne, might be influenced by the personal factor, is to a great extent met by the way in which the investigations were carried out, as a number of observers were employed. The interference currents of different frequencies and amplitudes were superposed on the speaking current of a telephone line, and the diminished speech efficiency was arrived at by means of the ratio of clear syllables received to the number of spoken ones.

I should not like it to be thought that Mr. Fennell's summary of the attitude of the Post Office towards the erection of power lines is entirely accurate. The paper was confined to the technical problems of interference, and makes no mention of protection or safeguards to prevent contacts between communication and power circuits; or of the legal position of the Post Office, or of policy which the legal position decides. Mr. Fennell introduces these other subjects in a somewhat challenging fashion and, whilst not denying their importance, I do not think that this is the right place in which to deal satisfactorily with the matter. I must, however, chal-

lenge the statement that the Post Office will try to prevent the erection of power lines. It is perhaps only necessary to remark that an over-statement has a very weakening effect on the very best case. As Mr. Fennell points out, the perfectly balanced telephone circuit would not be affected by induction from power circuits, but he ignores the converse—that a perfectly balanced power circuit would not affect neighbouring telephone circuits. As explained in the paper, it is not possible with overhead wires to maintain perfect balance—but a very high standard indeed is required to meet the inductive effects from other telephone and telegraph circuits—and it is contended that commercially that is the most that can be expected from the telephone administration. If inductive effects are experienced with the telephone lines up to this standard, then it is considered that the power line unbalance is excessive, and the "deficiencies" are with the power system and not with the Post Office. Mr. Fennell seems to imply that public interest is only concerned with the supply of electricity, and that telephones are a departmental interest only. This is not correct—both services are for the public, and it is of course equally the duty of the Department to see that the telephone service is not saddled with charges which are proper to the electricity service. Mr. Fennell says: "The Post Office cannot fairly claim to continue to follow railway routes when by so doing they impede or even prevent railway electrification." As pointed out in the reply to Mr. Wüthrich, the Post Office have paid large sums for wayleave facilities on many of the railways, and if those wayleaves are rendered valueless by railway electrification—which I hope will not be the case—a difficult situation may arise with which it is not within my province to deal. The use of earthed wires in reducing the electrostatic charging of wires is referred to by Mr. Fennell, and I am sorry that even on this I must differ from him. Mr. Fennell suggests that these wires should be placed on the telephone routes at the cost of the telephone administration; but why not on the power line supports at the cost of the power circuit owner? The analogy of the marker boards and armouring round underground power mains seems quite good, but those are provided by the power main owner and not by the other users of the road. This seems to be sound, as it is only just that the owner of the dangerous thing should guard it, as the marker boards, at least, have to be provided to safeguard other authorities who may open the road. One would assume from Mr. Fennell's explanation that the marker boards are provided voluntarily by the owner of the armoured cable primarily for his own protection, but I have always understood that it was a requirement of the Electricity Commissioners made in the interests of other road users. However that may be, it is pointed out that whilst on the one hand the use of earth wires may be beneficial in reducing the inductive effects from the residual voltages and currents, on the other hand it may increase the effects of balanced voltages and currents by distorting the fields.

Mr. Mercer refers to the interference effects sometimes picked up many miles away from the point of origin, and on circuits not directly concerned. Tertiary induction of this character is very often difficult to trace and the instance quoted of a note being picked up 100 miles from the power circuit is illustrative.

In answer to Mr. Breach, Fig. 43 refers to the currents in the earth connections on the 20 000-volt network only and not to that in the alternator earth connections. I agree that if a diagram had been given showing the earthing points the position would have been clearer. It was not given owing to the length of the paper and the already great number of diagrams. I am afraid my wording was not too clear in the quotation made by Mr. Breach from page 852. I did not wish to convey the idea that a second earth is required for the protective gear, but that apart from other considerations an earth may be wanted for that purpose alone. The additional details given by Mr. Breach concerning the application of the resonant shunt to the mercury-arc rectifier referred to in the appendix are of considerable interest and value. Prof. Marchant's reply to the question as to the size of the reactor used in connection with the arrangement of resonant shunts across the phases of an alternator is as follows:—"It is difficult to give any general figure which would represent the cost of a reactance necessary for a current of 3 000 amperes; each case would have to be dealt with on its merits and the value of the reactance necessary would depend on the amplitude of the harmonic which it was desired to eliminate from the wave-shape of the alternator."

Mr. Morton points out that unbalanced power lines may result when high-pressure overhead transmission lines are used for supplying current to sparsely populated agricultural districts, as loads will be tapped off at irregular intervals, probably by single-phase circuits. This is a problem that must be taken into consideration. It is apparently a feature of distribution in America, and a warning against such arrangements is included in the Report of the Inductive Interference Committee of the National Electric Light Association and Bell Telephone System. Mr. Morton asks whether I would anticipate inductive interference with underground telephone circuits owing to leakage on the outer of a single-phase concentric cable. No such case has come under my notice and, although I think that interference would not occur if the telephone circuit in the cable were balanced to the degree required for telephonic repeater working, it is possible that the paired circuits in the ordinary type of telephone cable might be affected, depending to a certain extent upon the type of apparatus in use. Such interference has been caused by neighbouring cables carrying current supplied by mercury-arc rectifiers, and by cables connected to generators supplying three-phase current with the neutral point earthed. A case of the former type has developed since the paper was read. I am afraid that I did not make the position clear as regards the supposed necessity for earthing at the neutral point on three-phase systems. I have understood that for the operation of certain types of protective gear an earth is required at the neutral point. I know, however, that the earthing is not required solely on that account. If the earthing, for whatever purpose it is provided, results in interference, as it does in many cases, then it is objectionable on that account.

In reply to Mr. Teago, the type of receiving apparatus would doubtless have some influence on Fig. 1, but the main characteristics are decided by the ear. As pointed out previously, Lord Rayleigh's figure of maximum sensitivity was not based on the effect on a telephone receiver. Mr. Teago says that it would be a difficult and expensive matter to eliminate harmonics from electric machinery to the extent desired, and suggests, as an alternative, self-help by the telephone engineer. It is also a difficult and expensive matter to provide telephone circuits that will not be affected by those harmonics, and although self-help is practised it is not out of place to point out that, apart from other considerations, the elimination of harmonics at the source will hold good for all existing and future telephone circuits. On the other hand, if they are not removed the added difficulty experienced in the construction and maintenance of telephone circuits is a continuing one, involving not only initial expense but permanent increase in maintenance expenditure and additional cost in the provision of future circuits.

In answer to Mr. Rettie I should say that more trouble has been caused by three-phase than by single-phase lines. The former system is, however, more extensively used. So far as I know, we have had no trouble from partial earths on three-phase systems worked with the neutral unearthed. Mr. Rettie expresses pleasure at the fact that interference is caused by direct current as well as by alternating current, and says that the disadvantage, being common to both, cancels out. The pleasure is wholly Mr. Rettie's, however, as although the disadvantage may cancel out as an argument it unfortunately does not cancel out in actual fact. From the communication engineer's point of view it would be better if only one system had the disadvantage; it would halve his troubles.

A NOVEL METHOD OF STARTING POLYPHASE SYNCHRONOUS MOTORS. *

By E. V. Clark, B.Sc., Associate Member.

(*Paper first received* 19*th November*, 1923, *and in final form* 31*st March*, 1924.)

Summary.

This paper records that while some difficulty may ordinarily be experienced in starting up a polyphase synchronous motor simultaneously with the alternator supplying the circuit, the difficulty is greatly reduced if the alternator is of the asynchronous type; and that with small laboratory plant this method of starting is simple in the extreme.

Further, if the asynchronous alternator has a wound rotor and an adjustable rheostat in its rotor circuit, then the synchronous motor may be run up to speed by the operation of the rotor rheostat, with the asynchronous alternator running at full speed throughout.

A scheme for operating small synchronous motors in a factory with this method of starting is outlined as being technically feasible, though inferior to other methods in general convenience and, therefore, devoid of much commercial utility.

Three fields where this method of starting may be of appreciable or occasional use are cited, viz. technical school laboratories, testing-shops of manufacturers, and emergency use by supply authorities.

A standard method given in the earlier textbooks for starting a synchronous motor is to run it up with the alternator, i.e. to connect it electrically to the alternator while the latter is at rest, to excite both alternator and motor, and then to start the alternator very slowly, giving the motor a start by hand. The motor should come into synchronism and thereupon the alternator may be gradually raised in speed, bringing the motor up to speed with it. The author's students attempt each year this method of starting a synchronous motor in the electrical engineering laboratory of the Adelaide University, but with very little success, as the conditions are unfavourable. The two three-phase machines available for the experiment have very different waveforms, and one has to be considerably under-excited when they are used in conjunction. Thus the synchronizing force at low speed is small, and the motor readily falls out of step if the alternator is accelerated at all rapidly.

It would appear that an asynchronous alternator should be much more suitable for use with this method of starting, since the motor would completely determine the voltage and periodicity of the circuit; while irregularity of the acceleration of the alternator would only mean irregular negative slip, and the torque on the synchronous motor would always be positive. Thus, if once the motor is properly running there should be no tendency for it to slow down and come to rest, unless the alternator is accelerated so rapidly (having regard to the inertia of the motor) that the negative slip becomes

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

great enough to reduce the torque below that necessary to overcome the no-load losses of the motor.

Experiment showed this to be the case. There is very little difficulty in starting up the laboratory 5 kW three-phase alternator as a synchronous motor when power is supplied to it electrically by a 2 h.p. three-phase induction motor, used as an asynchronous alternator and belt-driven from a d.c. motor. This induction motor has a wound rotor which may be short-circuited for the experiment. The synchronous motor is excited, the switch connecting it to the asynchronous alternator is closed, and the motor driving the latter is then started. As an asynchronous alternator has no power of self-excitation, it follows that no current flows between it and the synchronous motor. But if, as the asynchronous alternator is started, a moderate hand-turn is given to the synchronous motor, this at once generates an E.M.F. and produces sufficient current both to excite the asynchronous alternator and to keep the motor running. The alternator may now be run up to speed quite rapidly, and the motor will follow with no tendency to "fall out."

With the provision of an asynchronous alternator with wound rotor and three-legged rheostat in the rotor circuit, however, it is not necessary to start up the synchronous motor at the same time as the alternator, since the latter may run at full speed throughout the starting operation. The alternator, not being self-exciting, may be connected electrically to the synchronous motor by closing the main switch, without any circulation of current. The motor is excited and the alternator rotor rheostat is placed on the first notch as if the alternator were being started up as an induction motor. And now, by giving a hand-turn to the synchronous motor, E.M.F. is generated, current flows, and the motor runs up to a speed corresponding roughly to that which would be attained on the first notch of the starting rheostat if the asynchronous alternator and synchronous motor were reversed in position. Also, by cutting out the resistance in the alternator rotor circuit notch by notch, the synchronous motor runs up to speed without any excessive rush of current, only a small kick being observed as each succeeding notch is used.

The simple and easy starting of a synchronous motor in these circumstances is just what one would expect from theory. The torque of an induction motor, for a given rotor resistance, flux and slip, is the same except for sign, whether the slip is positive or negative. Hence if the starting torque of a 50-cycle 4-pole induction motor at rest—i.e. when the slip is 50 cycles per second—on the first notch of its starting rheostat is T, then if we mechanically drive the induction motor at 1 550 r.p.m. and have electrically connected to it a 4-pole synchronous motor running at 50 r.p.m., we have a negative slip of 50 cycles per second and a torque of $-T$ with the same rotor resistance in circuit, provided the flux is the same in the two cases. But on a purely inductive circuit, a synchronous alternator of negligible internal resistance gives a constant current irrespective of speed, since the E.M.F. generated and reactance both vary as the speed. Hence as the resistance in the circuit comprising asynchronous alternator stator and synchronous motor armature is small, quite a small speed of the synchronous motor will cause a considerable current to flow and thereby produce the necessary flux.

Various tests of the two varieties of this method of starting synchronous motors have been carried out in the electrical engineering laboratory of the University of Adelaide with the small plant already referred to. Of the two ways, viz. running up simultaneously with a squirrel-cage type asynchronous alternator, and starting on the rotor rheostat of a wound-rotor type asynchronous alternator, the latter is found to be appreciably the better with the laboratory plant. To run up simultaneously needs considerably greater care, as the d.c. motor starts up very rapidly on the first notch of its ordinary starting rheostat, and the synchronous motor must be given the hand start at just the right moment. On the other hand, if a special d.c. rheostat is used and the first notch allows but little current to flow, the sudden access of load as the asynchronous alternator picks up may cause a drop in speed sufficient to let the synchronous motor come to rest. With the wound-rotor type of asynchronous alternator, the easiest way to start is to run this up to speed, set the rotor rheostat on the first notch (or on that notch which gives maximum torque at the speed adopted), connect the stator to the unexcited synchronous motor, give a hand-turn and then close the field switch. The synchronous motor used in the experiments has very excessive "tooth-lock action," and it is impossible to give the shaft any considerable spin by hand if the field is excited. With a type of synchronous motor having more uniform flux distribution, it would be a matter for experiment to determine whether the final act should be to throw in the field switch or the main a.c. switch. Naturally, excessive power is needed for the hand-turn if the motor is both excited and connected to the alternator, as suggested in the preliminary description of the method.

Tests of starting up a synchronous motor under load were made by belting the motor to a line shaft and thence to a set of three unexcited $2\frac{1}{2}$ kW machines with six bearings and rigidly coupled shafts. It was found just possible to start up on this load, if care was taken that as the rotor rheostat was moved from notch to notch the line current was not allowed to exceed the normal current rating of the asynchronous alternator by more than 25 per cent or so. If this were exceeded, the torque became too small and the synchronous motor came to rest. The motor was much under-excited, so that the stator flux would be considerably below normal.

To test this method of starting on a machine of greater magnitude, experiments were next made upon a rotary converter of 150 kW capacity in one of the converter stations of the Adelaide tramways. This is a three-phase 25-cycle 500-r.p.m. machine; and for the asynchronous alternator set the battery booster of the station was adapted, consisting of a 40 h.p. induction motor with wound rotor, driving a 200-ampere 150-volt booster. Temporary leads from a 100-volt tapping on the battery were connected through a water-bucket starter to the booster, by means of which it was run as a d.c. motor; and the stator leads of the induction motor were removed from its transformers and connected to the a.c. terminals of the rotary converter, the field

of which was separately excited. The induction motor is normally run off the transformers of one of the converters, so that its voltage was suitable. The experiments were quite successful, but it was found only just possible to give the converter the necessary hand-turn. The machine in question is provided with a belt-connected pony motor, by means of which it may be started from the a.c. side. With the belt removed, two men pushing on the pulley and armature barrel-end were not able to impart sufficient velocity to cause the machine to pick up. On replacing the belt, however, the greater facility thereby afforded for an effective hand-turn enabled the same two men to give the requisite start. No attempt was made to measure the required initial speed, but the author's impression is that it was in the neighbourhood of 30 r.p.m., or, say, somewhere between 5 and 10 per cent of the rated synchronous speed in this case.

Starting up was tried both on the rotor rheostat, and simultaneously with the rotor short-circuited. The former method enabled the set to be readily run up to speed for synchronizing on to the transformers. The latter tests showed that the set could be started up about as easily on the alternative method; but the conditions were abnormal, the d.c. starting rheostat of the battery booster set being an improvised water bucket which facilitated the running of the set at low speed but did not give sufficient range of resistance to enable the set to be brought up to full speed under load.

In all these tests it was found desirable to excite the converter field before giving the hand-turn, and to let the closing of the main a.c. switch be the final action when a sufficient hand-turn had been given. The difficulty of turning the armature by hand was much the same, whether the field was excited or not, if the main switch was open; whereas the closing of the main switch made considerable difference, probably due to currents caused by residual magnetism. In this respect the behaviour of the rotary converter was just the reverse of that of the laboratory synchronous motor.

In both laboratory and converter station tests, one fact was as evident as it was unexpected, viz. that starting up was very much easier if the synchronous motor was much under-excited. One would anticipate just the opposite. A somewhat superficial explanation that suggests itself is as follows: At the moment at which the circuit becomes active, whether by closing the main switch or the field switch, it is the synchronous motor which delivers energy to the circuit; and not until the flux of the induction motor is built up does that machine act as an alternator and supply energy. Hence the stored energy of rotation imparted to the synchronous motor by the hand-turn must be sufficient to supply this initial flow of electrical energy without bringing the machine to rest. Now at a given speed the voltage is proportional to the flux, while the current will be almost proportional to the voltage. The time taken for the flux of the induction motor to build up will be much the same at any voltage, since the time-constant of the circuit is but little affected. Thus it follows that at a given speed the energy to be supplied by the synchronous motor will vary almost as the square of its flux. The value of field excitation to give the easiest starting—that is, the minimum hand start—will therefore be the smallest value sufficient to provide enough torque to keep the synchronous motor in rotation. It is very noticeable in the laboratory tests how, at a speed quite sufficient with low excitation, the motor comes to rest with a jerk on switching on too strong a field current.

It will be noted that the line current, which lags relatively to the voltage generated in the synchronous motor by a small angle at the initial moment, must swing round to a lag of about 130° by the time the asynchronous alternator takes charge, since the latter can only deliver a leading current; and further, that as meanwhile the synchronous motor has given out energy and therefore dropped in speed, the frequency must fall steadily during this momentary transition period. A record by an oscillograph showing the waves of current and E.M.F. during the second or two following the closing of the circuit, would be of much interest and might render more evident the conditions required for the easiest starting up of a synchronous motor by this method.

Once the synchronous motor is properly running on the asynchronous alternator circuit, one may of course increase the field strength gradually with advantage to the torque transmitted. It would appear, however, that a sudden increase of field strength would momentarily cause the synchronous motor to give out energy and might therefore pull it up if the speed were too low.

Attempts to start up a single-phase synchronous motor in this manner met with very little success. The same two laboratory machines were used, with one of the three-phase star-connected legs disconnected. By giving the greatest possible hand-turn to the synchronous motor, one could occasionally get it to hold in, but this result was exceptional. The method might prove useful occasionally in running up to speed a single-phase machine that could be driven mechanically to, say, one-quarter full speed, but does not otherwise appear to afford much scope for use.

This method of starting polyphase synchronous motors would appear to have little scope for use in the factory, since it suffers from three defects. First, excitation must be available while the motor is at rest; secondly, a hand-turn or its equivalent must be given at starting; and thirdly, even though the asynchronous alternator may run at full speed throughout, yet there must be no pressure on the mains between the alternator and motor prior to the moment of starting. Nevertheless, it is not impossible to devise a scheme for the operation of a factory with a number of small synchronous motors to be started on this principle and operated from public supply mains. A control centre would be provided from which all motors would be started, and this would be equipped with an induction motor driving both the common exciter for all synchronous motors and also the starting asynchronous alternator which would have two poles more than the motor driving it. This set would run continuously while the factory was working. Each synchronous motor (with the exception of very small ones) would drive its load by means of fast and loose pulley or friction clutch, and would be connected to the control centre by five wires, viz. three a.c. armature

leads and two d.c. exciting leads. The control switchboard would include for each synchronous motor a field switch and rheostat and a three-pole double-throw main switch, connecting to the starting busbars in one position and to the public mains in the other, with intermediate "off" position. Starting busbars would be connected through an ammeter to the stator of the asynchronous alternator, the rotor of which would be wound and provided with a substantial three-legged rheostat. A synchroscope would be connected between the starting busbars and the public mains.

To start any motor, the workman operating it would signal by bell-push that he desired it to be started and would proceed to rotate it by hand. The switchboard attendant at the control centre would put the rotor rheostat of the asynchronous alternator on to the first notch, throw the main switch of the synchronous motor in question into the starting position and then close the field switch of that motor. His ammeter would indicate directly the motor started, and he would then bring the latter up to speed by means of the rheostat in the alternator rotor, keeping, if desired, the motor at the low speed of the first notch until he got a signal to tell him that the friction clutch was closed, or the belt transferred to the fast pulley. As the asynchronous alternator has two poles more than the motor driving it, the synchronous motor will readily run up to synchronous speed with respect to the supply mains; and the operator must synchronize in when throwing his motor switch from the starting position to the running position upon the public mains. He thus has entire charge of all motors, and by varying the exciting current either individually or collectively may keep the power factor in the neighbourhood of unity, or leading, as required. Any motors in the factory which have to start and stop frequently—e.g. crane motors—may be of the induction type and have their bad power factors neutralized by over-exciting the synchronous motors.

This scheme is merely put forward as indicating the technical possibility of operating a number of synchronous motors with this method of starting, for it is fully realized that the complexity of the scheme renders its commercial utility extremely small. In special circumstances, where a large number of small motors was desirable and power factor of prime importance, and where, in addition, labour was very unskilled, it might be advisable to install a system of synchronous motors with centralized starting and a common exciting source; but even under these conditions results could probably be obtained more satisfactorily by using synchronous motors equipped with amortisseur coils so as to be self-starting and self-synchronizing, and providing at the control centre a starting transformer with tappings. This would eliminate the hand starting and hand synchronizing which would appear inseparable from the method of starting by means of an asynchronous alternator.

There should nevertheless be some practical use of this method of starting synchronous motors, and three fields may be cited where it should have possibilities.

(*a*) In technical school laboratories, where it may be used both to illustrate the properties of the asynchronous alternator and to start up synchronous motors for the plotting of V curves, etc.

(*b*) In manufacturing-works' testing shops, to start up alternators in order to parallel them on to the a.c. supply mains, whereupon they may be tested as motors, either running light or by means of a rope brake.

(*c*) In substations, for emergency starting when the normal starting gear is broken down, in cases where an induction motor set is available. For example, Stuart-street station of the Manchester Corporation some 20 years ago contained an induction motor-generator set for exciting the main alternators. By means of this it should have been possible, without any temporary connections whatever, to start up on the a.c. side any motor-generator substation in which d.c. excitation was available, provided that the requisite "hand-turn" could have been given to the motor-generator set.

The author's thanks are due to Mr. W. G. T. Goodman, chief engineer and general manager to the Municipal Tramways Trust, Adelaide, for permission to carry out tests at one of the tramway converter stations; and to Mr. A. A. Watkins, chief assistant engineer, both for arranging the temporary connections necessary to enable the tests described to be carried out on one of the spare sets in the converter station, and for much assistance while the tests were in progress.

THE FIFTEENTH KELVIN LECTURE.

KELVIN AND THE ECONOMICS OF THE GENERATION AND DISTRIBUTION OF ELECTRICAL ENERGY.

By Guido Semenza, Member.

(*Lecture delivered before* The Institution, *24th April*, 1924.)

1. Lord Kelvin, at that time Sir William Thomson, enunciated his "conductor law" at a meeting of the British Association in 1881, that is 43 years ago. I should like to quote the words with which his paper began:

> "The most economical size of the copper conductor for the electric transmission of energy, whether for the electric light or for the performance of mechanical work, would be found by comparing the annual interest of the money value of the copper with the money value of the energy lost annually in the heat generated in it by the electric current."

As we all know, he came to the conclusion, as the result of a simple mathematical calculation, that the most economical area of a conductor is that for which the annual interest on the cost of the copper is equal to the value of the energy lost per annum in the conductor.

The law in this simple form has by some been considered to be of very little practical value because it neglects a number of items, which affect the total cost of the transmission, such as poles, insulators, etc. These items vary with the size of the conductor, and it is, in my opinion, this fact which has resulted in Kelvin's law being restricted to theoretical problems and in its losing, in the minds of most engineers, much of its practical value. I have always felt that this is to be regretted and I am glad of the opportunity of explaining the true meaning of the law.

If, on the one hand, I fully appreciate the honour conferred on me by the invitation to deliver this Lecture, on the other I feel that my task is by no means easy. I am an engineer and not a scientist, and I can only speak as an engineer; I fear, therefore, that I shall not be able to maintain the high standard of previous Kelvin Lectures.

There are, to my mind, two important features which make Kelvin's law very interesting. The first is its relation to the intellectual character of the man whom we are honouring; and the second is the development that this law can receive—and, by some, receives daily—in every kind of calculation relating to electrical matters.

2. We must go back to the time when the law was enunciated, the early days of electrical development, in order to realize its fundamental importance.

In 1881 the Edison incandescent lamp had been shown for the first time at the Paris Exhibition, although it was in existence at Menlo Park two years before, and its appearance at the Paris Exhibition was preceded by much scepticism. Before that time only a few arc lamps had been used, and the transmission of power to a distance was still a dream. True, it had been discussed to a small extent, and in America somebody had prophesied the transmission of energy from Niagara Falls over a long distance, but nothing very conclusive appears to have been done before the experiments of Marcel Desprez, which were started in 1881 and were conducted on a practical scale only in 1885—four years after the time we are considering—when he succeeded in transmitting 50 horse-power from Creil to Paris, a distance of 50 km, but at a very low efficiency.

In 1881 Edison already had in mind a distributing network, and in 1882 one of these became a reality in New York and one in Milan (Italy). I have tried to find out how he calculated the cross-sections of the conductors, and I have come to the conclusion that the only factor taken into consideration was the drop in voltage. From the earliest days networks of mains and feeders were not very simple, and therefore the proper sections were determined by experimental methods, the tests being carried out on a model of the network constructed to a reduced scale. It appears that no economic considerations influenced the determination of the conductor areas. As regards the methods of Edison, his biographers report the following remark by him: "I had not much use for mathematicians either, for I soon found that I could guess a good deal closer than they could figure, so I went on guessing." And so I suppose he did the same in calculating his networks, but I think it is only fair to say that we owe a great deal to Edison's "guesswork."

We can also realize that in those days, when everything connected with electricity was still uncertain and vague, things were done more on an empirical than on a scientific basis. They were years of nervous and intense research. Electric light was a rising star on the horizon, and all sorts of inventors were directing their efforts to the development and perfection of the new discoveries which promised to yield renown and wealth. Many of these pioneers, I am afraid, did not understand the difference between energy and current, and the necessity of accurate measurement was not then felt. At the time of this rush comes the Glasgow professor who calmly put a question which nobody had yet thought about: "How can the size of a conductor be determined in order to obtain the maximum economy from an electric transmission?" I am sure that some of the nervous inventors present at the lecture must have exclaimed: "Why ask such a curious question?"

Sir William Thomson, however, was looking into the future. With his deep knowledge, he clearly foresaw the coming importance of the applications of electricity, he already had the conviction that electrical energy would be transmitted many miles and that electric lamps would be as common as candles, and so he realized the importance of the cost of the conductors used. In his well-known paper of 1881 Kelvin had already discussed the size of conductors necessary to transmit 21 000 h.p. from Niagara Falls a distance of 300 miles, and in the same year he had read a paper on "The Sources of Energy in Nature Available to Men for the Production of Mechanical Effect." He was foreseeing the future and was guiding the others. And Kelvin's law enunciated in 1881 was before its time.

3. That this vision of the future was right, has been proved not only by the present importance of electrical engineering, but also by his having discovered and published an economic law which has, in practice, had wide influence. In fact, recent developments in connection with efficiency in the electrical industry have shown that the great majority of technical problems involved in construction, manufacturing and power generation and distribution, are questions of minima or maxima. We nearly always discover that the limiting conditions of a given quantity are obtained by comparing economic factors acting in different directions and following different laws. It is such conditions that limit the dimensions of our ships, the speed of our trains, the size of our smelting furnaces, and the height of our buildings. The general application of this law might even bring the natural philosopher to suppose that it is inseparable from the properties of matter and energy, which latter are the essential elements of industry. Is it not possible that by more careful investigation the principles governing this law might be discovered? It may be mentioned, for instance, that very few laws controlling matter and energy are of a linear character. Friction, gravitation, every kind of distant action, losses due to electric current, magnetic induction, etc., are non-linear functions; even in geometry, owing to surfaces being quadratic and volumes cubic, contents increase much more quickly than linear dimensions. Laws of this kind may possibly determine the ultimate dimensions of crystals and organic cells, and the sizes of plants and animals.

Kelvin's conductor law is, I believe, the first statement of this general law.

4. It does not appear that Lord Kelvin, occupied, as he had been, with deeper problems, gave any further attention to the subject. This was, however, taken up by Professor Forbes in 1885 and subsequently by Dr. Kapp, both of whom developed the original law with a view to its practical application.

As I have already pointed out, however, the majority of those who, with the increase of electrical applications, had to deal with problems which were continually becoming more complicated, did not fully understand the importance of the law and assumed that it was not of much use to them. They preferred, instead, to solve their problems by tentative methods, or, shall I say—without blaming anybody—by guesswork. Moreover, although by a further development all the variables of the problem can now be properly taken into account, objections are still raised to this method of solution. It is said, for instance, that one cannot foresee the price at which the energy will be sold, and that as the prices of metals are continually varying, so that careful calculations are apt to be upset by the first fluctuation of the market, why trouble to undertake long and complicated calculations when the assumptions on which they are based are so unstable? Others raise the objection that there are, in addition to the economic, many other important considerations in fixing voltage-drops and conductor cross-sections.

Some of the objections I do not propose to consider, as they are opposed to the spirit of engineering. Others are to some extent true, but, even so, it is still a fact that calculations of this kind constitute a very good method for a first attack on a problem, or what is sometimes called a first approximation. We may, for good reasons, depart from the results given by our calculations, but we shall always know where we are and where our calculations are leading us, and we shall in any case be prevented from adopting an absurd solution.

5. Some years ago I expressed the opinion, for two reasons, that calculations of this kind should be made by the graphical rather than by the analytical method. The first reason is that some of the variables of the problem cannot be expressed by a formula, and the second one is that by a graphical method it is easy to see how the resultant function varies in the neighbourhood of its maximum or minimum value. I may add that investigation of many cases has shown that the curve giving the desired result is nearly always very flat in the neighbourhood of its maximum or minimum, allowing, therefore, a certain latitude in the choice of the best cross-section. This is fortunate.

Then, to an engineer at least, graphics tell much more than formulæ. Lord Kelvin used to say, speaking of physical phenomena: "I am never satisfied until I can make a mechanical model." Graphics are to formulæ what models are to phenomena: when a mathematical process is plotted in the form of a curve we can see all its characteristics and satisfy ourselves especially as to the effect of altering one or more of the assumptions.

Kelvin's law to determine the most economical area of a conductor has been largely applied in the last 20 years and some very complicated cases have been treated by means of the graphical method.

The cross-section of conductors to give the minimum capital outlay, or the minimum cost per kilowatt or per kilowatt-hour delivered at the end of the line, i.e. to give the highest return on the invested capital, has been determined, and hydro-electric and steam-plant loads have been studied with the assistance of the amplified Kelvin law. I shall therefore not deal with this matter further, but I should like to show how this law has permeated neighbouring fields and I shall start with hydro-electric plants.

6. In every country in which water power is utilized, some very interesting problems are apt to arise. Water-power plants can be divided into two types: (1) Those which I shall term "continuous-flow power plants," in which the natural flow of a river is utilized without any

correction; and those which I shall call "reservoir power plants," in which means are provided for the storage of water. The necessity of storage presents itself when there is a marked difference between the diagram representing the natural flow of the river and that representing the power demand. The natural flow may be high in summer and low in winter, while the reverse is usually the case with the demand for power. On every power-distribution system there is generally an evening peak, although the flow of water may be constant; hence a reservoir is obviously necessary in order to provide for an annual, a seasonal, or a daily difference, according to circumstances.

The cost of the reservoir is generally a very important item and it increases very rapidly with the height of the dam. Also, the number of kilowatt-hours stored increases with the height of the dam, but not always at the same rate. On the other hand, we know that the above-mentioned difference between the flow of water and the demand for power may also be dealt with by using auxiliary steam-power plants. We are thus faced with the economic problem of choosing between three different sources of energy, namely, a continuous flow of water, which cannot be controlled; a reservoir, which can be controlled within certain limits; and thermal plant, the output of which can be varied at will.

When a case of this kind occurs, it is necessary to ascertain in what proportion these three different sources should be used in order to obtain the most economical result. Instead of treating the problem in a general way, I propose to discuss a particular case to show the application of the method.

Let us consider a power supply from an Alpine river the flow of which is very small in winter, when all the high ground is frozen, and very abundant in summer, when the sun melts the snow and ice. In Fig. 1 the curve ACDC′A′ shows the variation in the flow of such a river. For simplicity, the curve has been so plotted as to show the number of kilowatts available throughout the year. With a view to making this example as simple as possible I shall assume that there is a constant demand for electrical energy for 10 hours a day all the year round. A more complicated assumption can, of course, be made if desired.

It is at once clear from Fig. 1 that unless we have at our disposal either some method of storage or auxiliary plant, we could not supply more than 30 000 kW, that is to say, an output corresponding to the minimum flow during the year.

Let us suppose that on the same river a large reservoir could be built. If a reservoir were constructed of such a capacity as to provide an annual storage represented by the area CDC′, then 40 000 kW would be continuously available and could be sold throughout the whole year. We thus obtain an increase in revenue, but also have a larger capital outlay.

We could also fill up the hollow in the diagram by power from steam plant, or partly from a reservoir and partly from steam plant.

Several economic problems can be considered. Let us suppose that it is very important that the cost per kilowatt-hour should be as low as possible and that the demand for energy is unlimited; and let us ascertain what proportion of storage gives the minimum cost per kilowatt-hour, or, in other words, at what height it is most advantageous to draw the line CC′ in Fig. 1. As the demand for power is, for simplicity, assumed to be constant for 10 hours a day, each kilowatt of demand will represent 10 kWh per day, or 3 000 kWh per year (neglecting Sundays and holidays). In Figs. 1 and 2 a curve MM′ has been traced, the abscissæ being kilowatt-hours and the ordinates kilowatts. This curve shows, for each position of the line CC′, the corresponding number of kilowatt-hours stored yearly in the reservoir, or the stored energy as a function of the rated total output of the whole plant. The first point corresponds to 30 000 kW and the shape of the curve depends upon the shape of the curve ACDC′A′.

In order to build a reservoir we must spend a certain amount of capital—there is land to buy, sometimes even houses to destroy, a dam to build, canals, sluices, dischargers, etc. By making various assumptions as to

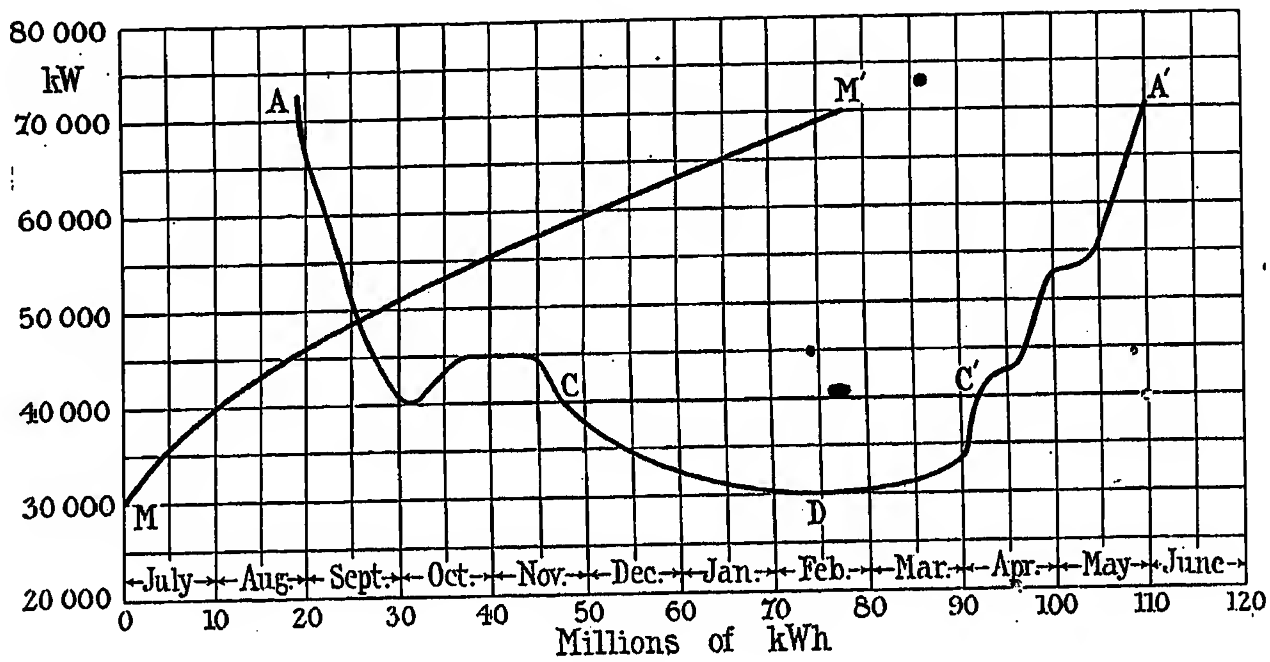

FIG. 1.

the amount of water we want to store, and from the hydraulic data applicable to the case, it is possible to plot a curve showing the capital outlay due to the reservoir, as a function of the total rated power of the plant. We can then derive from this curve the annual cost of the reservoir, that is, the sum of the interest on capital, the sinking fund, the cost of maintenance, labour, etc. Let us suppose that the curve NN′ (Fig. 2) represents such expenses as a function of the rated output of the plant. The abscissæ represent kilowatts, and the ordinates millions of lire.* The curve starts at 1 000 000 lire and does not rise very rapidly at first (which is natural because many expenses are more or less independent of the height of the dam), while it increases more rapidly for higher values of the storage.

Let us now consider the main part of the plant. This consists of canals, pipes, buildings, waterwheels, electrical equipment, etc. The cost of all these items increases with the rated output; and at a very high output it tends to become proportional to the number of kilowatts installed. Let the curve PP′ (Fig. 2) represent these costs. Like NN′, PP′ represents an annual cost. If we add the ordinates of PP′ and NN′ we get the curve POQ, which gives the total annual cost, including the reservoir, the hydraulic equipment and the power house. Dividing, now, each ordinate of POQ by the corresponding number of kilowatt-hours generated in the year, we can plot a curve SS′ showing the cost of these kilowatt-hours. This curve has a minimum value at about 55 000 kW. It also shows that the addition of the reservoir results in a more economical solution than that afforded by the continuous flow alone. In fact, at an output of 30 000 kW the cost per kilowatt-hour is 9·4 centimes, and the most economical output with the reservoir 8·2 centimes, which represents a saving of 11·5 per cent and an increase in the available power of 25 000 kW.

By consideration of this diagram other conclusions can be reached. If, for instance, the cost per kilowatt-

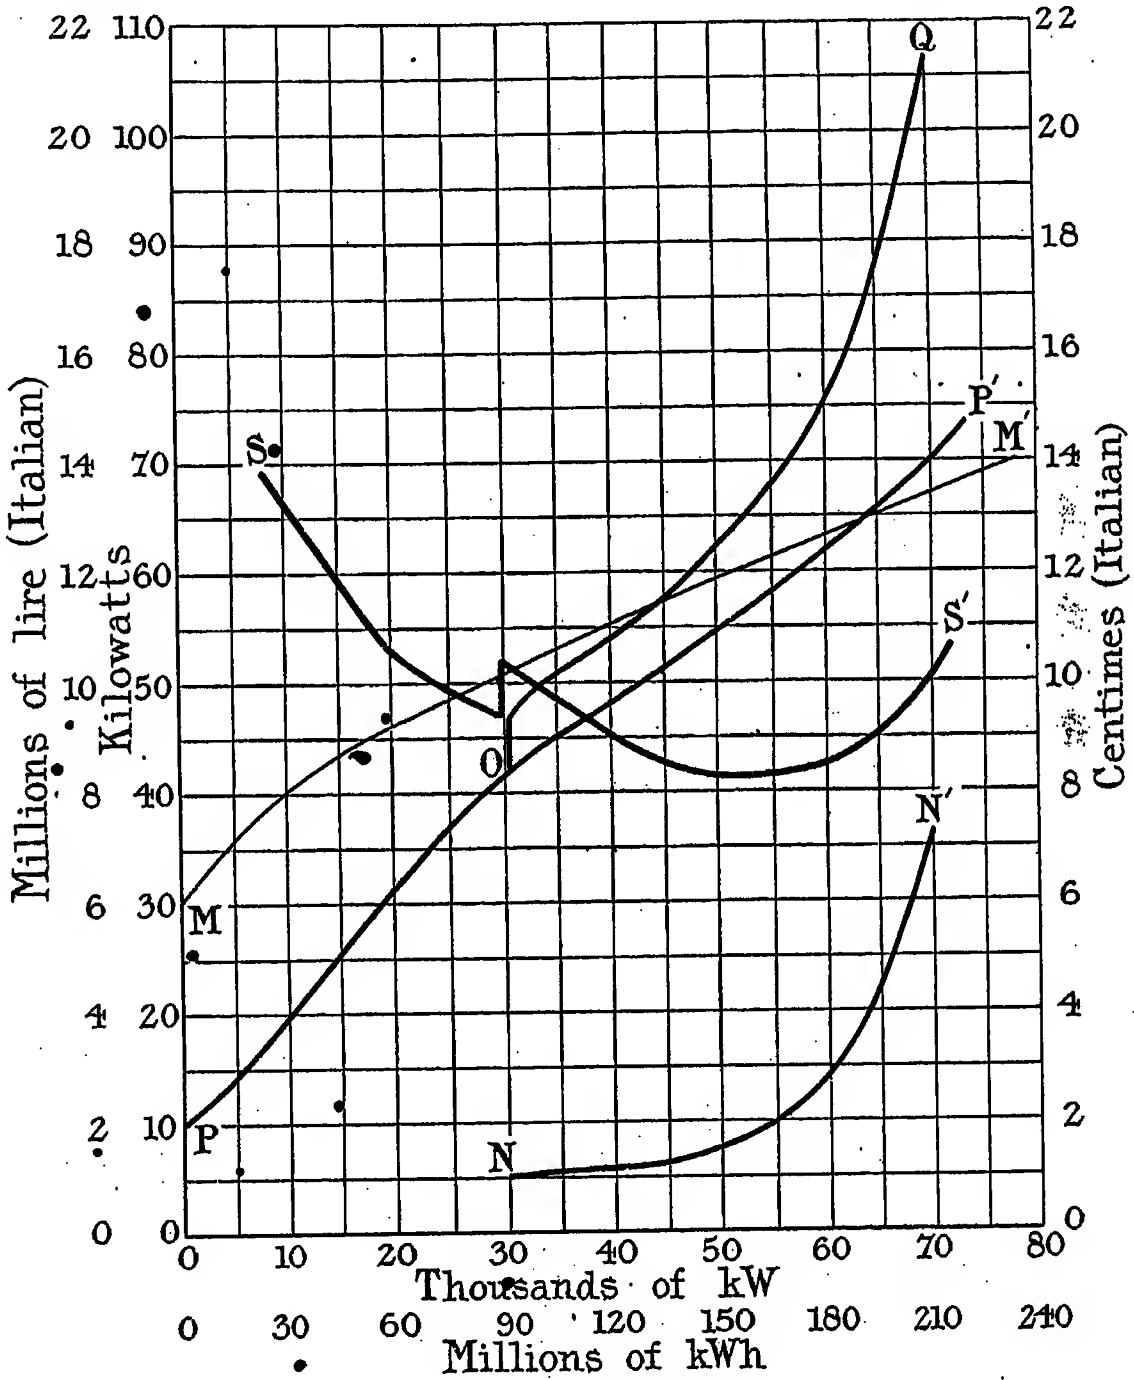

Fig 2.

* At the date of the delivery of the Lecture the rate of exchange was approximately 98 lire to the £.

hour supplied from the plant, assuming no reservoir, is reasonable, it appears that by the addition of the reservoir an output of 65 000 kW instead of only 30 000 kW can be obtained at the same cost per unit. Moreover, by taking into account the capital outlay on the plant, if the selling price of the energy is known it is easy to ascertain for different rated outputs the profit per unit, also the return on the capital outlay, and so on.

Now, if we want to take into consideration the use of steam plant, we shall have to start again from the curve MM′ showing the number of kilowatt-hours required to fill up the hollow in the curve AA′ (Fig. 1), and knowing the cost per kilowatt-hour generated by the steam plant we can calculate the annual cost of the steam power as a function of the total rated output of the plant. Using the same procedure as in the preceding case, we shall obtain a new position for the curve SS′, and a comparison of the two curves will show which is the better solution.

7. As a second example we can consider overhead-line construction. One of the hardest fights has been to convince people that power lines are just as much a question of engineering as a bridge, a railway, or a telpher line; and therefore engineering calculations can just as appropriately be applied to overhead lines.

I do not know why the construction of an overhead line has for so long been considered to be merely like stretching a rope between two poles for drying clothes. Fortunately, such times are over, and engineering—meaning thereby the art of doing what anybody can do, but doing it at the highest efficiency and at the lowest cost—is now applied also to overhead lines.

The mechanical problem of a power line consists, in general, in providing a suitable number of poles, structures or towers capable of supporting a certain number of conductors the sizes, characteristics and stresses of which are known.

We can use 20 supports per mile or we can use 10, but what number gives the greatest economy? Theory first, and experience subsequently, have shown that the length of the span does not affect the safety of a line—so much so, that even public authorities no longer insist on short spans for crossing roads. We must therefore be ready to adopt long spans if these prove to be advantageous. By lengthening the span, the number of supports decreases, but the supports must be higher owing to the greater sag of the wires, and heavier because the stress due to wind and snow on the conductors increases. The problem, therefore, becomes the determination of a minimum, which can be treated by the ordinary methods.

A very interesting investigation of this problem has been made by Mr. Carlo Fascetti of Leghorn.* The towers generally used for power transmission lines on the Continent are of the narrow-base type, the base almost always being square, and they are constructed entirely of standard angle-bar steel, except the arms, which may be of channel section (Fig. 3). The structure is in the form of a pyramid, having four angles connected by bracing lying in the faces of the pyramid.

By considering 12 different towers of this type built for various heights, spans and cross-sections of conductors, and calculated by engineers of different firms, Mr. Fascetti comes to the conclusion that for ordinary practice the relation between the weight of a support

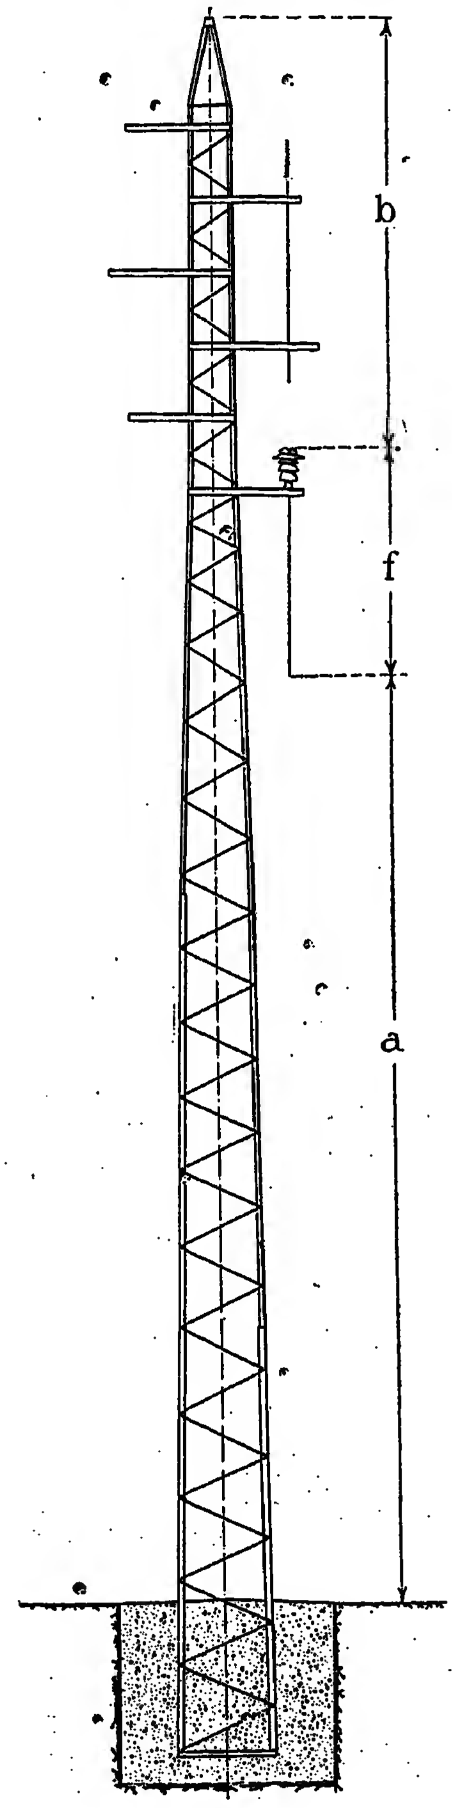

Fig. 3.

of this type and the moment of the acting stresses on the wires and the trellis structure itself, can be reduced to a simple expression of the form

$$P = 0{\cdot}025\,(nkdL + mH)H$$

where n is the number of conductors, d their diameter,

* *Elettrotecnica*, 1921, vol. 8, p. 486.

k a coefficient depending upon the effect of wind on round surfaces, L the span, m a constant depending on the pressure of wind on an iron structure, and H the height of the tower above the ground.

The above expression assumes that the pressure of the wind on the trellis-work is uniform and proportional to the height of the support. This assumption is justified by the fact that the angle of inclination of the columns is generally very small, and by the fact that the pressure on the arms carrying the insulators is neglected, this compensating for the difference in the surface of iron exposed to the wind.

Now a support of the type shown in Fig. 3 can be divided into three sections: the first, which I propose to call a, from the ground-level to the point to which the lowest wire is allowed to sag; the second, a length equal to the maximum sag f (which occurs with the maximum temperature and wind overload); and the third, the portion comprising the arms carrying the insulators, which I shall call b. The lowest section a and the top section b are independent of the sag, while the central one is a function of it. The height of the support above the ground can be written $H = (a + b) + f$, or, for simplicity, $H = h + f$. We know that the sag f is given as a function of the total stress G on the wire, the length L of the span, and the tension T per unit area of the conductor, by

$$f = \frac{L^2 G}{8T}$$

By making certain assumptions we can find the maximum value of f without making use of analytical processes, tables and curves. Let the maximum value be f_1 where

$$f_1 = \frac{L^2 G_1}{8T_1}$$

Then the weight of one support is given by

$$P = 0\cdot025\left[nkdL + m\left(h + \frac{L^2G_1}{8T_1}\right)\right]\left(h + \frac{L^2G_1}{8T_1}\right) \quad . \quad (1)$$

Now the number of towers per kilometre of line is equal to $1\,000/L$, where L is the span in metres, so that the total weight of iron per kilometre of line is $1\,000P/L = p$ say.

Equation (1) can then take the form

$$\frac{p}{0\cdot025} = nkdh + \frac{mh^2}{L} + nkd\frac{G_1}{8T_1}L^2 + m\frac{G_1^2}{64T_1^2}L^3 + 2mh\frac{G_1L}{8T_1} \quad . \quad (2)$$

in which the variables are p and L.

If we analyse the right-hand side of the equation into its components, we see that the first term $nkdh$ represents a horizontal straight line (1), the second term mh^2/L a hyperbola (2), the third term $nkdG_1L^2/8T_1$ a quadratic parabola (3), the fourth term $mG_1^2L^3/64T_1^2$ a cubic parabola (4), and the fifth term an inclined straight line (5).

Fig. 4 refers to an 80 000-volt line with three conductors, each 12·6 mm in diameter. The wind pressure is assumed to be 50 kg per metre of support, which may be taken to be an average value. Also let us assume the height above ground of the lowest point of the lower conductor to be 6 metres in warm weather, and the maximum stress on the wires to be 13 kg per mm^2.

If the above terms of Equation (2) are plotted in Fig. 4 the sum of their ordinates will give the total weight of iron in the towers per kilometre of line, corresponding to different values of the span. In order to reach a decision more quickly, we can consider the cost of the iron instead of its weight, and we then obtain curve (8) showing the cost of iron per kilometre of line.

We have now to add the cost of insulators and foundations.

8. The cost of insulators is constant for each support; hence if the cost of the insulators of one support is C, the cost per kilometre is $1\,000C/L$, and this is another parabola which has been plotted as (6) in Fig. 4. The relation between the cost of the foundations and the length of the span is not so simple. Opinions are very divided in regard to the method of calculating the foundations, and I shall therefore adopt the method which is most used.

The overturning moment of the foundation is given by the sum of the moments due to the wind stress on the wires and on the trellis structure.

$$\text{Thus } M = nkdLH + mH(\tfrac{1}{2}H)$$

This is a simplified formula, but is sufficiently accurate for our requirements. The resisting moment is given by

$$M_r = \tfrac{1}{2}Pc$$

where P is the weight of the foundations, and c the width of the block transversely to the line.

We can assume c to be proportional to H, so that we can put $c = BH$. Then, assuming that the resistance of the earth provides a factor of safety, we can write

$$\tfrac{1}{2}PcH = kndLH + \tfrac{1}{2}mH^2$$

or

$$\tfrac{1}{2}Pc = kndL + \tfrac{1}{2}mH$$

that is

$$P = \frac{2kndL}{BH} + \frac{m}{B}$$

The weight per kilometre of line is then

$$1\,000\frac{P}{L} = 1\,000\,\frac{2knd}{BH} + 1\,000\,\frac{m}{BL}$$

which is a hyperbola displaced from the axis of the abscissæ by the distance $2\,000knd/B$.

We can now determine the cost of the concrete, plot these different relations and sum up the ordinates of the various curves. The result is shown in the top curve in Fig. 4.

The minimum cost per kilometre of line is shown to be for a span of about 180 m, but the curve shows that good results can be obtained for any span between 150 m and 170 m, so that if there is any reason for departing slightly from the most economical span it can be done without much increase in cost.

In making the above calculations I have used a simple expression—which is only approximately correct—for the weight of the supports, but the method is fully justified by the result, which allows a certain latitude in the choice of the span.

9. I want to show, however, that as soon as the span is determined the structure itself can be calculated with much more accuracy.

In statics a tower of the type previously described could be considered to be a cantilever fixed at the base and subjected to a certain stress applied at a fixed distance from the ground. This stress, which is due to wind pressure acting on the conductors and on the tower itself, and also to components of the tension of the conductors, gives rise in the structure to a moment and a shear, which vary in accordance with the distance from the ground to the section of the tower under consideration.

If a definite section be considered, for instance the base section nearest to the ground, the values of the bending moment and shear on this section are completely determined, but we might design any number of structures capable of resisting the stress due to such a load, without the stress in the iron of the structure exceeding a particular value. Owing to their great length and small cross-section, it is important that the various parts of the structure should be capable of resisting buckling, and it is always necessary in this connection to employ a factor of safety.

As I have just mentioned, for a given factor of safety many different structures can be calculated capable of resisting the given bending moment and shear. These different structures are obtained by varying the dimensions of the individual parts, namely the width of the base, the area of the columns, the area of the bracings, and the angle of inclination of the bracings to the horizontal. How shall we choose between the various structures possible? This, again, is a question of determining a minimum value and is a new application of Kelvin's law. In fact if, for a given bending moment and shear, we increase the width of the base of the tower, the length of the bracings will increase and

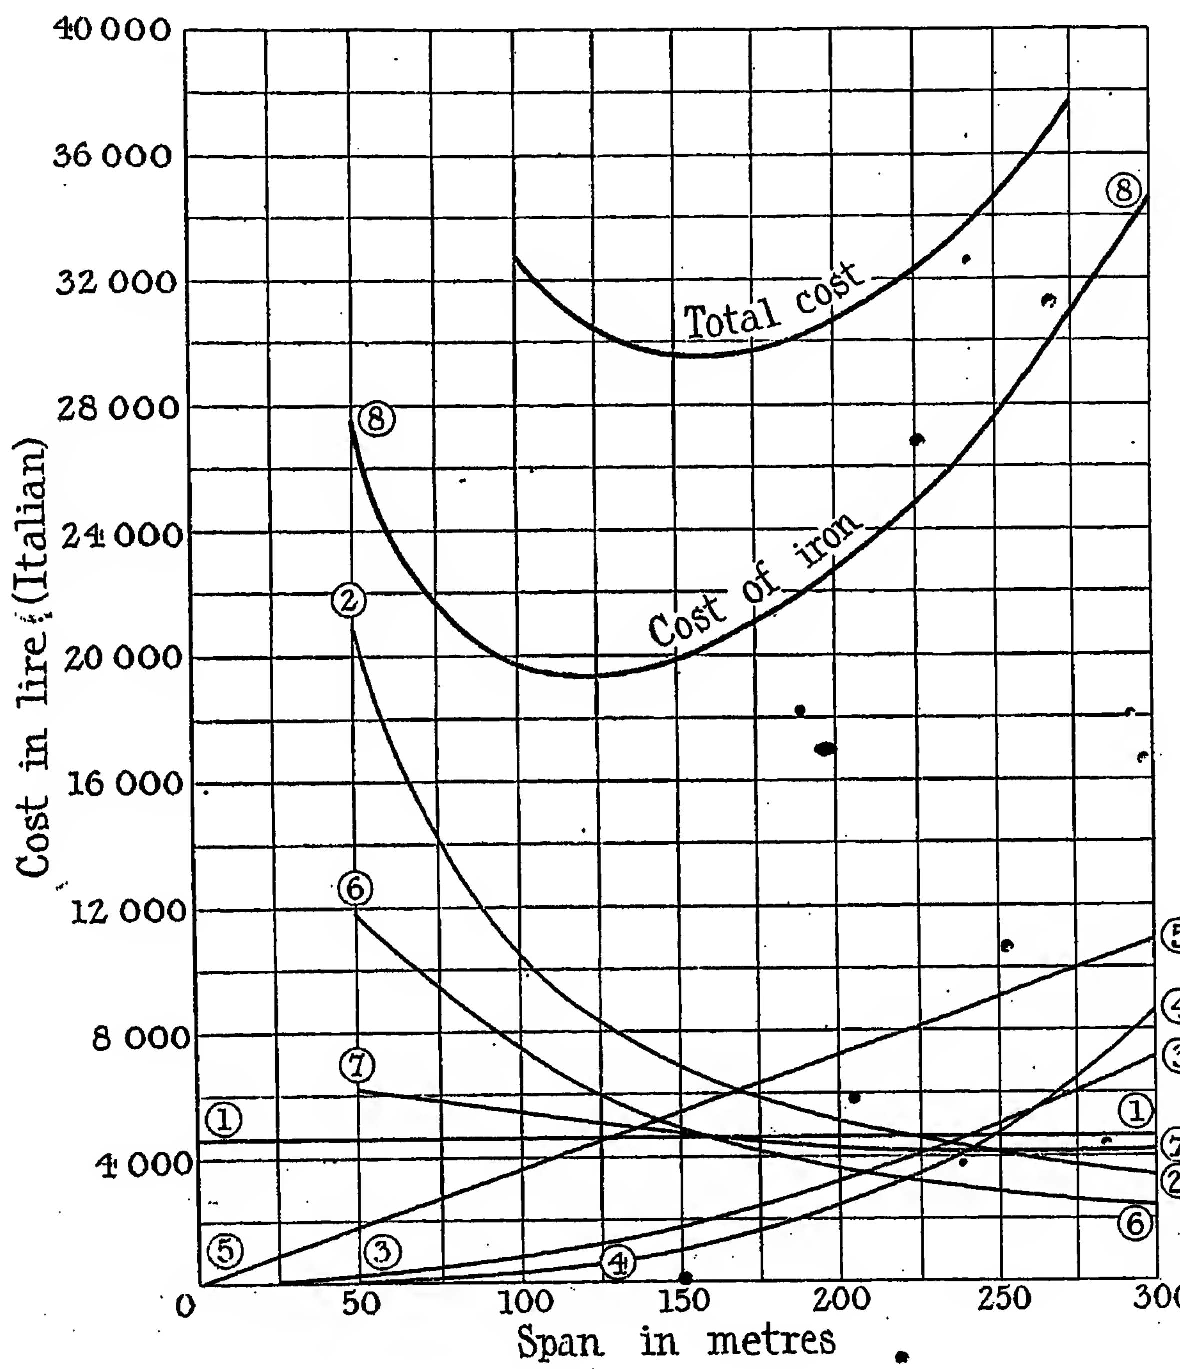

FIG. 4.

also their weight, the columns will be subjected to smaller stresses, and their cross-section will therefore decrease, so that we have a typical case of the sum of two quantities, one of which decreases when the other increases, and vice versa, so that the sum will reach a minimum under certain conditions.

It is unnecessary here to set out the calculation in detail, but Fig. 5 refers to a special case. The abscissæ show the width in centimetres of a square base, and the ordinates the weight in kilograms of the whole tower. It is interesting to notice the different manner in which the weight of the columns and the weight of the bracings vary, and the curve giving the total weight shows that it is not always true that a wider base results in a more economical structure. This answers a question which I am frequently asked: Why have the towers in connection with Italian transmission lines such narrow bases?

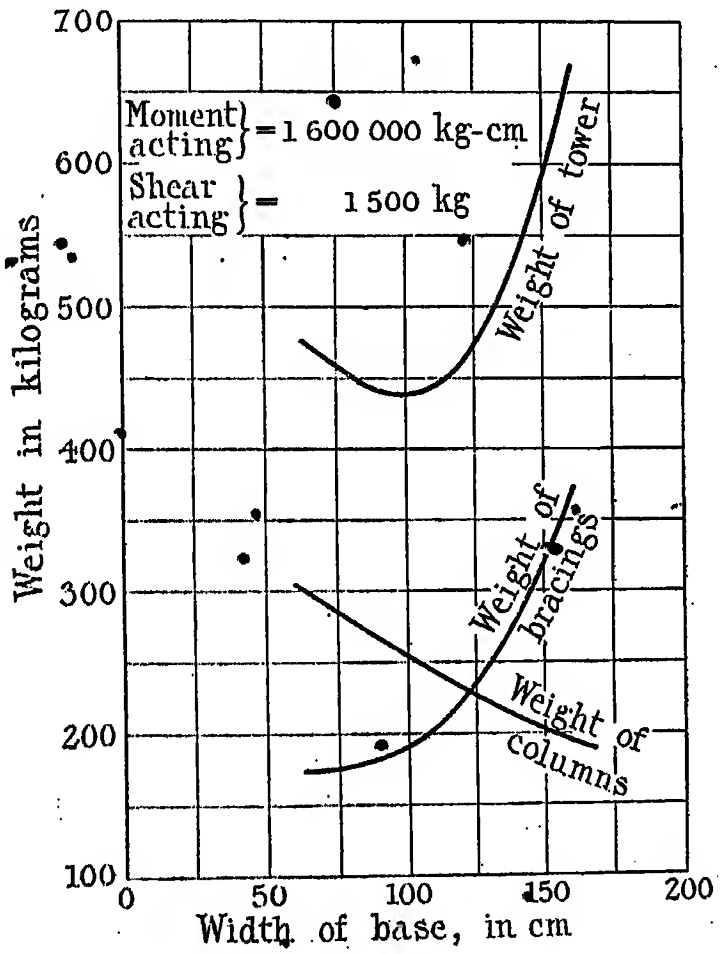

Fig. 5.

The principle explained above has been used in the preparation of tables and curves to allow us to calculate rapidly, when designing overhead lines, the dimensions of the towers to be used. The development of these methods is to be found in *Elettrotecnica*, 1921, vol. 8, pp. 220 and 454.

10. Let us now consider a problem which is more electrical than mechanical, namely, the choice of the most economical voltage for a transmission line. The voltage to be used for a transmission line has generally been settled either by the maximum permissible voltage or by the voltages of neighbouring installations. Years ago it was thought that the best result would always be obtained by using the highest voltage practicable, but when very high voltages were reached two new factors affected the solution. The first was the rapid rate of increase in the cost of insulators, towers, switchgear and transformers as the voltage was raised, and the second was the formation of a corona. As a result the simple law, which showed an economy in copper by raising the voltage indefinitely, conflicted with the general economic law, the extension of Kelvin's law; and also the problem of the most suitable voltage proved to be a question of determining the minimum cost.

Several attempts were made to solve the problem in a general way, and the most interesting work on this subject which I know is a paper by Mr. Claudio Castellani, who deals with the matter analytically.*

Owing to the corona effect, the problem is by no means simple. As long as the Joule effect alone is considered it is quite easy, but when the critical voltage is exceeded the diameter of the conductor must be made greater than its calculated size, in order to reduce the corona loss. The obvious solution would be to use a tubular copper conductor; but as a practical conductor of that type has not yet been economically produced the tube must be filled with copper. In other words, the area must be increased. Aluminium conductors can have a steel core, but this has more effect on the mechanical strength than on the carrying capacity of the conductor. The corona effect and the Joule effect are very different, the one depending on the voltage and the distance apart of the conductors, the other on the current.

Now, for a particular transmission the most economical voltage may be below or above the critical point corresponding to the conditions for the formation of a corona. Up to the present, lines have been so designed as to avoid the formation of a corona, and a definite conclusion has not yet been reached as to the desirability of allowing corona losses, although under special conditions the most economical transmission might necessitate a certain amount of corona loss. Up to the present we do not know how to settle this question.

The simplest way of dealing with the problem is first of all to ascertain the most suitable voltage without taking into account the possibility of a corona. Only if the calculated voltage and cross-section of the conductors for the assumed spacing should be above the critical point is it necessary to make a second calculation, taking into account the corona effect.

11. I do not propose here to describe the first calculation. That is based on the cost of the energy lost per annum due to the Joule effect, which is a function of the voltage and of the cross-section of the conductors, also on the cost per annum of the copper, which is a function of the cross-section of the conductors, and on the cost per annum of the insulation, supports, terminals, substations, etc., which is a function of the voltage. The result will be an expression containing as independent variables the voltage and the radius of the conductor, and the minimum cost can easily be determined. The graphic method of calculation presents no special difficulties.

The voltage and size so obtained disregard the possibility of a corona, leave out of consideration the spacing

* *Elettrotecnica*, 1921, vol. 8, p. 471.

of the wires, and make certain assumptions about the atmospheric pressure.

The spacing of conductors on high-tension lines is the result of experience, and I may say that the personal opinion of the designer also enters into the question. However, by collecting data from a large number of practical cases and plotting them on squared paper, I found that for pressures above 50 000 volts all the points lie close to a straight line passing through the origin. We are therefore justified in assuming a spacing proportional to the line voltage, the constant being about 3·14 (cm per kV).

12. Let us now suppose that in a particular case, taking into account the atmospheric pressure, the values of the voltage and radius calculated in the manner described above would involve conditions causing a corona loss. These values will no longer be applicable to the minimum conditions because a new loss has entered into the problem and was not allowed for in the previous calculation. It is necessary, therefore, to make new calculations.

In dealing with this problem it occurred to me, not only that a method could be devised for solving particular cases, but also that it was possible to obtain a general solution of problems of this nature. That is to say :—

(*a*) Is it possible to allow corona losses and find conditions for which the transmission will be more economical than if only Joule losses were considered ?

(*b*) For what conditions can this happen ?

(*c*) If for special reasons we want to allow a corona loss, how shall we determine the best condition ?

The corona losses for a three-phase line may be expressed as

$$w_c = Ar^2\left(\sqrt{\frac{r}{d}}\right)\left(\frac{V}{r} - B\log_e\frac{d}{r}\right)^2$$

where A = a function of the pressure of the air ;
r = radius of the conductors ;
d = spacing of the conductors ;
V = delta voltage of the line ;
$B = g_0 m_0 \delta$, and is a function of the pressure of the air.

Our calculations being confined to a determination of the most economical result throughout the year, we can determine in each case the mean atmospheric pressure throughout the year for the locality where the line has to be erected, so that we can now assume A and B to be constant.

We have shown that the spacing d between the conductors can be assumed to be proportional to the voltage, so that we are justified in writing $d = bV$. The expression for the corona losses then becomes

$$w_c = Ar^2\left(\sqrt{\frac{r}{bV}}\right)\left(\frac{V}{r} - B\log_e\frac{bV}{r}\right)^2$$

The sum of the corona and Joule losses will be

$$w = k\frac{W^2}{V^2r^2} + Ar^2\left(\sqrt{\frac{r}{bV}}\right)\left(\frac{V}{r} - B\log_e\frac{bV}{r}\right)^2 \quad . \quad (3)$$

This expression contains three variables, namely r, V and w, two of which are independent, so that it is a problem in three dimensions, and if we assume as independent variables r and V, the losses w are represented by points on a surface.

In considering the three dimensions let us set off the radius r of the conductors on the axis OX, the voltage V on OY, and the losses w on OZ.

Now we can easily find on the plane OX, OY, the positions where the corona effect occurs. The critical voltage corresponds to the conditions when the second term of Equation (3) vanishes, which occurs when

$$\frac{V}{r} - B\log_e\frac{bV}{r} = 0$$

It is easy to see that this equation determines the value of the ratio V/r, which we shall call m_0. The expression $V/r = m_0$ represents a straight line OM_0 passing through O, which I propose to call the critical line. All the points under the critical line OM_0 correspond to conditions which involve no corona loss, while corona loss arises for points above the line.

The solution of an expression of this form is not easy, but can be simplified by a proper choice of the variables. Instead of assuming as independent variables V and r, let us take V and the ratio $V/r = m$. The advantage of this assumption is that the expression in parentheses is constant for any particular value of m. By attributing different values to m, we proceed as if we explored the space by sectioning planes passing through the axis OZ (losses).

It should here be observed that all the solutions having the same value of m are similar in shape but of different dimensions, so that we can apply to this method all the properties of similar systems. For instance, when a calculation is made with a particular value of $V/r = m$, it is possible to find the minimum annual cost corresponding to the group of solutions which have in common this value of m. By a graphic method it is then possible to ascertain the group of solutions having the minimum value of m, that is, the minimum of the minima, and consequently the most advantageous point when the corona effect is taken into account, which is the desired solution. I should like to point out that, in endeavouring to determine this analytically, serious difficulties would be encountered, difficulties which are easily solved by graphic methods. It would take too long to discuss in detail in this Lecture this method of calculation, but it will be added as an Appendix.

13. I propose to confine my remarks to the method which I have just described. The two methods of calculation give two minima, one determined by neglecting corona losses, and the other taking such losses into account. These two minima have different dimensions.

Let us project the points representing these two minima on the plane OX, OY, and draw the straight line OM_0 which, as we saw, divides the plane into two parts—one in which corona losses occur, and one in which they do not. Each of these two minima, in order to have a real value and not be merely theoretical, must fall in the corresponding zone, the "corona" minimum above the line OM_0, and the "Joule" minimum below the line. The development of the method

shows that both these points can never have a real value, except under special conditions, when the points coincide, in which case they fall on the critical line.

A careful examination of the results brings us to the conclusion that in the normal conditions under which modern lines are constructed, and when the costs of energy, materials and labour are in their usual proportions, the majority of cases yield minima with Joule losses only. In order to fall in the zone of corona losses, the conditions must be rather unusual. The process enables us also to find the best conditions to be adopted when a corona effect is desired.

I do not propose to try the patience of members by discussing further examples, and I shall merely mention that Kelvin's law has been successfully applied to other hydraulic problems such as the determination of the best diameter of a penstock; to construction problems such as the determination of the best ratio between the iron and copper losses in a transformer; and to electric traction, in the determination of the most advantageous spacing of converter substations, and so on.

14. I do not know if I have succeeded in giving a sufficiently clear picture of the applications which Kelvin's law has received in all the fields of electrotechnics, and in convincing the members of the utility, in their everyday calculations, of the various developments of this law. However that may be, I can only say that the attempt to do so has given me the greatest pleasure, as I have regarded it as a tribute to the memory of the great master whom we have all come here this evening to honour.

My esteem for Kelvin dates from my college days when the magnitude of his work first impressed me so forcibly, and it was with deep emotion and respect that I approached him when, in the year 1906, as a representative of one of the kindred societies invited by this Institution, I came with other visitors to this country. On that occasion, during the receptions in Glasgow, I had the honour of presenting him, on behalf of the Associazione Elettrotecnica Italiana, with a facsimile of Leonardo's "Codex Atlanticus." I have ventured to mention this fact because it has often occurred to me since that such a gift had a special significance, as it brought together two great personalities who had from many points of view striking resemblances.

It is quite out of the question that the work of Leonardo could have had any influence on the development of Kelvin's ideas. During the latter's youth, Leonardo's scientific and philosophic works were almost unknown; his manuscripts, scattered, as they were, in different libraries, and written in a peculiar manner, which makes their reading very difficult, had been noticed only because of the beauty and originality of the sketches distributed throughout the text, to which sketches we owe the preservation of the manuscripts. Only after 1880 were they copied in legible characters and systematically studied, arousing general interest both for the depth and for the foresight of the ideas contained in them.

In reading Leonardo's notes, and having in mind Kelvin's personality, one is forcibly brought to compare these two men, born in different countries and separated in time by four centuries.

Silvanus Thompson, in his beautiful biography of Lord Kelvin, which formed the first of these Kelvin Lectures,* points out how Lord Kelvin always endeavoured to consider the physical meaning of any mathematical research, and shows the importance which he gave to the applications of science. "The life and soul of science is in its applications," he used to say. This tendency appears to have been somewhat original; and foreign students at that time who came to Great Britain to attend lectures in the universities, refer to it as a new feature in the methods of teaching due to Professor William Thomson.

In the forgotten notes of Leonardo, who lived when Aristotle's doctrines were still universally accepted, we find these words: "When you write on scientific matters be sure to add, after each proposition, the use you can make of it, if you don't want your science to be useless"; and, in a more poetic form, "Mechanics are the paradise of mathematical science, as by them we reach the mathematical fruit."

It will be remembered that Lord Kelvin used to say: "When you cannot measure or express in numbers what you are speaking about you have scarcely advanced to the stage of science." And Leonardo: "There is no certainty where one of the mathematical sciences cannot be applied." And further on, "No research can be called true science if it does not proceed through a mathematical demonstration."

I myself remember Lord Kelvin stating, in a private conversation in which the new electron theory was being discussed: "Marvellous things have been done in experimenting and calculating, but as to the physical meaning of all this we know nothing, and who can tell whether we shall ever know anything?" Leonardo did not hope for much more, as he wrote: "Although we know many of their effects, the knowledge of the intimate definition of the elements is forbidden to men." And many other resemblances between these two men could be quoted.

The coincidence of thought of these two scientists, widely separated in distance and in time, makes one thoughtful. It shows that the higher a scientist rises in intelligence, knowledge and power of research, the more he tends to reach a particular type. The identity of fundamental ideas and principles, found after the lapse of four centuries in men who had grown up quite independently and surrounded by radically different civilizations, culture and habits, shows that modern science, which embodies such ideas and principles, is proceeding along the right lines. The fact that Leonardo was born in Italy in the Middle Ages, and Kelvin in modern Britain, and that each was, on the whole, a genuine expression of his own race, shows once more, and perhaps under a new form, that science is the strongest international bond. From science will come the solution of the serious problem of how so many nationalities and races living and struggling on this little fragment of matter, wandering in the infinite, can exist peacefully one with another.

In conclusion I must express my indebtedness to

* *Journal I.E.E.*, 1908, vol. 41, p. 401.

Mr. Dino Nobili and Mr. Marco Semenza for their assistance in connection with the mathematical and engineering calculations in the Lecture.

APPENDIX.

In dealing with calculations in regard to the most economical voltage when corona losses are permissible, it is convenient to express by a formula the relation between the annual cost of the installation and the line voltage. By investigation of a number of practical cases it was found that the following relation can be adopted with fair accuracy:—

$$S_t = TV^2 + c \quad . \quad . \quad . \quad . \quad . \quad (4)$$

where,

S_t = annual cost;
V = voltage, expressed in kilovolts;
T = sum of three terms, the first based on the cost of the insulators, the second on the cost of the towers, and the third on the cost of the terminal substations. The first two terms are proportional to the length of the line, and the third to the amount of power transmitted.

In this Lecture it has been stated that the spacing d between the conductors can be assumed to be

$$d = bV \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

A group of three conductors of a three-phase circuit is defined by the radius of each conductor and the spacing (which we shall assume to be uniform). Equation (5) allows us to substitute the voltage for the spacing.

The particular kind of system which is here considered is of the type for which $V/r = m$; that is to say, all systems having the same value of m are similar (see Fig. 6). For convenience, we shall assume the variables to be V and m. The annual cost of transmitting W kilowatts at a voltage V, when no corona loss occurs, is

$$S_j = J\frac{W^2}{V^2 r^2} + Rr^2 + TV^2 + c \quad . \quad . \quad . \quad (6)$$

where J is proportional to the length of the line, to the resistivity of the metal used, to the cost per kilowatt-hour, and to the number of hours of use, and inversely proportional to the square of the power factor; R is proportional to the length of the line, to the specific weight and cost of the metal used, and to the interest and sinking fund charges on the capital outlay on the conductors; and T is the same as in Equation (4).

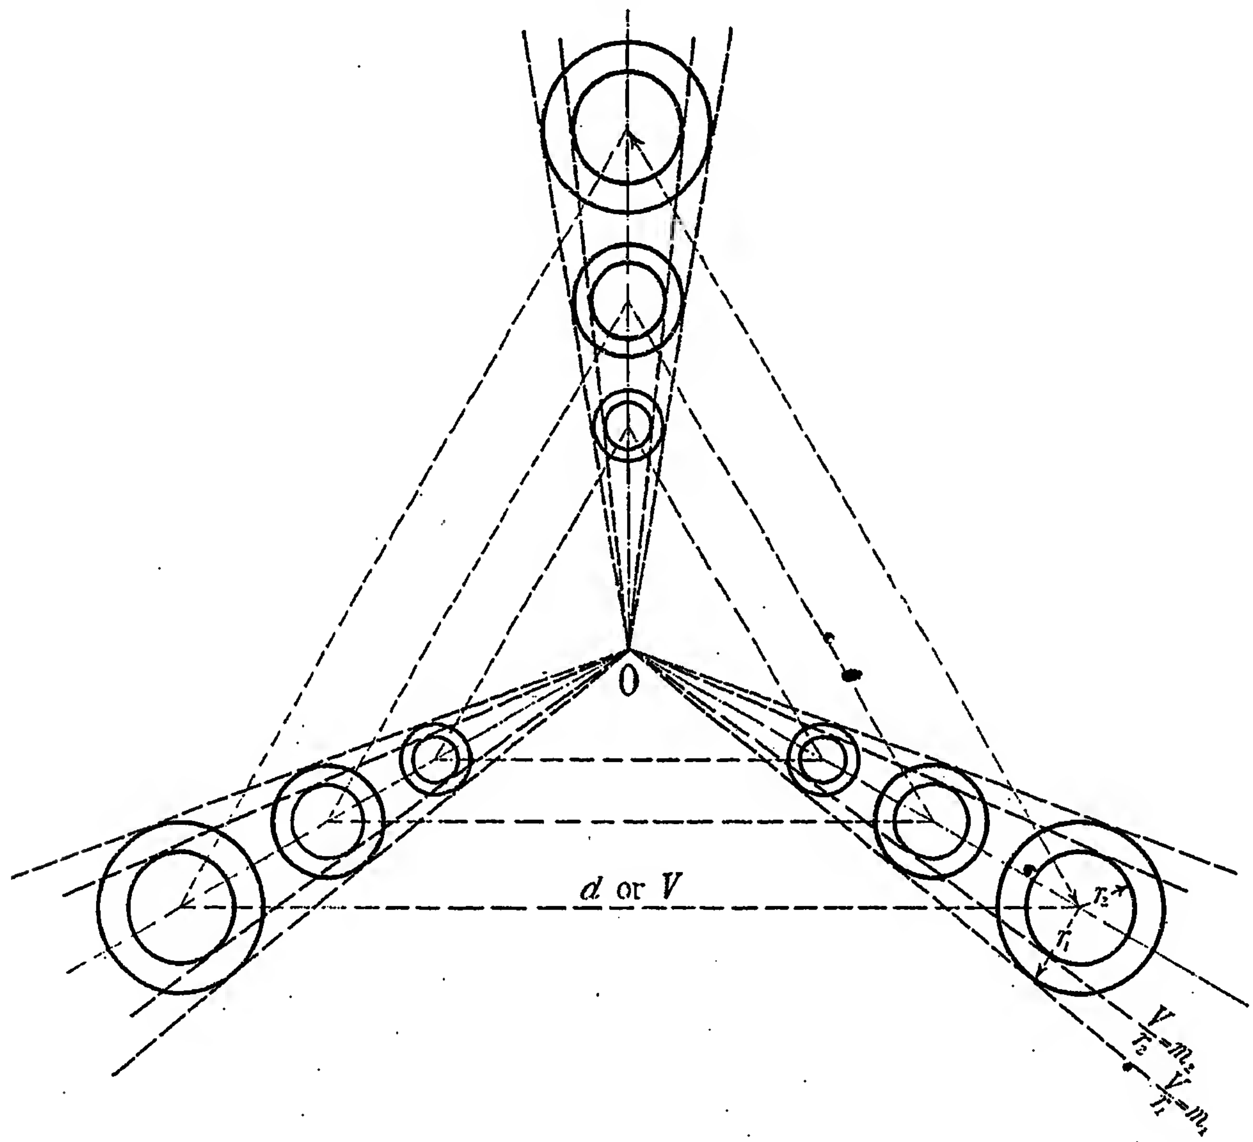

Fig. 6.

By substituting $m = V/r$ we obtain

$$S_j = J\frac{W^2m^2}{V^4} + \left(\frac{R}{m^2} + T\right)V^2 + c \quad . \quad . \quad (7)$$

Let us now assume for m a concrete value applicable to a particular system, the value of V corresponding to the minimum value of S_j. The annual cost of all systems having a common m is given by $\frac{dS_j}{dV} = 0$, that is by

$$-4J\frac{W^2m^2}{V^5} + 2\left(\frac{R}{m^2} + T\right)V = 0$$

which gives $$V = \sqrt[6]{\left(\frac{2Jm^4W^2}{R+Tm^2}\right)} \quad . \quad . \quad . \quad . \quad . \quad (8)$$

and $$(S_j)_m = \frac{3}{\sqrt[3]{4}}\sqrt[3]{\left[JW^2\left(\frac{R}{m} + Tm\right)^2\right]} + c \quad . \quad (9)$$

What we are seeking is the minimum value of $(S_j)_m$ when m varies; that is, to find what value of m gives the minimum value of the various minima.

Inspection of Equation (9) shows that, in order to have $(S_j)_m$ a minimum, it is sufficient that $(R/m + Tm)$ should be a minimum; and, by making the derivative equal to zero, the condition for a minimum is $m = \sqrt{(R/T)}$, and the minimum itself, which we shall call $(S_j)_\mu$, is given by

$$(S_j)_\mu = 3\sqrt[3]{(JRTW^2)} + c$$

The corresponding cost per kilowatt-hour will be

$$(s_j)_\mu = \frac{3}{h}\sqrt[3]{\left(\frac{JRT}{W}\right)} + \frac{c}{hW} \quad . \quad . \quad . \quad (10)$$

The value of the resulting voltage is

$$V = \sqrt[6]{\left(\frac{JR}{T^2}W^2\right)} \quad . \quad . \quad . \quad . \quad . \quad (11)$$

Let us now consider the expression $m = \sqrt{(R/T)}$.

From Peek's formula for corona losses it can easily be shown that the value of m corresponding to the critical voltage is

$$m_0 = B \log_e bm_0$$

This equation can easily be solved by using tables of hyperbolic sines and cosines.

If $\sqrt{(R/T)} < m_0$, no corona losses occur.

If $\sqrt{(R/T)} > 0$, there will be corona losses.

Corona losses are expressed by

$$w_c = Ar^2\frac{(m - B\log_e bm)^2}{\sqrt{m}}$$
$$= \frac{A(m - B\log_e bm)^2}{\sqrt{m}} \cdot \frac{V^2}{m^2}$$

The cost of the energy loss by corona effect is given by

$$S_c = ALhc_k\frac{(m - B\log_e bm)^2}{\sqrt{m}} \cdot \frac{V^2}{m^2}$$

where L = length of the line;
h = number of hours per annum during which the voltage is on the line;
c_k = cost per kilowatt-hour.

Let us put $$\frac{(m - B\log_e bm)^2}{\sqrt{m}} = Q$$

then $$S_c = ALhc_kQ\frac{V^2}{m^2}.$$

Adding this cost to that of the conductor insulation and of the supports and terminal substations, we can express the total cost as

$$S_{jc} = \frac{JW^2m^2}{V^4} + \left(\frac{R + CQ}{m^2} + T\right)V^2 + c$$

where $C = ALhc_k$.

We could proceed to determine the minimum value of this function by the ordinary methods, but it is simpler to proceed in two steps, the first being the determination of the minimum value for a group of systems having the same value of m, which is therefore constant. In this case we can use the preceding formulæ, substituting $(R + CQ)$ for R.

The expressions for S and V become

$$S = \frac{3}{h\sqrt[3]{4}}\left\{\sqrt[3]{\left[\frac{J}{W}\left(\frac{R}{m} + mT + \frac{CQ}{m}\right)^2\right]} + \frac{c}{hW}\right\}$$

and $$V = \sqrt[6]{\left(\frac{2Jm^4W^2}{R + CQ + Tm^2}\right)}$$

The smallest of the minimum values should be calculated by equating to zero the first derivative of the equation

$$\frac{R}{m} + Tm + \frac{CQ}{m} = \Phi$$

The process would, however, prove very long and complicated. It is easier to plot the curve of Φ as a function of m. The ordinates of this curve are the sum of the ordinates of the hyperbola $(R/m + mT)$, which corresponds to the losses when corona effect is absent, and of the ordinates of the expression CQ/m, which is Peek's equation divided by m.

This equation can assume the following form

$$F = C\frac{(m - B\log_e bm)^2}{m\sqrt{m}}$$

This function, in the region in which it has a real meaning, namely $(d > 2r)$, has only one minimum, and this is zero. The sum of the ordinates of these curves gives us the curve of Φ, and the minimum of this quantity establishes the conditions of maximum economy for the transmission.

The following remarks can be made in conclusion:

(1) It is impossible to calculate the most economical voltage without taking into consideration at least two independent variables, and the most convenient are V and $V/r (= m)$.

(2) The simplest graphic representation is by projecting on a plane the intersection of a number of parallel planes and the surface considered.

(3) The surface representing the case in which no corona effect occurs is different from that representing the surface for which corona losses occur, but the

intersection of these two surfaces is contained in a plane perpendicular to the plane of reference, the projection of which on this is the straight line OM_0 (see Fig. 7).

(4) Each minimum, in order to have a physical meaning, must fall in the region applicable to the conditions, otherwise the solution is merely mathematical.

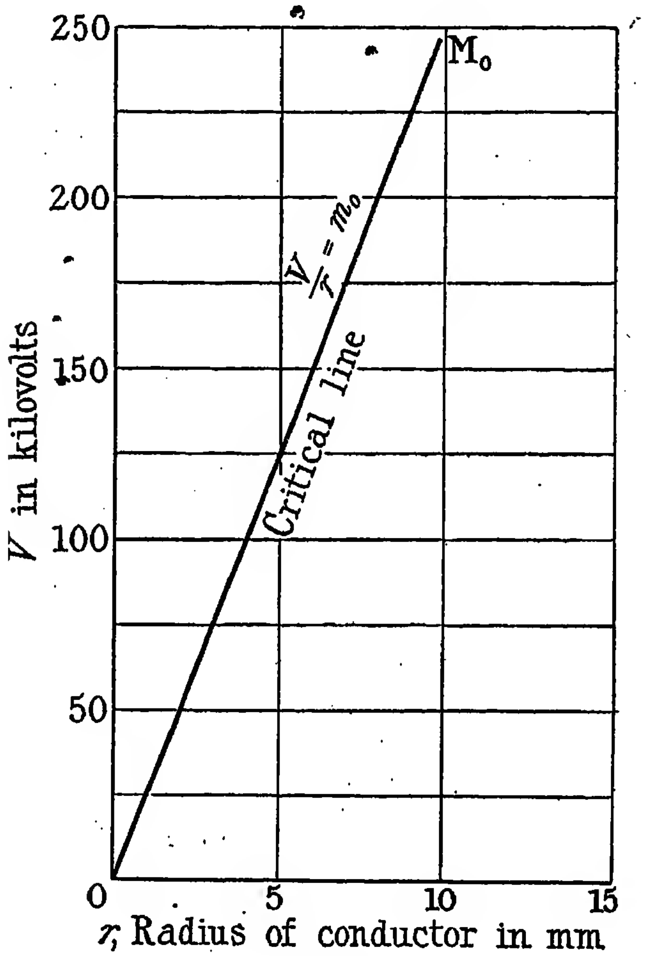

FIG. 7.

(5) In every case in which the minimum falls in a region in which corona losses occur it will be interesting to examine the effects of a change in the relation between V and d with a view to avoiding corona losses.

Near the beginning of the Appendix it was stated that the different costs can, for convenience, be expressed by simple relations. Such relations have been determined by plotting a number of practical values and drawing a smooth curve as near as possible to the figure which results if such points are connected by straight lines. By making use of present costs I have obtained the following expressions:

$$
\begin{aligned}
J &= 0\cdot008455\ LC_w h \\
R &= 80\cdot12 pkL \\
T &= 0\cdot1503\ L + 0\cdot000148\ W + 3\cdot18 \\
c &= 608\ L + 4\cdot32\ W + 28\ 800
\end{aligned}
$$

where L = length of the line in kilometres;
C_w = cost per kilowatt-hour delivered to the line;
h = number of hours during which current is used per annum;
p = cost of copper per kilogram; and
k = interest and sinking fund charges on the copper.

The resistivity of copper has been assumed to be 1·7, and its specific gravity 8·5.

We have seen that in the formula $d = bV$ the practical value of b is 3·14 when r is expressed in centimetres.

Example. 30 000 kW has to be transmitted a distance of 120 km by three-phase current.

Let us assume:

power factor = 0·8;
C_w (cost of kilowatt-hour delivered to line) = 0·10 lire;
p (cost of copper) = 9 lire per kilogram;
k (interest charges, etc.) = 8 per cent;
h (hours of utilization) = 4 000.

We have

$$
J = 405\cdot84 \qquad R = 6\ 923
$$
$$
T = 25\cdot66 \qquad c = 231\ 360
$$

Inserting these values in the equation $m = \sqrt{(R/T)}$, we find $m = 16\cdot43$.

We can now find the critical value of m_0, which is $m_0 = 24\cdot25$. In order that the corona effect may be present we ought to have

$$
R/T \geq m_0^2, \text{ that is } R/T \geq 588
$$

But $R/T = 269\cdot8$, and therefore the minimum falls in the region where no corona effect occurs.

By applying the preceding formulæ we find the most economical voltage, $V = 128$ kilovolts.

The cost of the transmission, $s_j = 0\cdot0119 \sim 0\cdot012$.

The radius of the conductor, $r = 8\cdot95$ mm; and the distance between conductors, $d = 402$ cm.

COUPLING BETWEEN TWO OSCILLATORY CIRCUITS, WITH SOME APPLICATIONS.*

By L. S. PALMER, M.Sc., Ph.D., Associate Member, and H. W. FORSHAW, M.Sc.Tech., Graduate.

(Paper first received 10th March, and in final form 7th July, 1924.)

SUMMARY.

(1) *Introduction.*

The different methods of coupling two oscillatory circuits are conveniently classified as follows:—

(i) Indirect coupling through a field of force common to both oscillatory circuits.
(ii) Direct coupling through an impedance common to both circuits.
(iii) Direct coupling through an impedance not included in either oscillatory circuit.

(2) *The Physics of Tuned Coupled Circuits.*

An easy method of obtaining the values of the two resonant frequencies for each system is described. The method is based upon current considerations and is applicable to the case when the two circuits are tuned to the same frequency. The method is illustrated by applying it to a type of inductive coupling.

(3) *The Frequency Variations.*

The properties peculiar to the two resonant frequencies for each type of coupled circuit are discussed, and coupling units are described by which the resonant frequencies of the directly coupled circuits may be made continuously variable.

(4) *Applications.*

These coupling units are applied to an aerial circuit in such a manner that each resonant frequency of the system can be varied independently of the other, over any desired range of frequency. By this method of dual reception each wave-length is properly tuned and one aerial only is employed.

Finally, the coupling units are applied to the intervalve system of a high-frequency amplifier, thereby enabling the amplifier to be readily tuned to any frequency and to amplify two signals independently and simultaneously.

(1) INTRODUCTION.

Various technical publications have dealt with several forms of coupling between wireless oscillatory circuits. The various possible methods may be conveniently divided into three classes:—

Class (i). Indirect coupling through a field of force common to both oscillatory circuits.

Class (ii). Direct coupling through an impedance common to both oscillatory circuits.

Class (iii). Direct coupling through an impedance not included in either circuit.

These classes are depicted in Fig. 1, resistance coupling being neglected. In what follows, resistances in the oscillatory circuits will be neglected, as, unless they are very large, they will not affect the resonant frequencies of the systems.

Circuits coupled as in Figs. 1 (*a*), 1(*c*), 1 (*d*), and 1(*f*) have been treated from some aspects in most standard textbooks, whilst the forms of coupling depicted in Figs. 1 (*b*) and 1(*e*) have been added for completeness. Fig. 1 (*b*) is intended to represent two circuits coupled by placing one condenser in the field of force set up by the other.

In every case the coupled system has a minimum value of impedance for two values of ω, where ω is

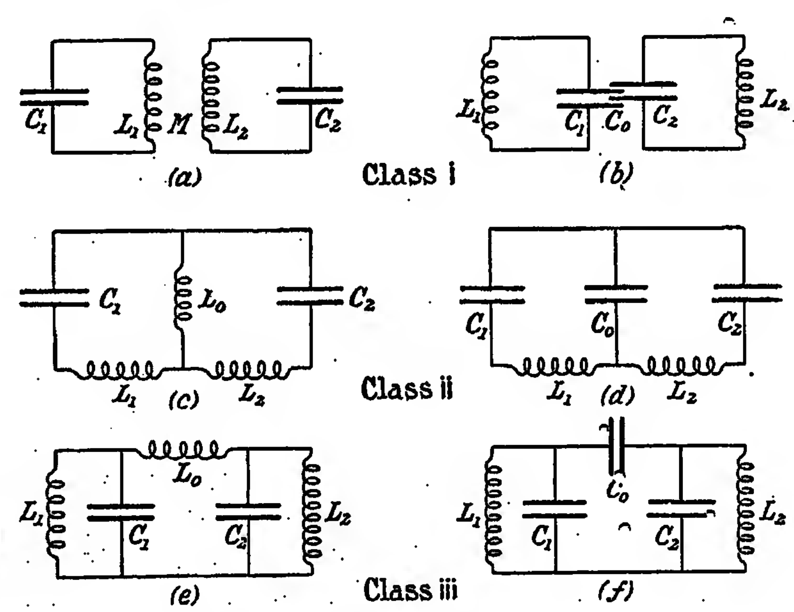

FIG. 1.

equal to 2π times the frequency. The variations in the resonant frequencies with variations in the coupling unit depend on the conditions of tuning. For the simplest and most usual relationship between the LC products the resulting resonant frequencies are collected in Table 1, where the symbols have the significance indicated in Fig. 1.

(2) THE PHYSICS OF TUNED COUPLED CIRCUITS.

Many of these results have been published elsewhere and all of them can be obtained by the usual analytical methods. There is, however, a simpler method of obtaining the more important results for which the condition $L_1C_1 = L_2C_2 = LC$ is fulfilled. With this particular condition the two resonant frequencies occur when the currents in the separate circuits are, at any instant, circulating in the same or in opposite directions respectively. The system, as a whole, presents alternative relative directions to the currents, and the

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

direction of rotation depends upon the particular frequency of the incident energy. This will be illustrated with reference to Class (iii) e which has not been dealt with hitherto.

Experiments carried out with this form of circuit, in which vacuum thermo-junctions and galvanometers had been inserted, revealed the fact that when incident energy was of the frequency $\omega_1/2\pi$ [where $\omega_1 = 1/\sqrt{(L_1C_1)}$] whole system. The impedance of L_0 is negligible compared with infinity, and its value will also have no effect on the resonant frequency. Thus the resonant frequency of the system with this particular current distribution will be the same as that of either of the circuits separately. Such a current distribution will thus account for the frequency $\omega_1/2\pi$. In practice the current in the coupling inductance is not quite zero

TABLE I.

Circuit	ω_1	ω_2	Conditions
(i) a	$1\Big/\sqrt{\left[LC\left\{1+\frac{M}{\sqrt{(L_1L_2)}}\right\}\right]}$	$1\Big/\sqrt{\left[LC\left\{1-\frac{M}{\sqrt{(L_1L_2)}}\right\}\right]}$	$L_1C_1=L_2C_2=LC$
(i) b	$1\Big/\sqrt{\left[LC\left\{1+\frac{C_0}{\sqrt{(C_1C_2)}}\right\}\right]}$	$1\Big/\sqrt{\left[LC\left\{1-\frac{C_0}{\sqrt{(C_1C_2)}}\right\}\right]}$	$L_1C_1=L_2C_2=LC$
(ii) c	$1\Big/\sqrt{\left[LC\left\{1+\frac{L_0}{\sqrt{[(L_1+L_0)(L_2+L_0)]}}\right\}\right]}$	$1\Big/\sqrt{\left[LC\left\{1-\frac{L_0}{\sqrt{[(L_1+L_0)(L_2+L_0)]}}\right\}\right]}$	$(L_1+L_0)C_1=(L_2+L_0)C_2=LC$
(ii) c	$1/\sqrt{(LC)}$	$1/\sqrt{\{LC+L_0(C_1+C_2)\}}$	$L_1C_1=L_2C_2=LC$
(ii) d	$1\Big/\sqrt{\left[LC\left\{1+\sqrt{\frac{C_1C_2}{(C_1+C_0)(C_2+C_0)}}\right\}\right]}$	$1\Big/\sqrt{\left[LC\left\{1-\sqrt{\frac{C_1C_2}{(C_1+C_0)(C_2+C_0)}}\right\}\right]}$	$L_1\frac{C_1C_0}{C_1+C_0}=L_2\frac{C_2C_0}{C_2+C_0}=LC$
(ii) d	$1/\sqrt{(LC)}$	$1\Big/\sqrt{\left\{LC\left(\frac{C_0}{C_1+C_2+C_0}\right)\right\}}$	$L_1C_1=L_2C_2=LC$
(iii) e	$1\Big/\sqrt{\left[LC\left\{1+\sqrt{\frac{L_1L_2}{(L_1+L_0)(L_2+L_0)}}\right\}\right]}$	$1\Big/\sqrt{\left[LC\left\{1-\sqrt{\frac{L_1L_2}{(L_1+L_0)(L_2+L_0)}}\right\}\right]}$	$\frac{L_1L_0}{L_1+L_0}C_1=\frac{L_2L_0}{L_2+L_0}C_2=LC$
(iii) e	$1/\sqrt{(LC)}$	$1\Big/\sqrt{\left\{LC\left(\frac{L_0}{L_1+L_2+L_0}\right)\right\}}$	$L_1C_1=L_2C_2=LC$
(iii) f	$1\Big/\sqrt{\left[LC\left\{1+\frac{C_0}{\sqrt{[(C_1+C_0)(C_2+C_0)]}}\right\}\right]}$	$1\Big/\sqrt{\left[LC\left\{1-\frac{C_0}{\sqrt{[(C_1+C_0)(C_2+C_0)]}}\right\}\right]}$	$L_1(C_1+C_0)=L_2(C_2+C_0)=LC$
(iii) f	$1/\sqrt{(LC)}$	$1\Big/\sqrt{\left\{LC\left(1+\frac{C_0}{C_1}+\frac{C_0}{C_2}\right)\right\}}$	$L_1C_1=L_2C_2=LC$

no current was measurable in the coupling inductance L_0; whilst when the incident energy was at the frequency $\omega_2/2\pi$ $\left[\text{where } \omega_2 = 1\Big/\sqrt{\left(LC\frac{L_0}{L_1+L_2+L_0}\right)}\right]$ the current in L_0 was approximately equal to the difference of the currents in L_2 and in C_2. The interpretation of these results is as follows. At the frequency $\omega_1/2\pi$ the currents in the two circuits were oscillating in opposite directions at any one instant, whilst at the frequency $\omega_2/2\pi$ the currents were oscillating in the same direction at any instant. This is shown in Fig. 2(a) by the dotted and full-line arrows respectively.

When currents flow in the directions indicated by the dotted arrows they pass downwards through the condensers and upwards through the inductances simultaneously. Then the two points A and B will be at the same potential and consequently no current will flow in the coupling inductance. The circuits will act towards each other as rejector circuits and provide infinite impedance paths parallel to their inductance or capacity. The presence of this path, therefore, will not affect the resonant frequency of either circuit or of the owing to the ohmic losses in the circuit L_2C_2, and consequently a small power current flows in L_0 to compensate for this wastage. This is equivalent to saying that there will be a small potential difference between the points A and B.

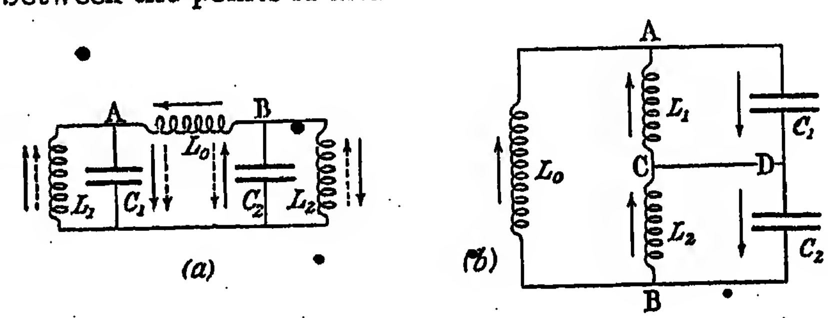

FIG. 2.

The second resonant frequency arises when the currents flow in the directions indicated by the full-line arrows. In this case the currents in C_1 and C_2 are, at any instant, flowing in opposite directions and the points A and B will be 180° out of phase, with a consequent flow of current in the coupling inductance.

Suppose the circuit be re-drawn as in Fig. 2 (*b*). Then, since $L_1C_1 = L_2C_2$,

$$(1/\omega C_1)/(1/\omega C_1 + 1/\omega C_2) = \omega L_1/(\omega L_1 + \omega L_2)$$

and therefore the potential fall from A to C is the same as that from A to D. Hence C and D will be at the same potential and no current will flow along CD. The frequency $\omega_2/2\pi$ will therefore be the same as the frequency of a simple oscillating circuit in which the equivalent inductance L' is equal to the value of L_0 in parallel with L_1 and L_2 in series, that is :—

$$L' = \frac{L_0(L_1 + L_2)}{L_1 + L_2 + L_0}$$

The equivalent capacity C' will be given by C_1 and C_2 in series, that is :—

$$C' = \frac{C_1C_2}{C_1 + C_2}$$

Hence $\omega_2 = 1/\sqrt{(L'C')}$

$$= 1\Big/\sqrt{\left[\frac{L_0(L_1 + L_2)}{L_1 + L_2 + L_0} \cdot \frac{C_1C_2}{C_1 + C_2}\right]}$$

or $$1\Big/\sqrt{\left(\frac{L_1C_1C_2 + L_2C_2C_1}{C_1 + C_2} \cdot \frac{L_0}{L_1 + L_2 + L_0}\right)}$$

Since $L_1C_1 = L_2C_2 = LC$, this reduces to

$$\omega_2 = 1\Big/\sqrt{\left[LC\left(\frac{L_0}{L_1 + L_2 + L_0}\right)\right]}$$

This value is identical with that obtained by equating the total circuit impedance to zero and solving the resulting equation for ω, and hence justifies the interpretation of the experimental results stated above.

The method is quite general for those cases where it is possible to keep the circuits in tune, whilst varying the coupling unit.

(3) The Frequency Variations.

An examination of the results collected in the table reveals the fact that with class (i) both the resonant frequencies are equally dependent on the value of the coupling unit. This is necessarily the case because the value of the product of the inductance and capacity of either circuit is dependent on the value of the coupling, and vice versa. With class (ii) the normal condition is for one frequency to be fixed, or independent of the value of the coupling unit. The other frequency increases from zero to $1/[2\pi\sqrt{(LC)}]$ as the coupling inductance decreases from infinity to zero, whilst the frequency value increases from $1/[2\pi\sqrt{(LC)}]$ to infinity as the coupling capacity decreases from infinity to zero. Thus a coupling unit comprising both inductance and capacity will enable the frequency $\omega_2/2\pi$ to be varied at will over any range of frequency.

The other solutions for class (ii) are only obtained when special precautions are taken to fulfil the required conditions. In other words, the value of one of the circuit components must be continually varied as the coupling unit is varied. This requirement prohibits any convenient practical application of the result.

In class (iii) one frequency ($\omega_1/2\pi$) is again fixed or independent of the coupling unit, whilst the other depends upon it. This second frequency ($\omega_2/2\pi$) increases from zero to $1/[2\pi\sqrt{(LC)}]$ as the capacity coupling decreases from infinity to zero. This is comparable with the effect of inductance coupling in class (ii). The frequency increases from $1/[2\pi\sqrt{(LC)}]$ to infinity as the inductance decreases from infinity to zero; a result obtained by decreasing the capacity in class (ii). Thus with a coupling unit including both inductance and capacity, $\omega_2/2\pi$ for this type of coupling can also be varied to any extent required.

(4) Applications.

(*a*) *A method of dual reception.*—The presence of two frequency values for which the impedance of two coupled circuits is a minimum suggests the possibility of receiving or sending simultaneously two signals at these particular frequencies. The simplest method would be to utilize an aerial with suitable tuning capacity and inductance as one oscillatory circuit and to couple them by a combined condenser and inductance coupling unit to a second oscillatory circuit as in classes (ii) or (iii), where L_1C_1 would be replaced by the aerial circuit.

This method, however, has the obvious disadvantage that only one frequency ($\omega_2/2\pi$) can be varied without upsetting the other frequency ($\omega_1/2\pi$). The difficulty can be overcome by a somewhat complicated gearing arrangement between the three condensers and inductances.

A better method is that indicated in Fig. 3, which enables each operator to receive signals over the whole

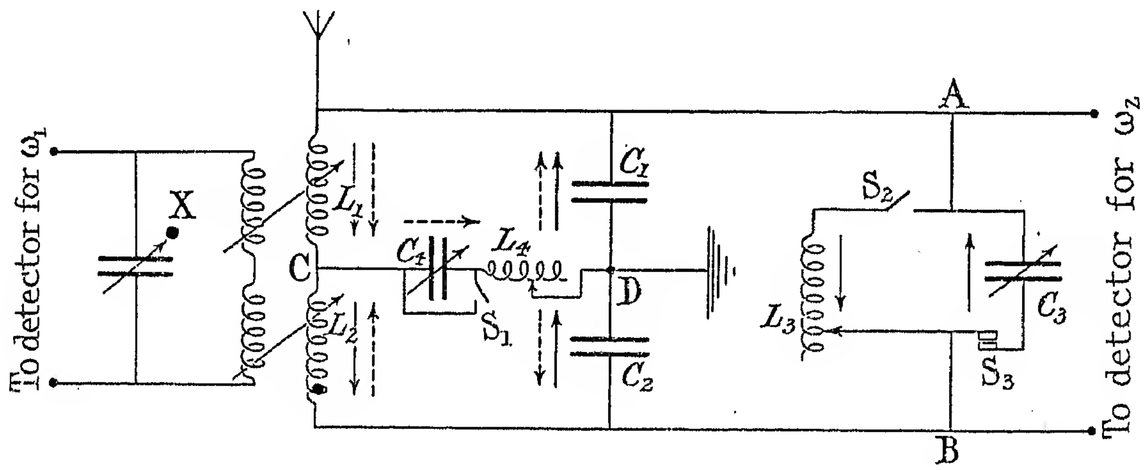

Fig. 3.

range of possible frequencies. This arrangement requires only one aerial and combines all four forms of coupling shown in Figs. 1 (c), 1 (d), 1 (e) and 1 (f). The method of operation can be most readily understood by a consideration of the arrows indicating instantaneous current directions. When currents at the frequency $\omega_1/2\pi$ are induced in the system the directions at any instant are indicated by the dotted arrows. The points A and B are at the same potential (since $L_1C_1 = L_2C_2$) and consequently C_3 (or L_3) does not affect the resonance frequency of currents taking these paths. When the currents flow in the direction of the full-line arrows, their frequency being $\omega_2/2\pi$ there is no difference of potential between C and D, and hence $\omega_1/2\pi$ can be varied by manipulating C_4 (or L_4) without affecting $\omega_2/2\pi$. Each operator will therefore control one coupling unit, thereby varying, in whatever manner he may desire, one only of the two resonance frequencies of the system. Each resulting frequency will be entirely independent of the frequency determined by the other control unit.

It will be noticed that L_3 and C_3 are used in parallel to vary $\omega_2/2\pi$. This is desirable because at the frequency $\omega_2/2\pi$ the path through L_3 is in parallel with that through L_1 and L_2 (Fig. 3, full-line arrows), and to bring $\omega_2/2\pi$ from higher values to $1/[2\pi\sqrt{(L_1C_1)}]$, L_3 must approach infinity. C_3 is in parallel with C_1 and C_2, and to bring $\omega_2/2\pi$ from lower values to $1/[2\pi\sqrt{(L_1C_1)}]$, C_3 must approach zero, i.e. approach infinite impedance. L_3 and C_3 in parallel fulfil these requirements if tuned to $1/[2\pi\sqrt{(L_1C_1)}]$. The variation with frequency of the impedance of such a circuit is shown in Fig. 4 (a).

For a similar reason L_4 and C_4 are used in series to bring $\omega_1/2\pi$ nearer to $1/[2\pi\sqrt{(L_1C_1)}]$. Considering the distribution of currents for $\omega_1/2\pi$ (Fig. 3, dotted arrows) it will be seen that for $\omega_1/2\pi$ to approach $1/[2\pi\sqrt{(L_1C_1)}]$ the combined impedance of L_4 and C_4 must approach zero. This is accomplished by putting them in series, when zero impedance is obtained if $L_1C_1 = L_4C_4$. The variation of impedance with frequency in this case is shown in Fig. 4 (b).

In the practical form it will be necessary to vary the condenser C_1 to tune the aerial circuit to the same value as L_2C_2. L_3 and C_3 will be provided with open-circuiting switches (S_2 and S_3) operating automatically (not shown in detail in Fig. 3) so that as each or either decreases appreciably from its maximum impedance value the other is cut out. C_3 only is used when $\omega_2/2\pi$ is less than $1/[2\pi\sqrt{(L_1C_1)}]$, and L_3 only is required for frequencies greater than $1/[2\pi\sqrt{(L_1C_1)}]$. L_4 and C_4 can be so constructed that they short-circuit themselves, L_4 when it reaches its minimum value and C_4 when it reaches its maximum value (switch S_1 in Fig. 3).

Signals at frequency $\omega_2/2\pi$ can be detected by connecting the detector to AB (Fig. 3). These points are always at a potential 180° out of phase for $\omega_2/2\pi$ and in phase for $\omega_1/2\pi$, so that signals of this latter frequency will not be detected unless strong enough to give a fall of potential due to resistance differences.

Signals at frequency $\omega_2/2\pi$ can be detected across C and D (Fig. 3) except in the special case when $L_1C_1 = L_4C_4$, when the resonance frequency is such that the impedance between C and D is zero and the signal strength is consequently zero. This can be overcome in practice by using a circuit X (Fig. 3) tuned to $\omega_1/2\pi$ and loosely coupled to L_1 and L_2 in such a manner that the induced E.M.F.'s due to currents at the frequency $\omega_1/2\pi$ add up in the loose-coupled circuit. With such an arrangement currents of frequency $\omega_2/2\pi$ will induce opposing E.M.F.'s in the loose-coupled circuit (see arrows in Fig. 3). $\omega_2/2\pi$ will be unaffected provided that the two couplings of the loose-coupled circuit remain equal.

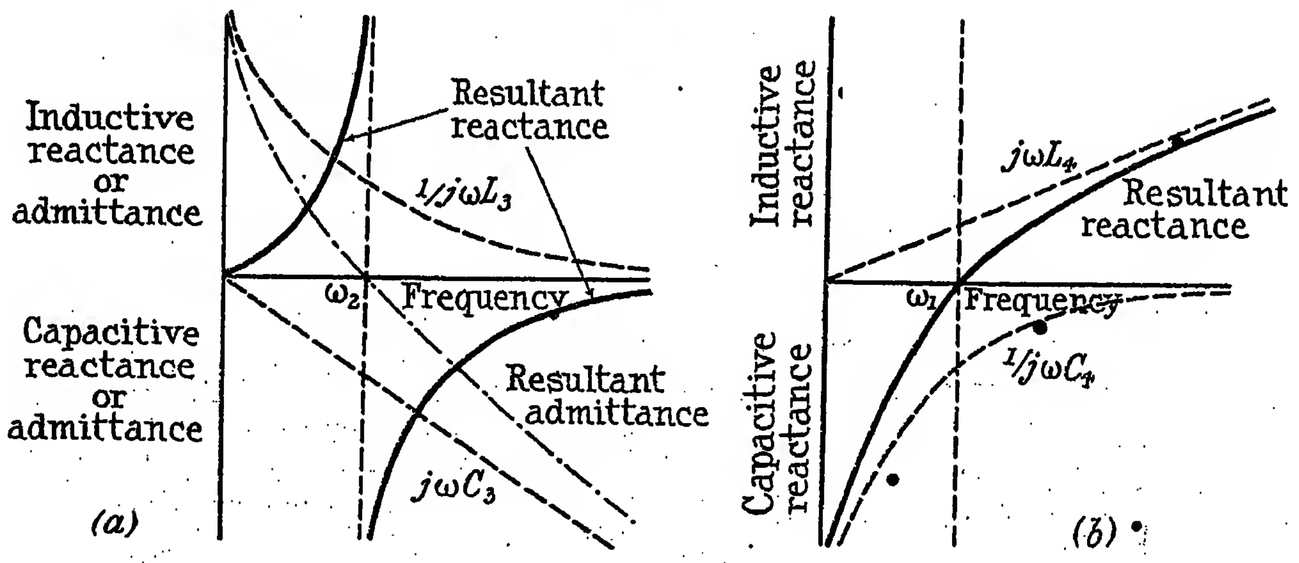

FIG. 4.

A similar loose-coupler can be used for signals at $\omega_2/2\pi$, but this method is not as good as that already indicated because for the higher values of $\omega_2/2\pi$, when L_3 is small compared with $L_1 + L_2$, the current through L_1 and L_2 will be small compared with that through L_3.

A receiving circuit designed on these lines was found to function in this manner and to be capable of receiving simultaneously and independently two signals of any required frequencies. Resonance curves were taken which showed the two resonant frequencies to be quite independent. The decrement of either path was not affected by the presence of the other, for the curves indicated decrement values of the same magnitude as for simple LC circuits including similar components. These resonance curves were obtained by inserting vacuum thermo-junctions in the various branches of

the circuit, and thereby obtaining direct-current measurements. The source of energy was a valve generator controlled to give constant current in the exciting circuit to which the circuit under test was coupled by a fixed mutual inductance. By this method the E.M.F. induced in the test circuit varied directly

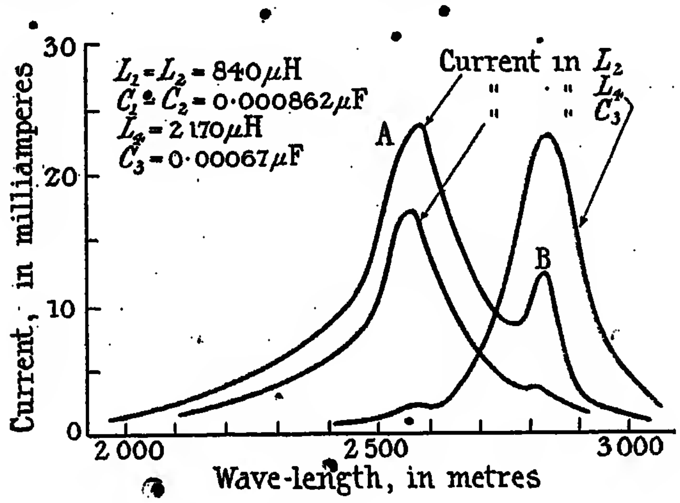

FIG. 5.

as the frequency. Consequently the height of the resonance peak B (Fig. 5) is less than that of A.

Apart from this, the variation of the height is in accordance with the resistance variation in the respective paths taken by the currents. Some typical curves are given in Fig. 5 from which it can be seen that the current at a frequency of $v/2$ 850 in the coupling inductance L_4 is quite independent of the current at a frequency $v/2$ 550 in the coupling capacity C_3 (where v is the velocity of light).

(b) *An intervalve system for high-frequency amplifier.*— A common type of high-frequency amplifier is that shown in Fig. 6, except that the coupling unit C_0 is usually a fixed condenser of large value and the circuit L_3C_3 is replaced by a third valve.

This tuned choke intervalve system may be compared with two oscillatory circuits coupled as in Fig. 1 (*f*). The first circuit comprises the anode choke L_A and the valve capacity (anode to filament) C_A, whilst the second circuit consists of the grid choke L_G and the valve capacity (grid to filament) C_G. To obtain maximum amplification these two circuits are both tuned to the frequency of the signals it is desired to amplify. Neglecting ohmic resistances the paths from anode and grid to earth are of infinite impedance at this frequency, while the anode and grid circuits themselves have zero reactance to currents of this particular frequency which circulate in them. As this infinite impedance is attained without the use of high resistances, the system is particularly efficient. It suffers, however, from the disadvantage that it will only amplify effectively at the one frequency, unless some means is provided for re-tuning the anode and grid circuits to the new frequency.

The foregoing discussion on this form of coupled circuit has shown that there is another frequency at which the system offers zero reactance to currents in L_A and L_G, which frequency depends on the value of the coupling condenser.

At this frequency, which has been called $\omega_2/2\pi$, the potentials of the anode of any valve and the grid of the following valve are 180° out of phase. Hence the grid will again be subjected to large potential variations. If C_0 is made variable (as shown in Fig. 6) this frequency can be varied and the system made to amplify efficiently for any wave-length within the range determined by the values of the component inductances and capacities. If all the coupling condensers are geared together as shown, the process of tuning the whole amplifier is reduced to one operation.

Besides this simplification of control, the intervalve system has the additional advantage that a step-up in voltage is possible, making the variations of grid potential greater than the variations of anode potential. This can be seen from the fact that the currents in L_A and L_G for the frequency $\omega_2/2\pi$ are equal (see page 897), and hence if $L_A < L_G$ there will be a voltage step-up given by L_G/L_A. In general, since the effective value of the valve grid-filament capacity (C_G) is smaller than the anode-filament capacity (C_A), this step-up is assured.

Normally the potential ratio in this intervalve system is unity, and the large coupling condenser merely allows the grid potential to vary equally and in phase with the anode potential of the preceding valve. The value

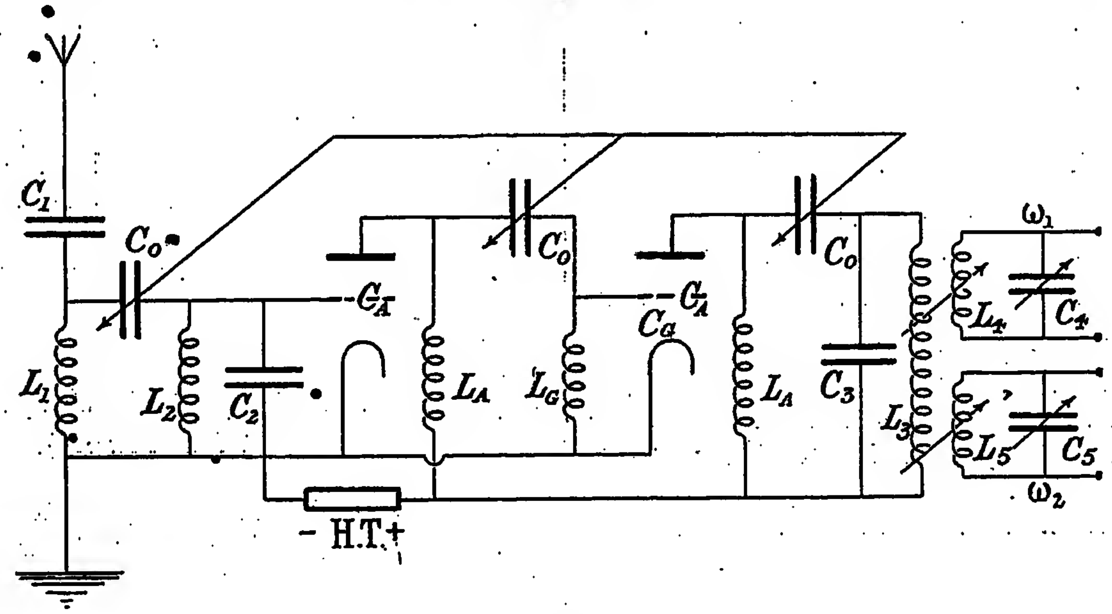

FIG. 6.

of C_0 therefore matters little as long as it is not too small, thereby making its reactance comparable with that from anode or grid to earth. Thus, with C_0 variable the amplifier will still amplify signals at the fixed frequency $\omega_1/2\pi$ as long as C_0 is not too small.

If, therefore, such an amplifier were connected as shown in Fig. 6, where $L_1C_1 = L_2C_2 = L_AC_A = L_GC_G = L_3C_3 = L_4C_4$, it will be possible to receive on this particular fixed wave-length simultaneously with reception on a variable wave-length depending on the values of C_0. L_5C_5 will be tuned to this latter variable frequency, so that the two frequencies are separated in the two detector circuits. This arrangement only allows the amplifier to receive signals at wave-lengths equal to or greater than that of the fixed wave-length determined by the product L_1C_1. By using an inductance coupling the variable wave-length can be made less than $2\pi v\sqrt{(L_1C_1)}$ and the complete range of wave-lengths could, therefore, be obtained by using a condenser and inductance in parallel. In this form it is not a practical proposition, because the inductance will not prevent the high-tension battery from affecting the grid of the valve. The difficulty can, however, be overcome by putting the parallel coupling unit in series with a fixed condenser of very large value, and therefore of very low impedance compared with that of the controlling unit. This design of amplifier is easily tuneable to any frequency in addition to the fixed frequency, but, as with all other amplifiers, is subject to self-oscillation after four or five such systems have been placed in cascade unless special means of preventing such oscillations are employed. Such a system is, however, economical in both amplifiers and aerials and is very easy to operate.

INSTITUTION NOTES.

Associate Membership Examination Results.

APRIL 1924, SUPPLEMENTARY LIST.*

Passed.

Batham, G. S. M. (New Zealand).

Passed Part II only.

Dalton, G. A. (South Africa).

AUGUST 1924, OFFICERS OF THE ROYAL CORPS OF SIGNALS.

Passed.

Allen, Capt. F. J. (P.W.O. Scinde Horse).
Bowen, Capt. W. O. (1/6th Gurkha Rifles).
Brown, Lieut. J. H. [Royal Garrison Artillery ("B" Corps Signals, India)].
Cameron-Webb, Capt. J. H. (1/11th Sikh Regt.).
Galwey, Lieut. W. C. V. (King's Own Royal Regt.).
Gemmell, Capt. G. W. (2/7th Rajputana Regt.).
Hardisty, 2/Lt. R. W. [47/2nd London Divisional Signals (T.A.)].
Kennard, Lieut. W. G. L. (Royal Field Artillery).
Knowles, Lieut. C. (Rifle Brigade).
Penney, Lieut. C. H. L. (Royal Field Artillery).
Rosenberg, Lieut. R. L. M. [Royal Garrison Artillery ("B" Divisional Signals, India)].
Schneider, Lieut. L. W. (Royal Field Artillery).
Tayleur, Capt. G. (4/2nd Punjab Regt.).
Walford, Lieut. J. E. S. (Worcestershire Regt.).
Wheatley, Lieut. M. S. (Dorset Regt.).
Williams, Lt.-Col. T. R. (Australian Staff Corps).
Willoughby, Capt. B. D. (P.W.O. Scinde Horse).
Wiseman, Lieut. H. J. (Durham Light Infantry).

THE ECONOMICS OF POWER CONSUMPTION.*

(WITH SPECIAL REFERENCE TO SMALL D.C. MOTORS.)

By D. J. Bolton, B.Sc. (Eng.), Associate Member.

(*Paper first received 6th March, and in final form 16th June, 1924.*)

Summary.

The possibility of determining the frame size of a motor on economic instead of physical grounds is first discussed, and a basis is laid down for economic comparisons. The capital and working charges are considered in turn, and in connection with the latter the efficiency of a shunt motor when suitably under-run is examined. Applying this method to the case where $\frac{1}{8}$ h.p. at 1 000 r.p.m. is required, the economical position is indicated for various conditions of service and prices of energy, and it is found that a $\frac{1}{6}$-h.p. or $\frac{1}{4}$-h.p. frame is preferable in all but exceptional cases. Applying the method to sizes ranging from $\frac{1}{4}$ h.p. to 15 h.p. similar results are obtained, and it is found that the usual physical criteria are only satisfactory as a sole basis of choice when energy is exceptionally cheap or hours of service are short. The possible extension of the method and the effect of various changes are briefly reviewed.

It is characteristic of many physical operations—notably that of the flow of current in a conductor or of magnetic flux in an iron circuit—that the losses are dependent upon the density. It follows that in any relatively simple piece of apparatus, such as a bare conductor (and, to a lesser degree, a cable, a transformer or even an electric motor), the larger the apparatus selected for a given purpose the smaller will be the loss. Hence in totalling the cost of performing any given service the cost of the plant and the cost of the energy wasted are reciprocally related with reference to the plant size, and one particular size will frequently indicate a minimum total cost.

It will be seen from the above that there are two entirely different and unrelated methods of fixing the size of plant to perform a given service. On the one hand there are the usual physical limits of heating, sparking, overloads, etc., and when the size selected is the minimum necessary to comply with some such specification it will be here referred to as the *physical* choice. On the other hand the size may be fixed so as to give the least total expenditure on plant plus upkeep, and this will be referred to as the *economic* choice. The determination of this position—known by economists as the point of maximum return, and found by Lord Kelvin in the case of a plain conductor—will here be attempted in the more complex case of a direct-current motor, and its size will be compared with the corresponding physical choice.

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

In view of the increased interest in economics of recent years, both in this country and in America, and of its many applications (such as scientific costing) in engineering production, it is surprising that there has been so little attempt at the costing of the *consumption* of engineering products. This may be due to the general backwardness of the consumer (in science and enterprise) as compared with the producer, even when the two are the same person in different capacities; and also to the fact that the manufacturer, however anxious to save himself expense, is not always so careful to do as much for his client. Much more is it due to the belief that in almost every case the economic choice will indicate a size smaller than that permissible on physical grounds, and will therefore be inadmissible on this account. This assumption is examined in the case of small d.c. motors in the present paper.

It will be clear from the above that the ordinary processes of design and selection do not neglect economics, but in paying exclusive attention to the physical limits of the materials employed they are all based on the assumption that the less the materials used the lower will be the cost. It follows that when a new point of view is brought in—that of the consumer—and the manufacturer's economy or "cost of article" is broadened to become "cost of service," a new basis will be established both for the design and for the selection. Primarily it is a problem for the designer, since if more money than necessary is to be spent on the plant in order that less need be spent on its upkeep, the most useful field for such expenditure will usually lie in the direction of improved quality of iron and insulation and better space utilization, rather than in a mere all-round increase in the quantity of the materials employed.

In spite of these facts this paper has been written from an entirely different point of view—that of the individual power user—and one way of putting its conclusions into practice consists simply in choosing a standard machine from the maker's list, of a larger size than the physical minimum. The reasons for thus leaving the more promising field of design and treating only that of selection are, in the first place, that the designer has no particular interest in reducing the cost of a service, and, if he had, would never persuade the majority of purchasers to pay more for their motors—action in this case must be primarily individual. In the second place, the manufacturing costs of qualitative departures from standard are extremely difficult to compute beforehand, whereas the data used in this

paper are the result of past experience and are generally available without the need for "inside information." Thirdly, it will be clear that if a case can be made out for using larger (standard) frames there will be a far better case for the design of special machines of higher quality wherever this is commercially practicable.

With particular regard to the last-mentioned possibility, the cases selected for treatment here are the smaller sizes—from fractional horse-powers up to 15 h.p., commencing with direct-current machines. In such cases the individual user may be a large-scale purchaser, employing the machines for ventilation, loom driving, etc., and may be in a position to commission qualitative alterations if the calculations indicate that this is likely to be advantageous. Another advantage which may appear in small sizes is that, the efficiencies being so low, the margin for improvement is considerable and its cost slight, but it must not be forgotten that the value of a given efficiency improvement is larger the greater the output.

It will be clear that there are a great many different economic problems in connection with the choice of a power unit. For instance, there might be alternative sorts of supply, or the type or speed of the unit might be in question. In most cases, however, the physical limits and local conditions will determine these matters, and the only problems here dealt with concern the choice of a motor to give a fixed power and speed for a given number of hours a year. The simplest of such problems arises when there are only two alternatives, as when the same or rival makers quote different efficiencies at correspondingly different prices, but it is rare thus to get a pair of machines which are identical in all other respects. In the cases dealt with below, a range of alternatives will therefore be considered and the exact point of economic choice will be indicated.

The first steps in solving any economic problem are to decide the basis of the comparison and then to tabulate on this basis all the expenses involved. The most usual basis, and much the best in this case, is that of annual costs, assuming the service to continue indefinitely. Thus if the service required is 5 h.p. at 1 000 r.p.m., it will be assumed that a suitable motor is purchased, and at the end of its life is replaced by another, and so on, all expenses being reckoned on an annual basis. As it is convenient to have a separate name for these regularly recurring expenses, all costs reckoned on an annual basis are here called "charges."

Reference has already been made to the fact that almost all kinds of operation involve two elements—the machine or structure made use of, and the labour, energy, etc., necessary for its performance. In making a schedule of the annual cost of performing the operation there are therefore two main groups, the "capital" or overhead charges necessary to provide and renew the plant, and the "work" charges necessary to operate it. Referring to these as the C and W components respectively, it will be seen that the former are chiefly financial and are largely independent of whether or not the machine is in use, whilst the latter are chiefly materials, labour, coal and electrical energy.

The actual preparation of a complete schedule of the charges involved in any service would be an extremely long affair, but it can be greatly simplified by omitting every item not affected by the change in question. Bearing in mind that the only alteration proposed is the substitution of a machine having a larger frame than the minimum size physically necessary, the following assumptions will be made:—

(1) That the only change in the capital charges will be the increase due to the substitution of interest and depreciation on the larger capital outlay (adjusted possibly for a longer estimated life). This assumes that there is no additional charge due to such items as insurance or additional floor space, etc.

(2) That the only change in the work charges will be the decrease due to the improved efficiency. This assumes that other items involved in the upkeep, such as repairs, etc., are unaltered. In order to simplify this item still further, the actual input watts to the motor will be divided into two portions, the one (equal to the output) which can be regarded as transformed directly into useful power, and the other which supplies the losses. This "loss coefficient," as it has been called, is equal to $[(1/\text{efficiency}) - 1] \times$ output and is the only item considered in the following treatment.

It is now possible to visualize the form which the economic comparison is to take. Graphically it will consist in plotting, to a base representing frame sizes to some suitable scale and commencing with the minimum size physically necessary, two curves, C and W, representing the structural and operation charges respectively, or rather such portions of them as are affected by the change in frame size. The former curve will rise and the latter will fall with the increase in frame size, and their sum will indicate total charges and should show a position of minimum charge which may or may not lie to the right of the physical frame minimum. The same thing can be done algebraically by expressing all charges as constants or variables relative to the frame size. A point of the latter is then found at which the rate of change of the two groups of charges is equal and opposite, and if this point indicates a larger frame than the physical minimum it will be economically sound to choose this one.

It will be noticed that this operation is strictly comparable with the application of Kelvin's law to cables. In the case of cables the independent variable is the area of the conductor, and (being a simple homogeneous material) both the watts lost and, usually, the cost of the whole cable are linear functions of it, and an algebraic solution becomes easily possible. In the case of motors, one is dealing with a complex structure in which both losses and costs are made up of a number of elements, and, although empirical formulæ can be developed, a graphical solution is usually preferable.

A difficulty arises as to the choice of scale for the base line of the curves. Whilst representing in all cases the size of the structure or frame there are various ways in which this can be measured, the most obvious being to plot with an even or logarithmic scale the maximum horse-power outputs which the frames are

rated to give. Instead of doing this, however, the author has found it best to choose a scale such that either the W or the C curve is a straight line, and these two methods are illustrated in the two cases treated in this paper, an even scale being employed in each case. In the former case the scale indicates watts saved per h.p. output, i.e. the values [(1/efficiency) − 1] are plotted from the right-hand side. In the second method the base divisions represent motor first cost, or, more strictly, annual expenditure on account of first cost, so that the C line is straight.

In a service which continues indefinitely there will come a continually recurring time at which the structure is worn out and has to be replaced. This necessity may arise through an actual failure to function, through a rapidly increasing repair bill, or merely because fresh inventions have improved the alternative structures available. In any case the owner must be presumed to make the change whenever it pays to do so, the length of the period being termed the "economic life," and the value of the old structure at the end of it (after deducting the cost of removal) the "salvage value." Looked at from an annual point of view, this necessity for periodic replacement is termed "depreciation" or annual loss of value on the part of the structure, although the actual "use value" to the owner may not diminish until the machine is finally discarded.

For the solution of the problems considered below it is necessary to find the annual figure which represents the cost of this periodic replacement, this being the amount which any sound concern should lay aside each year to amortise the liability. The particular financial arrangements by which this deposit is made, or the particular accounting arrangements by which it is equated to the annual depreciation in the yearly balance sheets, do not matter here, as, provided they are efficiently conducted, all the alternative methods will have (economically) the same result. It will therefore be convenient to assume the "sinking fund" method in which the equal annual deposits earn compound interest at the rate paid on the original loan, and are so chosen as to amount to the required figure at the end of the economic life.

Let C = first cost,
S = salvage value,
L = length of economic life, in years,
i = rate of interest on capital,
d_L = rate of sinking fund deposit, i.e. the annual end-of-year deposit which will realize unity at the end of L years.

Then $$d_L = \frac{i}{(1+i)^L - 1}.*$$

Just as with interest rates, this deposit figure can conveniently be given as a percentage, and is more usually taken from a table than worked out by formula. Table 1 is a convenient abbreviated table for percentage deposits ($100\,d_L$).

Using the above symbols it will be seen that the total capital charges consist of Ci units per annum for hire, and $(C - S)d_L$ for replacement of the plant employed. Where the salvage value is small or where it is a constant proportion of the first cost, the second item can be put Cd_L', where d_L' is the equivalent annual deposit $[d_L \times (C - S)/C]$. The capital charge then becomes $C(i + d_L')$, or, as it is usually termed, "interest and depreciation on the capital cost." Thus if interest is at 5 per cent, the life 16 years and the salvage value S is one-tenth of the first cost C, the total rate for hire and replacement will be $0{\cdot}05 + 0{\cdot}0423 \times 9/10 = 0{\cdot}088$, and the total capital charge will be $0{\cdot}088\,C$.

It has already been stated that the only item which is to be plotted for the W curve in the case of motors is that which represents the annual cost of supplying the machine losses, and which is referred to below as the "inefficiency" charge. The values of this curve will therefore depend upon two items which must first be considered—the conditions of service and the efficiencies of the motors when running below their rated output.

TABLE 1.

Life L	End-of-year deposit to realize £100 in L years with compound interest at—		
	4 per cent	5 per cent	6 per cent
Years	£	£	£
10	8·33	7·95	7·59
11	7·41	7·04	6·68
12	6·66	6·28	5·93
13	6·01	5·65	5·30
14	5·47	5·10	4·76
15	4·99	4·63	4·30
16	4·58	4·23	3·90
17	4·22	3·87	3·54
18	3·90	3·55	3·24
19	3·61	3·27	2·96
20	3·36	3·02	2·72

It will be clear that the expense of providing a given power in watts for, say, 1 000 hours a year with energy at 1d. per unit will be the same as for 2 000 hours at ½d. per unit, and it is therefore useful to have a composite term indicating the product of these two factors. The author has used the term "service-price" to indicate the hours of service per year multiplied by the price of energy in £, or the cost in £ of taking 1 kW for the number of hours per year for which the plant in question is connected. Thus for a plant connected for 8 hours per day and 300 days per year to mains with energy at 1d. per unit (or 24 hours a day with energy at ⅓d. per unit) the "service-price" would be 10. Thus the working charge W, i.e. the annual cost of wasted energy in £ = service price ÷ 1 000 per watt of inefficiency.

With regard to the efficiencies of motors which are permanently and intentionally under-run it might be thought that the ordinary efficiency curve plotted to a base of output would correctly represent the performance, but this is not the case. When a motor designed for maximum efficiency at full load or thereabouts is run at a lower load than this, the efficiency falls not

* It will be noted that d_L is less than $1/L$ owing to the fact that the deposits earn interest—thus it becomes approximately half this amount in a 30-year life with interest at 5 per cent.

because it is necessarily less for the smaller input, but because the balance between the iron and copper losses has been upset. To find its true efficiency at a lower load it is necessary to re-design it, or else to under-run it with regard to pressure simultaneously with the current reduction.* Under these circumstances a given frame will give only slightly lower efficiency at a half or a quarter of its rated load than it does at full load.

In order to make this point clearer, suppose that a 1-h.p. shunt motor is to be run at about one-quarter of its load, and assume in the first place that the permeability of its field system is constant. If a 200-volt motor is selected and run at 100 volts, and loaded so as to take half full-load current, this means that the applied and back E.M.F.'s are both half their previous values, and, as the field is half what it was, this halved back E.M.F. will be produced by the same armature speed. In other words the speed will be the same as before. With the current and field each halved, the torque will be reduced to a quarter of its original value and (at the same speed) the power output will also be reduced in the same proportion. The armature and field copper losses will be one-quarter of their previous values, as will also the losses proportional to B^2. Hence current. The freedom from distortion of the field flux depends upon the *ratio* of the field and armature ampere-turns, and in fact, with each of these reduced to one-half, a slightly "stiffer" field can be anticipated, since with better permeability the tendency of the flux to spray will be diminished. Moreover, although the commutating E.M.F. for a given brush position will be halved, the armature current requiring reversal will also be halved. This point, like the other, was amply borne out by the tests referred to, and in no case was the commutation noticeably inferior to that on full load.

It must not be supposed that merely to select a large standard machine and under-run it on the above lines is in any way to be recommended as ideal, since in all cases some degree of re-design or rearrangement is preferable. All that is claimed is that such a course is quite practicable, even down to one-quarter of the rated output (at which point the running is liable to become unstable), whilst for small changes it may well prove to be the most economical way of increasing the iron and copper sections. In any case it provides a convenient hypothetical course of action, by means of which the economic advantages of plant-increases can be tested.

TABLE 2.

Column 1 Frame	Column 2 Rated load	Column 3 Full-load efficiency	Column 4 Price	Column 5 Estimated life, L	Column 6 Capital charge	Column 7 Estimated efficiency when giving $\frac{1}{8}$ h.p.	Column 8 Corresponding losses
	h.p.	per cent	£ s. d.	years	£	per cent	watts
a	$\frac{1}{8}$	53·5	5 16 0	10	0·750	53·5	81
b	$\frac{1}{6}$	63	6 12 0	11	0·800	59·6	63
c	$\frac{1}{4}$	67	7 15 6	12	0·877	62·4	56

e	1	74·5	18 18 0	16	1·740	—	—

it will be only the friction, windage and a small proportion of the iron losses which will prevent the efficiency remaining constant and will cause the curve to tilt downwards slightly on the lower inputs. Furthermore, as the permeability will actually not be constant but will be considerably better at the lower exciting voltage, the speed on half voltage will be less than normal and will have to be brought up either by means of the field resistance or by fitting a different set of field coils. Even in the former case the field loss will then be less than one-quarter of the full-load value, and this will still further tend to keep up the efficiency.

With a view to a practical confirmation of the above reasoning, the author had a number of tests made on small shunt machines of the sizes dealt with in this paper and in no case was there any marked reduction of efficiency down to one-quarter of the rated output.

It might be anticipated that the commutation of such under-run machines would be impossible on account of the weakening of the field, but this will be found to be fully balanced by the reduction in the armature

* The advantage of doing this will, of course, depend upon the proportions of the different losses. If the armature I^2R loss is greater than the sum of the iron and field losses, the ordinary method of under-running will be preferable: but if (as is more likely) these latter are the greater, it will be preferable to under-run the pressure even more than the current if the commutation permits.

FRACTIONAL HORSE-POWER SERVICE.

The first case to be considered is where the service required is $\frac{1}{8}$ h.p. at 1 000 r.p.m. from a shunt motor on d.c. mains. A number of quotations were obtained for motors of this speed ranging from $\frac{1}{8}$ h.p. to 1 h.p., and one set of these, as shown in the first four columns of Table 2, was selected. (All of these figures were taken from a single quotation, dated December 1923, with the exception of frame *b* which was taken from a precisely similar range of machines by another maker. In all cases except the first the prices include an extra for supplying to a non-standard voltage. The selection of a quotation was made as far as possible with a view to getting a typical as well as a sufficiently continuous range of figures, but from a comparison with figures given later it would appear that the efficiencies of the $\frac{1}{4}$-h.p. to 1-h.p. sizes is slightly above the average usually obtained.)

The position then is that a certain service is required, for which machine *a* costing £5 16s. and having an efficiency of 53·5 per cent is physically adequate. But by spending more money on the machine (a tendency represented by frames *b* to *e*) higher efficiencies can be obtained, and the problem is to find out to what extent

(if any) this tendency should be followed. The first step is to estimate the probable lives and efficiencies of the larger machines when performing the $\frac{1}{8}$-h.p. service.

With regard to lives, that of machine *a* has been taken as 10 years, but it is reasonable to suppose that the lives of the larger machines will be progressively greater, both intrinsically and because they are giving so much less than their rated output. These lives are therefore taken as ranging from 11 to 16 years, as shown in col. 5, and taking interest at 5 per cent and salvage value zero, the figures in col. 6 are obtained by multiplying the first cost by the sum of the rates for hire plus replacement, as mentioned earlier in the paper.

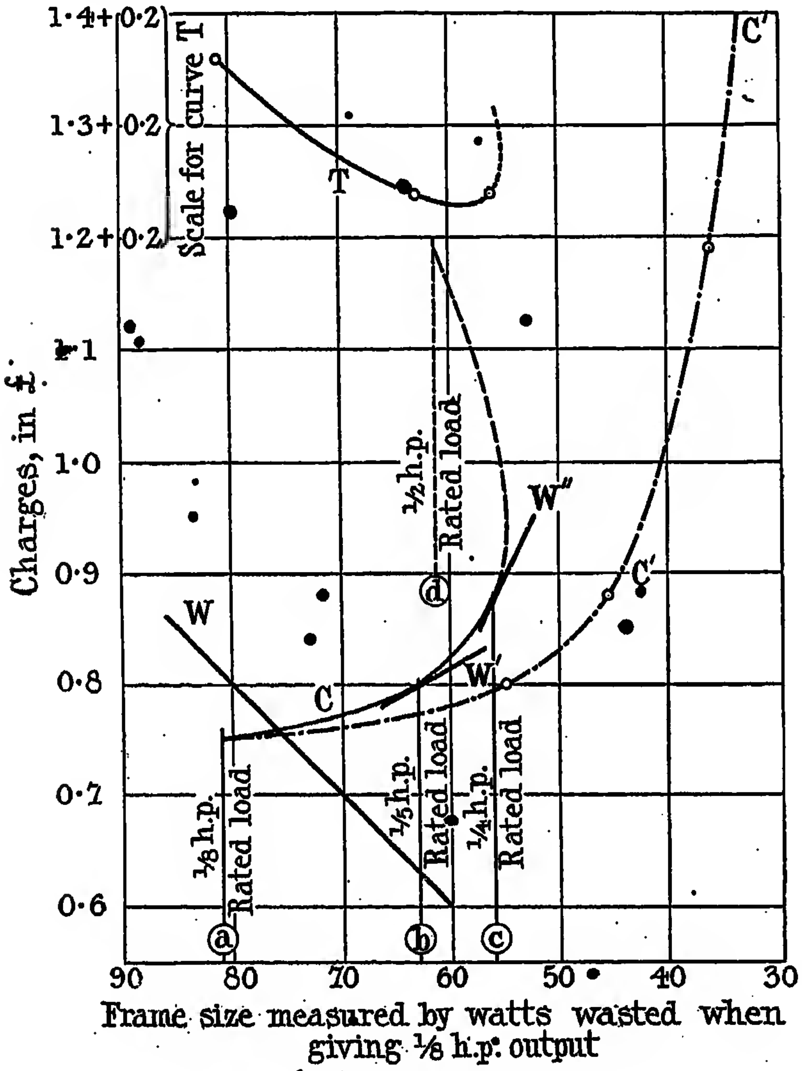

Fig. 1.—Fractional horse-powers.

With regard to the efficiencies of the larger machines when under-run, and assuming suitable selection as regards voltage, etc., reasons have already been given for supposing that in the majority of cases, particularly if the normal flux density is high or if the range of selection is not limited entirely by the printed price-list, the full-load efficiency can be maintained almost intact down to one-half or less of the output. On the other hand, in a small machine, particularly if run at a high speed, the friction and other "constant" losses (not reducible by pressure or current reductions) may constitute a considerable proportion of the whole, and in order to make a conservative estimate, and also to illustrate the method as fully as possible, it will be assumed that in this case the irreducible losses amount to one-sixth of the total full-load loss. Col. 7 shows the estimated efficiency (when giving $\frac{1}{8}$ h.p.) calculated on this basis, and it will be noticed that this rules out frames *d* and *e*.

The losses at $\frac{1}{8}$ h.p. output, corresponding to these efficiencies, are shown in col. 8, and these figures are used as the abscissæ in Fig. 1. The base of this graph represents, in general terms, the frame size, but the actual scale employed is that of watts saved, so that the values [(1/efficiency) — 1] × 746/8 are scaled off from the right-hand side. On the above basis the upright lines, a, b, c and d, represent the first four frames quoted, and marking off ordinates to represent the corresponding capital charges the curve C is obtained. (Had the full-load efficiencies been maintainable for all degrees of under-running, the upright lines representing frames *b* to *d* would occur more to the right, and the chain-dotted curve C′ would have been obtained, frame *d* being now a useful contribution.) Curve C therefore represents the annual cost of saving energy by means of larger plant equipment; it rises slowly at first, but more steeply later, when the gain in efficiency for additional expenditure becomes steadily less.

With the base scale chosen it will be clear that curve W representing the annual cost of the energy wasted in the motor will be a straight line depending upon the annual hours of service and the price of energy. It has been seen that for a "service-price" of 10 (e.g. 8 hours × 300 days with energy at 1d. per unit) the working charge is £0·01 per watt of inefficiency, and this gives a line W at 45° to the axes. Adding curves C and W gives a total curve T * which shows a minimum somewhere between frames *b* and *c*.

For any other service-price the line W will have a difference inclination, and, in order to avoid redrawing, it can be reversed and made tangential to curve C at some point which will then indicate the economic position. Thus energy at half the above price, or hours of service proportionally shorter, would be represented by the reversed curve W′ which is tangential to curve C exactly at frame size *b*. On the other hand, a bigger service price, e.g. 20, would be represented by curve W″ which is tangential at about frame size *c*.

The economic advantages of under-running are here very apparent. Assuming a normal working day it will be seen that even with energy at only $\frac{1}{2}$d. per unit it will pay to employ the next larger size of machine, whilst with dearer energy a still larger frame (or better still the same frame re-designed) is called for. The slope of curve C at its commencement is less than half that of W′, showing that frame *a* is only economical for its rated output when energy costs less than $\frac{1}{4}$d. per unit.

Larger Horse-powers.

An attempt will now be made to extend the above method to the case of somewhat larger motors, and in so doing to construct a curve that can be used for a number of different horse-powers and conditions of service. For this purpose it has been thought best to take an average set of figures rather than one individual quotation, and in cols. 2 and 5 in Table 3 will be found the average of some half-a-dozen makers' net prices and full-load efficiencies for machines having rated outputs from $\frac{1}{2}$ h.p. to 15 h.p.

* For convenience this curve has been plotted minus £0·

The base of the curves to be drawn will represent (as before) the size of the structure, but the scale in this case is in units of annual capital costs (hire plus replacement) so that the "capital charges" curve C will be a straight line. The lives have been taken as ranging from 12 to 20 years (col. 3), with a salvage value of 10 per cent of the first cost in each case; and the figures in col. 4 are then obtained by using the interest table already given. These are used along the base scale (Fig. 2) to erect 13 upright lines representing the 13 frame sizes, having the maximum output ratings shown and costing each year in hire and replacement the amounts scaled along the base. As the ordinate scale in £ is the same as the base scale, a line C at 45° will represent the annual expense on account of structure (capital charge).

It will here be assumed that within the range of under-running proposed (usually not more than down to one-half the rated output) the full-load efficiency can be maintained intact by a suitable choice of voltage, etc.* Marking off these full-load efficiencies on the 13 upright lines and drawing a smooth curve through the points gives the curve shown at the bottom of Fig. 2, and it will be seen that (provided the makers' ratings fit in) it is possible, for an annual expenditure on hire and replacement of, say, £2, to purchase a frame having an efficiency of just over 78 per cent. The heating and sparking limit of this frame will prevent it being used above about 2½ h.p., but for the moment it will be convenient to neglect temperature limits entirely and proceed as though any frame could be used for any output whatever.

Above the efficiency curve and to the same base has been plotted its reciprocal the "loss coefficient" or "percentage loss" curve W, showing how the loss for any given output decreases with an increase in the size of frame employed. This curve will represent to some suitable vertical scale the annual cost of supplying the wasted energy, but the scale will depend not only upon the output but also upon the hours of service and price of energy. Thus each particular horse-power and set of service conditions will have a particular W curve of the shape shown.

Reference has already been made to the term "service-price" to indicate the annual hours of service multiplied by price of energy (£) and it here becomes necessary to group with this the power output, and to use the term "power-service-price" to indicate the product of the horse-power multiplied by the service-price. Since the power wasted in a motor equals [(1/efficiency) — 1] × output it follows that the annual cost of this in £ will be [(1/efficiency) — 1] × 746/1 000 × power-service-price. In Fig. 2 curve W is for a power-service-price of 10, e.g. for a 1-h.p. motor running 8 hours a day for 300 days with energy at 1d. per unit, or 24 × 300 hours with energy at ⅓d. per unit, and as the vertical scale is in £ the values for W are obtained from the expression [(1/efficiency) — 1] × 7·46 (col. 6).

It is now possible to add together curves C and W, giving a total T which shows a minimum just above the frame rated for a maximum of 1½ h.p. Thus for the output and service mentioned above, or for an even smaller power, if energy were more expensive it would be economically sound to purchase the 1½-h.p. frame and under-run it to this extent. In the case of energy costing ½d. or less per unit and where the motor runs 8 hours a day it will be seen that this frame size would be economical for outputs of 2 h.p. or over—in other

† Power-service-price.

* It is, of course, true that if frictional losses were a substantial item many of the actual sizes shown in the table would have an appreciably poorer efficiency if run at the next smaller listed rating. But the particular sizes listed must be regarded primarily as landmarks or points on a curve showing the trend of the manufacturing cost of improving the efficiency. In addition, since intermediate sizes are made, the individual user will frequently be able profitably to employ one of these (with a smaller degree of under-running), particularly if he can also command small changes in design such as new field coils, etc.

words the usual physical criteria would be justified as the basis of choice.

In the case of some other value of the power-service-price, say 20 (i.e. 2 h.p. for 8 × 300 hours at 1d. per unit, or its equivalent), the curve W should be re-plotted, in this case twice as high. To avoid doing this the ordinate scale can be halved, which will have the effect

The procedure outlined above can be carried out algebraically, either on the basis provided by the graph or by using the calculus. In the former case it is advisable to plot the rate of change of the loss coefficient with reference to annual capital costs and to draw a smooth curve through the results. The reciprocals of these values are shown in col. 7 of the table and represent the

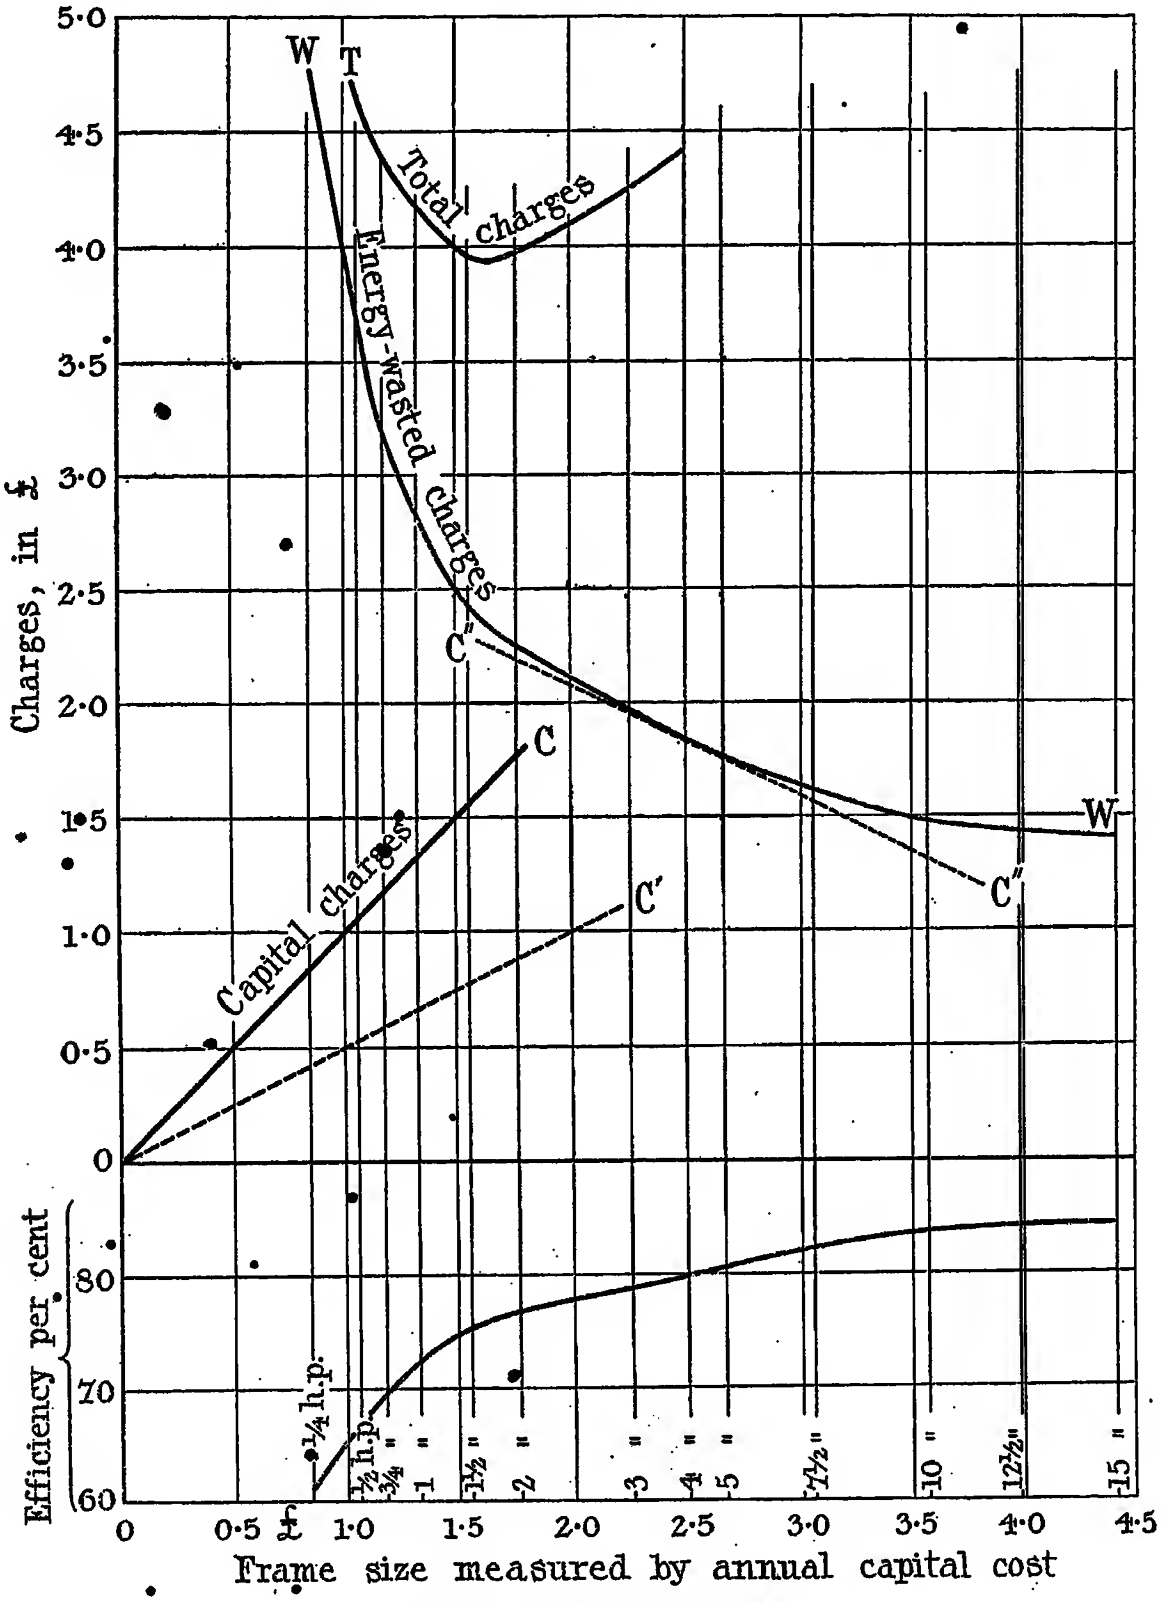

FIG. 2.—Larger horse-powers.

of bringing the capital charge curve to a new inclination (see dotted line C′). Instead of adding this to the W curve it can be reversed and then brought up to the latter in order to see at what point it is tangential (see dotted line C″). Thus it will be noticed that at or near the 4-h.p. frame the slopes of the two are the same, thus showing the economical position for this particular power-service-price.

power-service-price at which it would be economical to run the frame in question. Thus for a service-price of 10 it will be seen that the economical horse-powers are generally about half the physical output ratings.

In applying the calculus, the base scale previously used as the independent variable has been abandoned, and instead both charges have been calculated to a base of rated horse-power outputs (H). This serves as a

check on the graphical solution and in its turn can to some extent be checked by existing data which have been worked out on this basis. By plotting logarithms of the price and loss coefficient figures, empirical formulæ to some power of H can be devised for them both, although the latter requires several different formulæ to represent it accurately over the whole range.

From $\frac{1}{4}$ h.p. to 2 h.p. the loss coefficient (1/efficiency $- 1) = 0 \cdot 386\, H^{-0 \cdot 36}$ and hence the inefficiency charge $W = 0 \cdot 746 \times 0 \cdot 386\, H^{-0 \cdot 36} \times$ (power-service-price) in £. The price is found to be given by $14 \cdot 1\, H^{0 \cdot 5}$,* and taking a uniform life of 14 years for this range of sizes, and with interest at 5 per cent and salvage value 10 per cent of first cost, the capital charges $C = (0 \cdot 05 + 0 \cdot 051 \times 0 \cdot 9)\, 14 \cdot 1\, H^{0 \cdot 5}$. Adding these to get the total charge T, and differentiating with respect to H, T is found to be a minimum when

$$H = 0 \cdot 113 \text{ (power-service-price)}^{1 \cdot 16}$$

or when $\quad$ Power-service-price $= 6 \cdot 5\, H^{0 \cdot 86}$

Similarly from 3 to 10 h.p. the loss coefficient is $0 \cdot 36\, H^{-0 \cdot 26}$ and, taking a uniform life of 18 years and salvage value 10 per cent, T is found to be a minimum when $\quad H = 0 \cdot 061$ (power-service-price)$^{1 \cdot 32}$

or $\quad$ Power-service-price $= 8 \cdot 3\, H^{0 \cdot 76}$

The final expressions in both the above cases give values very similar to those in col. 7 in the table, allowing for graphical discrepancies and for differences in the estimated lives.

It will be understood that throughout this paper the object has been to demonstrate a method rather than to establish a result. Nevertheless, there are one or two conclusions which can be drawn, with some degree of certainty, in the case and with the figures treated above. If each quantity in col. 7 of the table is divided by that in the first column, a fairly uniform figure of 6 is obtained (col. 8), this being the service-price at which each particular frame size can be economically employed to give its actual rated output. For this particular length of service and price of energy the economic and the physical criteria coincide, and at 8 hours per day and 300 days per year this means energy at $0 \cdot 6$d. per kWh.

The above leads to the somewhat startling conclusion that for motors in use during an average working day the physical criteria by which alone they are at present selected become unsatisfactory when energy costs more than $0 \cdot 6$d. per unit. All cases at about these figures require to be considered on economical as well as physical grounds, and where energy costs 1d. or more per unit, a considerably larger machine will usually prove the cheaper installation.

More generally the results obtained may be said to prove two things: first that the extra expense of larger machines, as compared with the value of the energy they save, is far less than is generally realized; and secondly, that the advantage of under-running is no less marked on the larger than on the smaller powers and would emphatically appear to call for a general review of this question and a detailed consideration of all sizes of electric motors, both d.c. and a.c. It is not too much to suggest that such a review may lead to a complete revision of our methods of choosing motors for long-period service, future ratings being determined by economic considerations, whilst the heating properties, like the insulating properties, fix only a lower limit.

It only remains to consider one or two objections or modifications to the above, the chief of which concerns the question of what exactly constitutes the power of any particular service. In using the phrase "a 1-h.p. 1 000-r.p.m. service" it is assumed that 1 h.p. is the actual load whenever the motor is in use, or failing this the average load. Even if it is the former, many engineers would put in a $1\frac{1}{4}$-h.p. or $1\frac{1}{2}$-h.p. frame, and still more so if the 1 h.p. is an *average* output. Thus to speak of the 1 h.p. frame as the normal physical choice may be unfair to present-day choosers, many of whom may be yielding to an unconscious economic sense in specifying a larger machine than is necessary (although if so the application should be more scientific and should endeavour to under-run both the iron and the copper). More usually any under-running or over-specifying that may take place is with a view to possible overloads rather than on economic grounds, and it must be realized that the former is just as much a physical criterion as is the temperature-rise. Under-running on economic grounds is entirely distinct and takes different forms; thus a 2-h.p. frame under-run to give 1 h.p. on the lines suggested would *not* (unless re-designed) be suitable for giving 2 h.p. even occasionally, since its commutation would not be satisfactory. In the case of widely fluctuating loads it will be understood that although an approximate estimate might be made on the basis of the average load, this could not be considered very satisfactory, since the average efficiency of a machine whose copper loading alone was varied would be considerably below the maximum efficiency.

With regard to the factors likely to affect the results obtained above, the market prices of motors and energy are both fairly definite and fairly steady, but the rate of interest on capital is more problematical and would have to be adjusted to suit the circumstances of each individual case. Motors having a market value independent of the prosperity of the concerns in which they are used, should rank amongst the tangible assets paid for by debenture shares, and in this case the rate of interest on extra capital so employed need not be high; on the other hand, if their purchase is considered to involve a risk and has to be financed by more speculative investments, the rate of interest will naturally be higher. Two points should be noticed in this connection: first, the capital charge is not *proportional* to the rate of interest, since the depreciation item is less when the rate is greater; and secondly, a general alteration in the market rate of interest is unlikely to make any ultimate difference to the above results, since the price of energy is also to a large extent a function of interest on capital.

* L. A. Doggett in the *Electrical World* (1915, vol. 66, p. 746) gives the price of a new d.c. motor or generator as $4\,500 \left(\frac{\text{kW}}{\text{r.p.m.}}\right)^{0 \cdot 6}$ dollars, and although the difference in date makes it difficult to compare the two formulæ the similarity of the index figure is significant.

THE CURRENT-CARRYING CAPACITY OF SOLID BARE COPPER AND ALUMINIUM CONDUCTORS.*

By S. W. Melsom, Associate Member, and H. C. Booth.

[From the National Physical Laboratory.]

(*Paper first received* 8*th May, and in final form* 11*th August,* 1924.)

Summary.

The current-carrying capacity of bare copper and aluminum conductors is limited by the heating effects produced by the current. The dissipation of this heat is a function of the temperature elevation above the surrounding air, the size of the conductor, and the intrinsic condition of the surface. A cooling-curve method is described which was used in determining the coefficient of heat emissivity for a series of small sample lengths of round and flat copper and aluminium conductors of various sizes and surface conditions. This was checked by the direct electrical heating of longer lengths, which showed the two methods to be in close agreement. Tables for the current-carrying capacity of copper and aluminium busbars have been deduced from the constants obtained and are given in the paper.

An investigation was carried out on various sizes of round and flat copper and aluminium conductors ranging in diameter from $\frac{1}{2}$ in. to $1\frac{3}{4}$ in. in the case of round bars and from 1 in. × $\frac{1}{4}$ in. to 4 in. × $\frac{1}{2}$ in. in the case of the flat strips, in order to determine the rate of heat dissipation per unit area of exposed surface and the extent to which this is affected by the surface condition of the metal, and in the case of the flat strips by their position, i.e. whether vertical or horizontal. From the knowledge of this constant it then becomes possible to calculate the current-carrying capacity for any size of conductor for any given temperature-rise, if the resistivity of the metal at that temperature be known.

Two methods of determining the rate of heat dissipation are available; these may be called the "static" and the "dynamic" methods respectively. In the first the length of the bar, which must be sufficiently long to avoid any irregular heating or cooling effects at the ends (which will appreciably affect the result), is heated by the passage of a steady current and the temperature-rise is deduced from the change of resistance in the central portion, the temperature coefficient of a small sample cut from the bar having been previously determined. The change of resistance is most conveniently measured by means of a Kelvin double bridge and a standard resistance to which the conductor under investigation is connected in series.

The current must be maintained steady for a considerable period—in the larger bars some five or six hours—before the temperature-rise can be considered to have reached its maximum value. When this is attained the watts dissipated per unit length of the bar can be calculated from the current and the resistance (at that temperature). The temperature-rise is calculated from the change of resistance and from the specially determined value of the temperature coefficient. The heat dissipated per unit length of conductor is then equal to the square of the current multiplied by the resistance of unit length, or

$$W = I^2 r$$

where I is the current in amperes, and
r the resistance in ohms per unit length at the given temperature.

The average value of the heat dissipation per unit area is then W/p, where p is the perimeter of the section.

If θ is the temperature excess of the bar above the surrounding air, and assuming Newton's law of cooling, the heat dissipation per degree is

$$h = I^2 r / p\theta$$

But the heat dissipation is mainly due to convection and, since convection may be taken as being proportional to $\theta^{5/4}$, it is preferable to make use of this relation, in which case we have

$$h = I^2 r / p\theta^{5/4}$$

This method of deducing the value of h may be called the "static" method, since it is effected by measuring the amount of electrical energy dissipated as heat when the maximum temperature has been attained and conditions are stable. It involves, however, the use of a large amount of energy, especially when testing the larger-sized conductors, and the current must be maintained for a considerable time before stable conditions are reached. In order that the end-effects may not unduly affect the results it is necessary that the bars should be long, also that they should be shielded from extraneous draughts. This method was therefore used only as a control, and the majority of the results were obtained by an alternative method which may be called the "dynamic" method.

In the "dynamic" or cooling-curve method a short length (i.e. 1 or 2 ft.) of conductor bar can be used. It is heated in an oven until a suitable temperature elevation is obtained and is then placed in a draught-

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

free enclosure and supported on two knife-edges of some material of low thermal conductivity. These knife-edges in the experimental determinations were V-sectioned pieces of mahogany, so that the heat escaping by conduction through the supports could be regarded as negligible. The temperature of the bar was measured by means of an iron-eureka thermo-couple embedded in a small hole drilled in the bar. A micro-ammeter in series with the thermo-couple was calibrated by means of a resistance in series to read directly the temperature difference between the bar and the surrounding air. The amount of this temperature difference at various intervals of time was measured and from the readings obtained the cooling curve was drawn. The deduction of the constant h from these observations is as follows: When the bar is cooling, and on the assumption that the rate of heat dissipation is proportional to the 5/4 power of the temperature excess,

$$-dH = -m\sigma d\theta = ph\theta^{5/4}dt \quad . \quad . \quad . \quad (1)$$

Where H is the quantity of heat per unit length of bar; m the mass per unit length; σ the specific heat (expressed in joules) of the metal under consideration; θ the temperature excess; p the perimeter of the section of the bar; t the time in seconds, and h the emissivity constant. Hence

$$d\theta/\theta^{5/4} = \frac{-ph\,dt}{m\sigma} \quad . \quad . \quad . \quad . \quad (2)$$

which leads to

$$1/\theta^{\frac{1}{4}} = \frac{ph}{4m\sigma}(t + 1/\theta_0^{\frac{1}{4}}) \quad . \quad . \quad . \quad . \quad (3)$$

where θ_0 is the initial temperature difference between the bar and the surrounding air. If therefore $1/\theta^{\frac{1}{4}}$ be plotted against t, a straight line should be obtained the slope of which is $ph/(4m\sigma)$. If the slope of the line be equated to $ph/(4m\sigma)$ we have

$$h = \frac{4m\sigma\,(\text{slope})}{p} \quad . \quad . \quad . \quad . \quad . \quad (4)$$

A large number of observations were made on short lengths of various sizes of aluminium and copper conductor of both circular and rectangular cross-section—the latter in two positions, i.e. with the longer dimension (1) vertical and (2) horizontal. The effect of surface condition was also investigated and comparative tests were made on bars (1) left in their original condition, (2) cleaned with sandpaper, and (3) coated with various paints. The test bars were heated in the oven to about 100° C., and the cooling curve was taken down to 40° C. or 50° C. In all cases, on plotting $1/\theta^{\frac{1}{4}}$ against time a very satisfactory linear relation was obtained, as will be seen from the figures. This proves that over this range the assumption that the total heat emissivity is proportional to the 5/4 power of the temperature excess is very well justified.

The effect of these various factors on the heat emissivity will now be considered.

Flat Bars: Effect of Position.

As might be expected, the heat emissivity or mean emission of heat per unit area of the outer surface of a flat bar is very considerably affected by its position and is much greater when the bar is placed with the longer dimension of the cross-section vertical. The extent of this difference is shown in Table 1, which gives the ratio of the emissivities in the vertical and horizontal positions for various ratios of breadth b and thickness t of the cross-section for four flat aluminium bars ranging in size from $1\frac{1}{4}$ in. × $\frac{1}{4}$ in. to 4 in. × $\frac{1}{2}$ in.

Table 1.

Dimension of section	b/t	Ratio of emissivity: upright to horizontal
$1\frac{1}{4}$ in. × $\frac{1}{4}$ in.	5·0	1·16
2 in. × $\frac{3}{8}$ in.	5·3	1·26
$3\frac{1}{2}$ in. × $\frac{15}{32}$ in.	7·5	1·11
4 in. × $\frac{1}{2}$ in.	9·0	1·18
		mean 1·18

Graphs of $1/\theta^{\frac{1}{4}}$ plotted against t for the 2 in. × $\frac{3}{8}$ in. aluminium bar are shown in Fig. 1, together with the calculation of h from the slope for both the vertical and the horizontal position.

It will be seen that although the ratio b/t increases in a regular progression, the ratio of the two values of

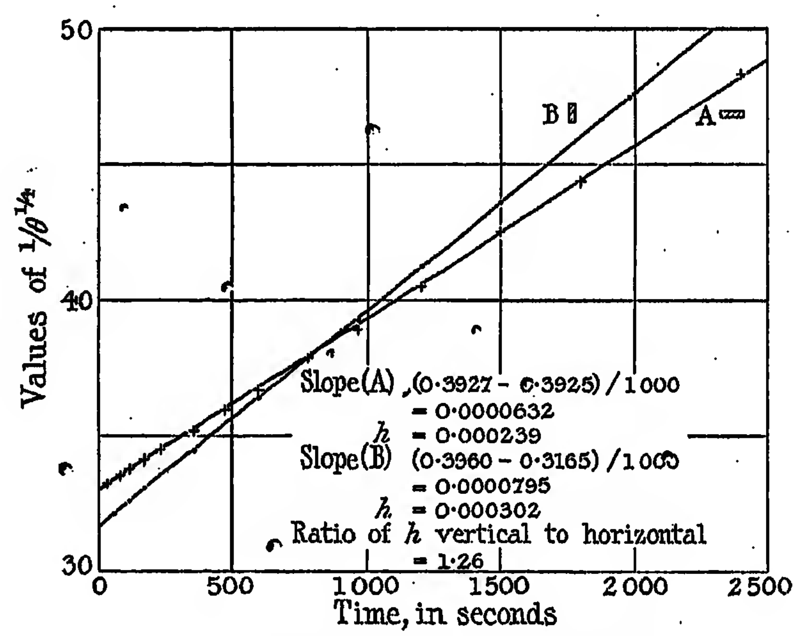

Fig. 1.—Effect of position on emissivity.

the emissivity varies somewhat erratically, being 1·26 for the 2 in. × $\frac{3}{8}$ in. strip and 1·11 for the $3\frac{1}{2}$ in. × $\frac{15}{32}$ in. strip. If 1·18 be taken as an average value of the ratio, then a flat conductor in the vertical position, all other things being equal, may be expected for the same temperature excess to dissipate approximately 18 per cent more heat than when in the horizontal position. This corresponds to an increase of about 9 per cent in the current-carrying capacity.

Effect of Surface Condition on Emissivity.

The effect of the condition of the surface is shown in Figs. (2), (3), (4) and (5), and in Table 2.

It will be noted that in the copper conductors the original condition was more favourable to the emission

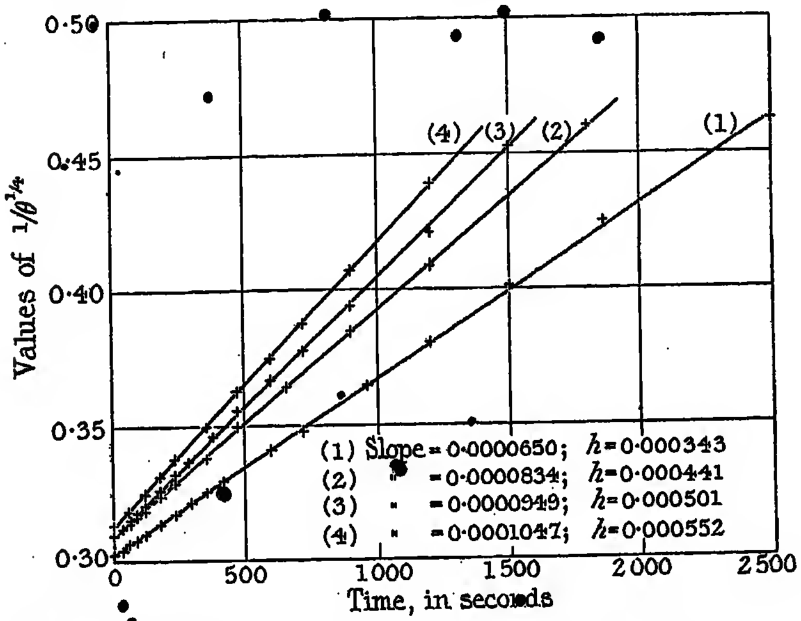

Fig. 2.—Effect of condition of surface: 2·22 cm round aluminium bar.

of heat than when the surface had been rubbed bright with sandpaper. The effect of painting the surface of the conductor a good dull black was to increase the emissivity by about 40 per cent and the current-carrying capacity for the same temperature-rise by

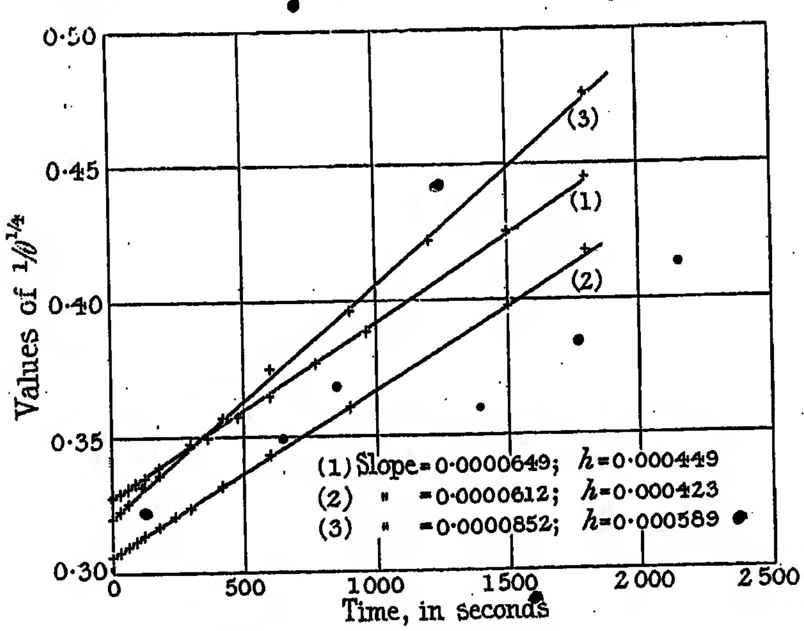

Fig. 3.—Effect of condition of surface: 1·9 cm round copper bar.

about 20 per cent. By the use of the best dull black paint available these values were increased to about 54 per cent and 24 per cent respectively.

Effect of Size of Conductor on Mean Emissivity.

As is well known, the heat emissivity, i.e. the amount of heat (conveniently expressed in watts) which is on the average emitted from each square centimetre of the surface of the conductor per degree of temperature difference, varies with the cross-section of the conductor. Both in round and in flat bars h is greater for small bars than for large ones. In order to investigate the nature and amount of this variation all the bars available of both round and rectangular cross-section were first painted with the same special dull

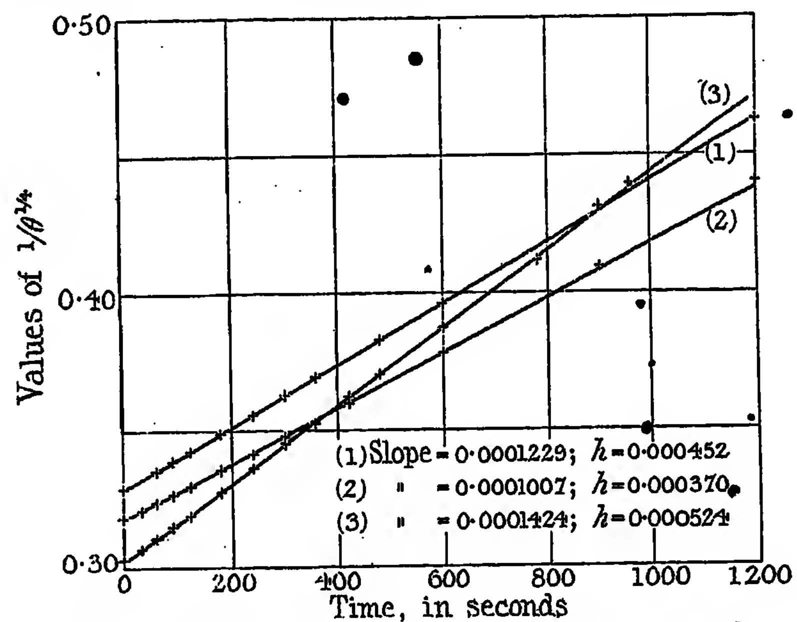

Fig. 4.—Effect of condition of surface: $1\frac{1}{2}$ in. × $\frac{1}{4}$ in. flat copper strip.

black paint so that the condition of the surfaces should be the same in all, and the value of h for each bar was then determined by the cooling-curve method. The rectangular bars—which were all aluminium—were taken with the longer dimension of the cross-section

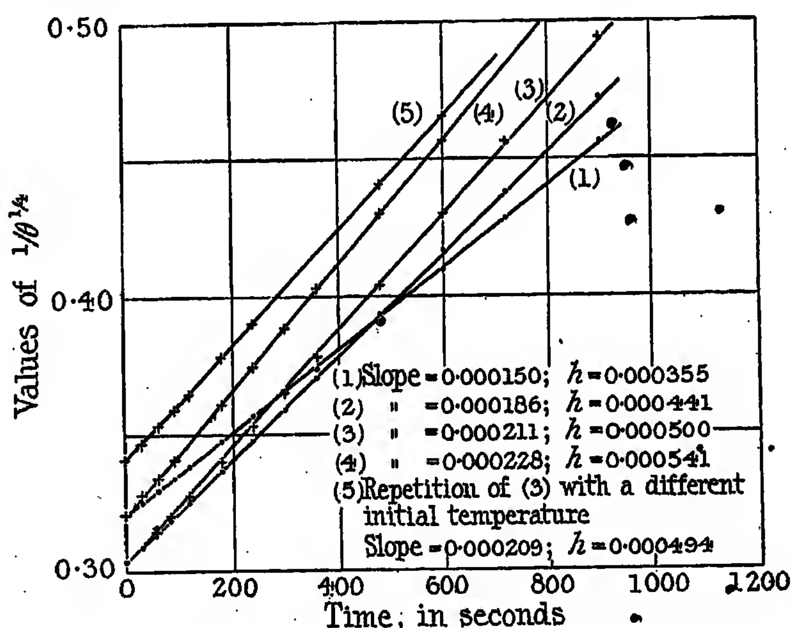

Fig. 5.—Effect of condition of surface: 1 in. × $\frac{1}{4}$ in. flat aluminium strip.

vertical. The round bars included both copper and aluminium. The results obtained are given in Table 3.

Corresponding values of p and h are also shown plotted in Fig. 6, the crosses referring to the flat and the small circles to the round bars. It will be seen that the points all lie along one well-defined and fairly regular curve, the divergence of any point from the mean curve not exceeding 2 per cent and being usually much closer. The values of h for flat bars in the horizontal position, assuming the relation of 1 : 1·18 as

explained in a preceding section, have also been computed and have been added for comparison.

In order to obtain an expression for the mathematical relation of h to p, the logarithms of these quantities, which are also given in Table 3, have been plotted and are found to lie in a fairly straight line. The divergence of the least favourable point from the best mean line is of the order of − 3 per cent. The ture difference between the bar and the surrounding air.

This relation refers to bars painted with a specially good dull black paint of high emissivity. The values obtained by this formula should therefore be reduced by about 8 per cent (see Table 2) where dull black paint of ordinary quality is used.[6]

The effect of variation of the perimeter of the bar

majority of the values for both round and flat bars whether copper or aluminium lie very much closer to the line. It follows from this that an approximate relation between h and p is

$$h = 0{\cdot}000732/p^{0{\cdot}140} \quad . \quad . \quad . \quad . \quad (5)$$

where p is the perimeter (in cm) of the bar whether of circular or rectangular cross-section, and h is the mean total heat emission (radiation and convection) in watts per cm² of exposed surface for 1 deg. C. of tempera-

on the mean emissivity in the case of conductors falling within the range covered is not as great as might have been expected. Thus the heat emitted under the same conditions of surface conditions and temperature difference from a bar 2 cm diameter, as compared with one of 4 cm, is

$$2^{0{\cdot}140} = 1{\cdot}102$$

If, as has been suggested, the emissivity varied inversely as the square root of the diameter, the effect

of halving the diameter would be to increase the emission by 41 per cent, i.e. four times the increase indicated by the empirical formula derived from this series of experimental results. It would not be safe, however, to assume that this formula remains valid for sizes of bars outside the range covered by the experimental determinations, nor, in the case of flat bars, for relative dimensions of breadth and thickness differing very widely from those investigated, which are those normally adopted for bare conductors in engineering practice.

Current-Carrying Capacity of Bare Conductors.

Assuming the validity of the formula within the range of sizes covered, the evaluation of tables of maximum permissible current for round or flat conductors can be deduced from the dimensions of the

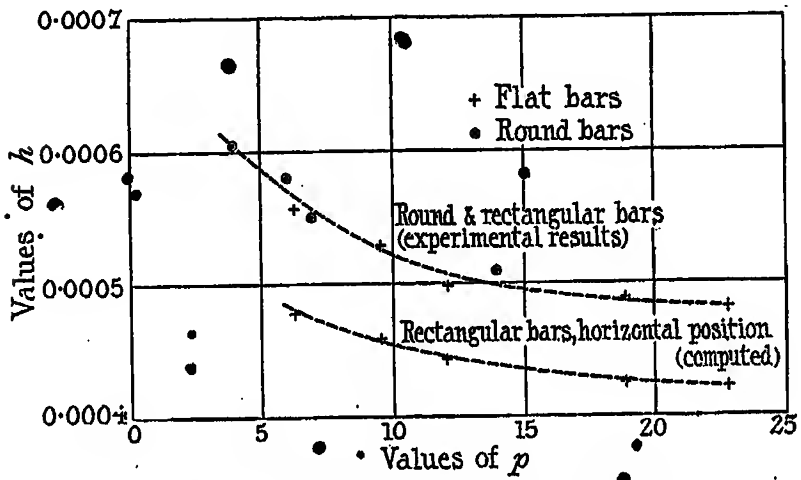

Fig. 6.—Emissivity of round and flat bars; general curve.

cross-section, the resistivity and temperature coefficient, for any given value of temperature excess.

Let p = perimeter or girth of the bar, in cm;
a = cross-section in cm^2;
ρ = resistivity of the metal in microhms per cm cube at 20° C.;
α = temperature coefficient of the latter;
I = current in amperes after stable conditions have been attained; and
θ = temperature excess of the surface of the metal above that of the surrounding air (supposed to be at 20° C.).

If H is the total amount of heat (expressed in electrical measure) generated by the current per cm run of conductor, we have

$$H = \frac{I^2(1 + \alpha\theta)p10^{-6}}{a} \quad . \quad . \quad . \quad . \quad (6)$$

and for the total amount of heat emitted per cm run we have

$$H = \frac{p \times 0 \cdot 000732 \times \theta^{5/4}}{p \times 0 \cdot 140} \quad . \quad . \quad . \quad . \quad (7)$$

whence $$I = 27 \cdot 0p^{0 \cdot 430}\sqrt{a}\sqrt{\left\{\frac{\theta^{5/4}}{(1 + \alpha\theta)\rho}\right\}} \quad . \quad . \quad (8)$$

As an overall check the formula was compared with results obtained by the direct method, i.e. by passing a steady current through lengths of conductors of various size and measuring the final temperature-rise. As an example, the ⅞ in. (2·22 cm) round aluminium bar coated with dull black paint (ordinary quality) reached a final temperature-rise of 38·5 deg. C. above that of the surrounding air when carrying 620 amperes. By the use of the formula and taking $\alpha = 0 \cdot 0039$, $\rho = 2 \cdot 84$ microhms per cm cube, $a = 3 \cdot 87$ cm^2, $p = 6 \cdot 97$ cm, and $\theta = 38 \cdot 5$, we should obtain

$$I = 27 \cdot 0 \times 6 \cdot 97^{0 \cdot 430}\sqrt{\left\{\frac{3 \cdot 87 \times 38 \cdot 5^{5/4}}{(1 + 38 \cdot 5 \times 0 \cdot 0039)2 \cdot 84}\right\}}$$
$$= 664.$$

This value must be reduced by 8 per cent since the bar was coated with ordinary dull black paint. We therefore obtain $I = 664 \times 0 \cdot 92 = 612$ amperes, a

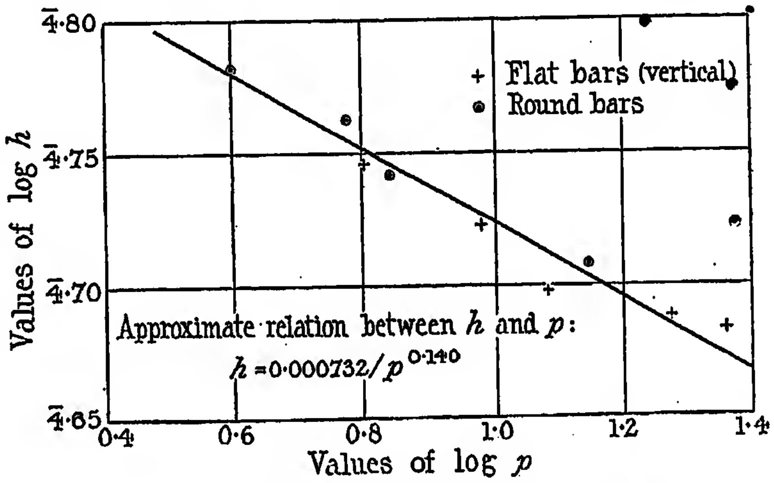

Fig. 7.—Emissivity of round and flat bars; general curve (logarithmic).

difference of 1·3 per cent from the value of 620 amperes obtained by direct experiment. Similar tests were made with other sizes and the results obtained were in close agreement, any slight difference being easily accounted for by unavoidable variations in the surface conditions of individual bars.

Calculation of Tables of Maximum Permissible Current.

For the calculation of tables of maximum permissible current for bare copper and aluminium conductors of the standard sizes given in the suggested B.E.S.A. Specification C.A. (E.L.) 5701, we proceed as follows:—

Starting with the general formula (8) we have

$$I = p^{0 \cdot 43}\sqrt{a} \times 27 \cdot 0\sqrt{\left\{\frac{\theta^{5/4}}{(1 + \alpha\theta)\rho}\right\}}$$

This, as it stands, applies to single bars covered with a specially good dull black paint, and in the case of flat bars when they are placed with the longer dimension of the cross-section vertical. The specification allows a temperature-rise of 30 deg. C. and a maximum surrounding air temperature of 40° C. The formula can therefore be further simplified by substitution of the appropriate values for θ and ρ.

Since $\theta = 30$, $\theta^{5/4} = 70 \cdot 2$.

For the terms involving ρ we have:—

(1) *Copper.*—Taking the resistivity of copper as

1·724 microhms per cm cube at 20° C., then at 40° C. $\rho = 1{\cdot}724(1 + 0{\cdot}0039 \times 20) = 1{\cdot}860$, and $(1 + \alpha\theta)\rho = 2{\cdot}070$.

The permissible current for these conditions is therefore given by the formulæ:

$$I = 157p^{0\cdot43}\sqrt{a}, \text{ for flat bars} \quad . \quad . \quad (9)$$

$$I = 264a^{0\cdot715}, \text{ for round bars.} \quad . \quad . \quad (10)$$

(2) *Aluminium.*—Taking the resistivity of aluminium as 2·84 microhms per cm cube at 20° C., then at 40° C. $\rho = 2{\cdot}84(1 + 0{\cdot}0039 \times 20) = 3{\cdot}061$, and $(1 + \alpha\theta)\rho = 3{\cdot}419$.

The permissible current for these conditions is therefore given by the formulæ:

$$I = 122p^{0\cdot43}\sqrt{a}, \text{ for flat bars} \quad . \quad . \quad (11)$$

$$I = 211a^{0\cdot715}, \text{ for round bars.} \quad . \quad . \quad (12)$$

Special allowance must be made, (1) when the bars are unpainted, or the surface condition is different from that specified; and (2) when the lead and return conductors are near each other and there is a mutual heating effect.

Effect of surface conditions.—Where ordinary black paint has been used the current values given in the tables should be reduced by 8 to 10 per cent. For unpainted bars the reduction should be 20 to 25 per cent, according to the condition of the bars.

TABLE 4.

Correction for Skin Effect.

Diameter of bar, in.		1	1⅛	1¼	1⅜	1½	1⅝
Current reduction per cent	Copper	2	4	5	—	—	—
	Aluminium	1	1	2	3	4	5

Proximity effect.—Where two bars are run close together the current-carrying capacity is reduced because of the mutual heating effect, and this is greater when the bars are painted black than when they are left with bright metallic surfaces, as in the latter case the radiation component of the emissivity is less. The effect will obviously be greatest when two flat strips are placed side by side and parallel with each other.

Where two dull black bars of equal size were run side by side and the distance between the opposite surfaces was equal to the breadth of the bars it was found that the emissivity was 6 per cent less than when the same bar was run alone. The current carrying capacity is therefore reduced by 3 per cent.

	1½	0·1875	1·210	428	2 280
	2	0·250	1·614	553	2 210
	2½	0·3125	2·015	648	2 190
	3	0·375	2·42	802	2 130
	4	0·500	3·23	1 046	2 090
$\frac{1}{16}$	½	0·0313	0·140	92·2	2 940
	¾	0·0467	0·210	132·0	2 820
	1	0·0622	0·280	172	2 770

* For ordinary black paint the current values should be reduced by 8 per cent, and for unpainted bars by 20 to 25 per cent, according to the condition of polish of the metallic surface.

TABLE 6.

*Current-Carrying Capacity of (2) Copper Bars, Round, with a dull black surface.**

Dimensions: Diameter, d		Area of cross-section		Current-carrying capacity	Current density
in.	cm	sq. in.	sq. cm	amps.	amps./sq. in.
0·236	0·599	0·0437	0·282	109·5	2 510
¼	0·365	0·0490	0·316	118·8	2 420
$\frac{5}{16}$	0·794	0·0766	0·495	164	2 140
⅜	0·952	0·1105	0·711	212	1 920
$\frac{7}{16}$	1·111	0·1505	0·907	265	1 760
½	1·270	0·1960	1·265	322	1 645
⅝	1·587	0·307	1·980	440	1 436
¾	1·905	0·442	2·85	572	1 296
⅞	2·222	0·603	3·87	711	1 178
1	2·540	0·786	5·07	864	1 100
1⅛	2·857	0·992	6·40	1 020	1 028
1¼	3·157	1·225	7·92	1 190	970

* For ordinary black paint the current values should be reduced by 8 per cent, and for unpainted bars by 20 to 25 per cent, according to the condition of polish of the metallic surface.

If, however, the distance is increased to twice the breadth of the bar, the reduction of the emissivity is almost inappreciable and the effect on the current-carrying capacity may be neglected.

When the bars are unpainted and have polished metallic surfaces, the effect of running two bars side by side is less and may be neglected if the distance between them is not less than the breadth of the bars.

TABLE 7.

*Current-Carrying Capacity of (3) Aluminium Bars, Flat, with a dull black surface.**

	$1\frac{1}{4}$	0·156	1·006	281	1 800
	2	0·250	1·614	430	1 714

* For ordinary black paint the current values should be reduced by 8 per cent, and for unpainted bars by 20 to 25 per cent, according to the condition of polish of the metallic surface.

Condition of ambient air.—For the purpose of calculating the tables the cooling effect of any extraneous draught has been excluded. This would be most difficult to define; where present, however, the effect would be to increase the current-carrying capacity. Generally it may be taken that the values apply to conditions surrounding busbars within a building such as a generating station, in which the only air currents are those due to convection set up by the heated conductors.

Alternating current.—The values given are in all cases for direct current. With alternating current the effective resistance of the conductors is increased because of the "skin effect," and the current ratings must be correspondingly reduced. Calculating by means of existing formulæ † for frequencies not greater than 50 periods per second, and for round bars less than 1 inch in diameter, or of the equivalent area of cross-section in the case of flat bars, it is found that the reduction of the rating will not exceed 1 per cent. For larger bars the reductions shown in Table 4 will apply.

For flat bars of equivalent cross-section the reduction in current will not be greater than for round bars and the above values will probably be sufficently accurate for the case of flat bars.

TABLE 8.

*Current-Carrying Capacity of (4) Aluminium Bars, Round, with a dull black surface.**

A NEW NETWORK THEOREM.*

By A. ROSEN, B.Sc. (Eng.), Associate Member.

(*Paper received* 28*th April*, 1924.)

SUMMARY.

A generalized theorem is given of which the well-known three-ray star-mesh transformation is a particular case. The formula is of a simple nature, and a great saving of labour results from its use. Three examples of application of the theorem follow: (1) To find the effective conductance between two points in a complicated network; (2) to find the effect of earth admittances on the balance of a Wheatstone bridge; and (3) to simplify the capacity network in the four-wire telephone cable and obtain the effective unbalance capacity.

The star-mesh theorem as applied to a star of three rays was first given by Kennelly in 1899 † and is now well known. It may be stated as follows:—

In any network the star OA, OB, OC [Fig. 1(a)] may be

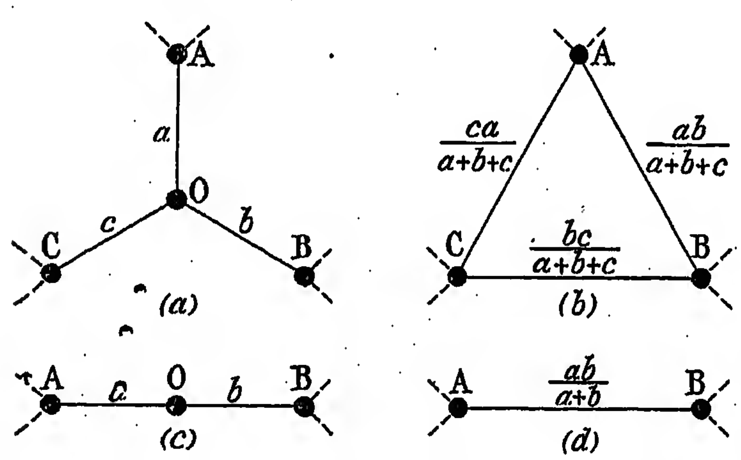

FIG. 1.—Three-ray and two-ray star-mesh transformations.

replaced by the mesh AB, BC, CA [Fig. 1(b)] without affecting the rest of the network, where, for conductance operators,

$$\mathrm{AB} = \frac{ab}{a+b+c}; \ \mathrm{BC} = \frac{bc}{a+b+c}; \ \mathrm{CA} = \frac{ca}{a+b+c}$$

Again, two conductors in series [Fig. 1(c)] may be regarded as a two-ray star OA, OB, and this is equivalent to AB in Fig. 1(d), where $\mathrm{AB} = ab/(a+b)$.

These are both particular cases of the following general theorem:—

In any network, a star of n rays, $\mathrm{OA} = a$, $\mathrm{OB} = b$, $\mathrm{OC} = c \ldots \mathrm{ON} = n$ (Fig. 2) may be replaced by a mesh of $\frac{1}{2}n(n-1)$ conductors joining every pair of the points, A, B, C, . . . N (O being eliminated), without affecting the rest of the network; then for conductance operators

$$\mathrm{AB} = \frac{ab}{\Sigma a}, \ \mathrm{BC} = \frac{bc}{\Sigma a}, \text{ etc.,}$$

where $\Sigma a = a + b + c + \ldots n.$

The following indicates the reasoning which justifies the generalization given:—

The mesh system must be symmetrical; therefore there must be a conductor joining every pair of points, i.e. a total of $\frac{1}{2}n(n-1)$ conductors in a system of the nth order where there are n rays in the star.

The expression for the value of any conductor, say AB:—

(1) must be of symmetrical form, homogeneous, and of first degree;
(2) must vanish when a or b becomes zero; and
(3) must become of one order lower as any of the other rays equals zero, and must eventually reduce to the form $ab/(a+b+c)$, the known expression for the three-ray star, and $ab/(a+b)$, the expression for the two-ray star.

Considering the form of the expression, we see from conditions (1) and (3) that it must consist of a single fraction. The denominator of the fraction can only

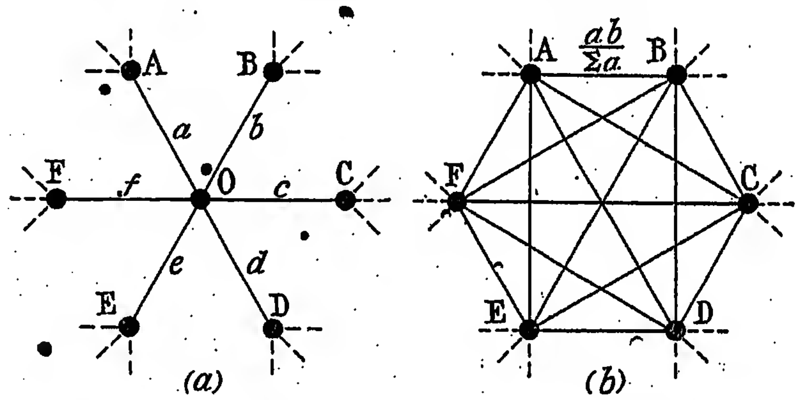

FIG. 2.—General star-mesh transformation.

be Σa to satisfy (1) and (3); the numerator from (1) can only contain terms of the second degree; and, from (2), all must contain a and b, i.e. it can only be λab, where λ is a numerical factor. By (3), λ is seen to be unity. Hence the expression $\mathrm{AB} = ab/\Sigma a$ is the only one to satisfy all conditions.

For impedance operators the result is

$$\mathrm{AB} = ab\Sigma\left(\frac{1}{a}\right), \ \mathrm{BC} = bc\Sigma\left(\frac{1}{a}\right), \text{ etc.,}$$

where $\Sigma\left(\frac{1}{a}\right) = \frac{1}{a} + \frac{1}{b} + \frac{1}{c} + \ldots \frac{1}{n}.$

Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

† A. E. KENNELLY: "The Equivalence of Triangles and Three-pointed Stars in Conducting Networks," *Electrical World*, 1899, vol. 34, p. 413.

This can be derived from the expression for conductances, or in a manner similar to the above; in this case condition (2) is " AB must become infinite when a or b is infinite," and condition (3) is " AB must become of one order lower as any of the other rays becomes infinite, and must eventually reduce to the form

$$ab\left(\frac{1}{a} + \frac{1}{b} + \frac{1}{c}\right)$$

the known expression for the three-ray star, and

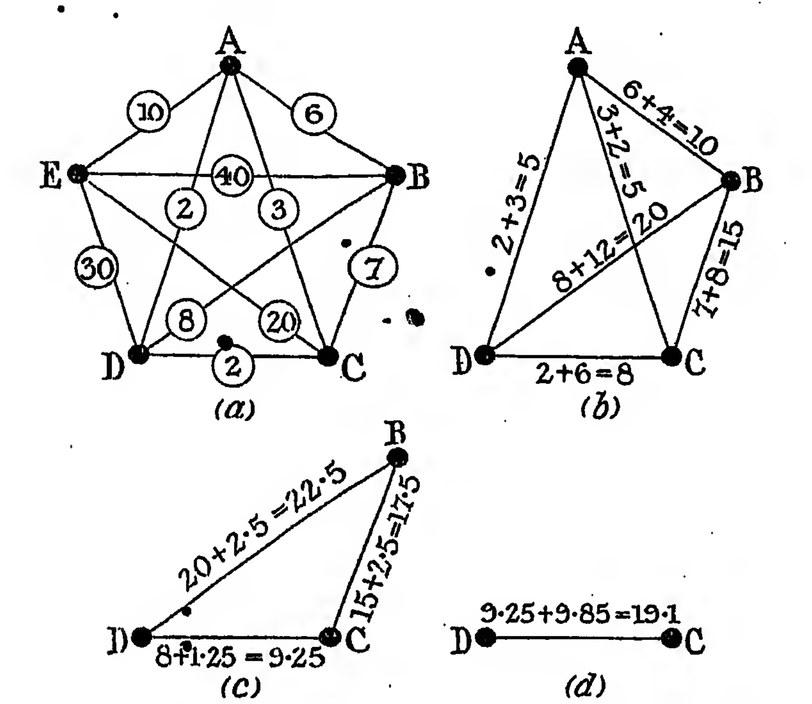

FIG. 3.—Stages in simplification of complicated network.

$(a + b)$, the expression for the two-ray star." The impedance formula is not so convenient in use on account of the frequent addition of conductors in parallel resulting from the transformations, as can be seen in the following examples.*

number of rays, and a triangular mesh can always be replaced by an equivalent star. The formulæ are, for admittances,

$$a = \text{AB} \times \text{AC}\left(\frac{1}{\text{AB}} + \frac{1}{\text{BC}} + \frac{1}{\text{CA}}\right), \text{ etc.,}$$

and for impedances,

$$a = \frac{\text{AB} \times \text{AC}}{\text{AB} + \text{BC} + \text{CA}}, \text{ etc.}$$

Applications.—The star-mesh transformation is of great assistance in simplifying the work in network problems. The case of most frequent occurrence is the three-ray star, and examples are given by Kennelly* and Butterworth.† Networks in which stars of higher order occur are necessarily more complicated, and a correspondingly greater saving in labour is obtained in applying the transformation. Three examples are given below.

(1) *To find the effective conductance between the points* C, D *in the network shown in Fig.* 3(*a*), *the values being expressed as conductances.—Step* (*i*).—Transform the four-ray star AE, BE, CE, DE into the corresponding mesh. $\Sigma a = 10 + 40 + 20 + 30 = 100$. Fig. 3(*b*) shows the resulting network with the new values of the conductors.

Step (*ii*).—Transform the three-ray star BA, CA, DA in Fig. 3(*b*) into its mesh. $\Sigma a = 10 + 5 + 5 = 20$. The resulting network is shown in Fig. 3(*c*).

Step (*iii*).—Transform the two-ray star CB, DB in Fig. 3(*c*) into its mesh. $\Sigma a = 17 \cdot 5 + 22 \cdot 5 = 40$. The final result, viz. the effective conductance across CD, is shown in Fig. 3(*d*), the value being $19 \cdot 1$.

(2) *To find the effect on the balance of a Wheatstone bridge of earth admittances located at the four corners* A, B, C, D.—Applying the four-ray transformation to

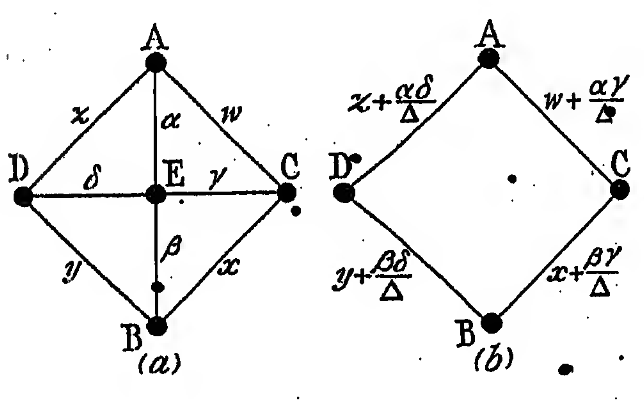

FIG. 4.—Effect of earth admittances on balance of Wheatstone bridge.

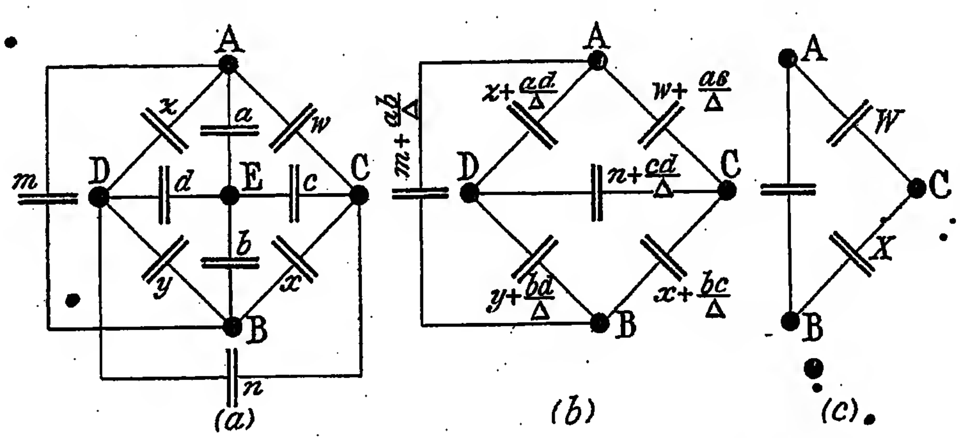

FIG. 5.—Capacity network in four-wire telephone cable.

It will be observed that since, in general, the number of mesh conductors is greater than the number of rays of the corresponding star, the theorem is not reciprocal, i.e. no mesh in which the members are arbitrary can be converted into a star. In the case of three points, however, the number of mesh conductors equals the

AE, BE, CE, DE (Fig. 4) the new condition for balance can be written down immediately as

$$\left(w + \frac{\alpha\gamma}{\Delta}\right)\left(y + \frac{\beta\delta}{\Delta}\right) = \left(x + \frac{\beta\gamma}{\Delta}\right)\left(z + \frac{\alpha\delta}{\Delta}\right)$$

where $\Delta = \alpha + \beta + \gamma + \delta$, and all quantities are expressed as admittances. The admittances across

* The impedance formula for the case of a four-ray star is given by K. KÜPFMÜLLER: "Über das Nebensprechen in mehrfachen Fernsprechkabeln und seine Verminderung," *Arch. f. Elektrotechnik* 1923, vol. 12, p. 160.

* *Loc. cit.*

† *Proceedings of the Physical Society*, 1921, vol. 34, p. 1.

AB, CD can be ignored as they shunt the source and detector and do not affect the balance.

A similar equation applies to generalized double-bridge networks. A particular case of the Wagner double bridge as applied to the Wien bridge has been worked out in detail by the author.*

(3) *To deal with the network of capacities obtained in the quad form of telephone cable in which there is a capacity between every pair of the wires* A, B, C, D, *and each wire has a capacity to the sheath* E [*Fig.* 5(*a*)].—Transforming the four-ray star AE, BE, CE, DE, the equivalent network is shown in Fig. 5(*b*). For example, to find the effective unbalance capacity between AC and BC, D being free, transform the star AD, BD, CD into its mesh AC, BC, AB. The effective value of AC is

$$W = w + \frac{ac}{\Delta} + \frac{\left(n + \frac{cd}{\Delta}\right)\left(z + \frac{ad}{\Delta}\right)}{y + z + n + \frac{d}{\Delta}(a + b + c)}$$

* "The Use of the Wien Bridge for the Measurement of the Losses in Dielectrics at High Voltages, with Special Reference to Electric Cables," *Proceedings of the Physical Society*, 1923, vol. 135, p. 249.

where $\Delta = a + b + c + d$

The effective value of BC is

$$X = x + \frac{bc}{\Delta} + \frac{\left(n + \frac{cd}{\Delta}\right)\left(y + \frac{bd}{\Delta}\right)}{y + z + n + \frac{d}{\Delta}(a + b + c)}$$

The unbalance capacity is

$$W - X = p + \frac{cu}{\Delta} + \frac{(\Delta n + cd)\left(q + \frac{du}{\Delta}\right)}{\Delta(y + z + n) + d(\Delta - d)}$$

where, in the usual notation, $p = w - x$, $q = z - y$, $u = a - b$. This result has been previously obtained by means of the usual methods, but naturally only after a great deal of labour. The application of this formula is discussed in an article on "Trunk Telephone Cables" by E. A. Beavis.*

DISCUSSION ON

"SOME RESEARCHES ON THE SAFE USE OF ELECTRICITY IN COAL MINES."*

Discussion at a Joint Meeting of the Western Centre of the Institution and the South Wales Section of the Association of Mining Electrical Engineers, at Lydney, 3 May, 1924.

Mr. I. Jones: Although the ignition tests carried out during the meeting and given in the paper were made on non-inductive circuits, they clearly show the advantage of alternating over direct current in these circumstances. In nearly all cases in actual practice, however, the circuits are inductive, and it would have been of further interest had the author carried out tests with inductive circuits, corresponding to power factors of, say, 0·6 lagging. Since the 1915 and 1916 reports on battery bell signalling by the present author and Dr. Wheeler, there is no question that considerable advance has been made in the design of signalling apparatus for underground use. The practice in the South Wales district with either the bare wire circuit (with or without pull-switches) or the insulated wire circuit with pull-switches, is to use flameproof d.c. bells, with or without relays, or a.c. bells with relays, as circumstances permit. Where a suitable a.c. lighting supply at 110 volts is available a small transformer of about 50 watts capacity with tappings on the secondary side, giving 0–25 volts in steps of 5 volts, is used for a.c. bells, together with a flameproof relay connected to the external bare wire signalling circuit. This arrangement is found very reliable in practice; the transformer having an earthed metal shield placed between the primary and secondary windings, and an a.c. bell having a small 14-volt 2-watt metal filament lamp connected across the winding. This suppresses the spark at the break and also gives a visible indication of a signal. The reactance of these transformers varies from 33 per cent to 8 per cent according to the tapping which is used; the short-circuit current is 30 amperes on the 5-volt tapping and 25 amperes on the 25-volt tapping. There is no reason why the capacity of these transformers should not be reduced to, say, 15 or 20 watts, and the reactance increased, or a small non-inductive resistance placed in the circuit, to keep down the short-circuit current to a much lower value. I should be glad to have the author's views on a.c. signalling, as this system, if made equally as safe as the d.c. system from the point of view of the flash occurring at break, is by far the best system to use in the mine. Lighting underground is at present confined to the pit bottom, and the main roadways for a comparatively short distance inbye and also engine rooms, where an electric supply is available. The voltage generally used is 110 or sometimes 50, and if the correct type of control switches, lighting fittings, and armoured cable is used, there can be no question that when properly maintained it is a sound, though

* Paper by Dr. W. M. Thornton (see page 481).

somewhat expensive, system to install. Roughly speaking, the cost of lighting underground with the present system is £2 10s. to £3 per point. The lighting in the main roadways inbye should undoubtedly be extended, as this would result in a considerable improvement in the handling of the traffic. The difficulty in the deeper mines of South Wales is to maintain the main roadways in a condition suitable for the installation of electric light, otherwise the cost of repairs and renewals would be prohibitive. Taking, for example, a main roadway of 1 000 yards in length from the pit bottom to a main parting inbye, and adopting the system of lighting advocated by the author, I take it that the method which would be adopted would be to use a main medium-tension armoured cable and to install small transformers such as were introduced by Messrs. Reyrolle. These transformers are of small capacity, and are made up in the form of straight-through joint boxes; switchgear would be used on the secondary side only, and bare wire employed for the lighting circuit in sections of, say, approximately 200 yards. This length would be nearly the maximum possible for 25-volt distribution, owing to the voltage-drop. The cost of lighting a roadway of this length would be approximately 10s. per yard. I should be glad of some further information as to the system which the author had in mind for a case of this kind.

Major E. I. David: The part of the paper in which I was particularly interested was that where the author shows what a small amount of gas is necessary to provide an inflammable mixture, when coal dust is present in large quantities. I appreciated his reference to Professor Galloway's experiments in this connection, which were commenced at Tredegar in 1895. Prof. Galloway proved most emphatically that coal dust could be ignited by a very small explosion, and would ignite most forcibly. A percentage of something under 2 per cent of methane would give an explosion every time. I think that the policy of a number of mining engineers in South Wales of using compressed air coal-cutters in dry places is the right one. Although I heartily agree with the provision of more light in every part of the pit, if this means the introduction of electricity into dry coal faces I do not think it is the right way to attack the problem. We must have a better hand lamp, rather than carry electricity to those places. I agree with Mr. Jones that it is unfortunate that the particular experiments shown by the author were not carried out with inductive circuits, because practically every circuit underground must be inductive. I find that an ordinary 25-volt a.c. bell has a resistance of 18 ohms, and an inductance of 326 mH. On a 15·5-volt circuit it takes 2 volt-amperes and has a power factor of 0·174. This means that a current of 138 mA has to be broken on the signalling wires; surely not a dangerous current, judging by the figures given in the paper. The relay which we have developed has a resistance of 323 ohms and an inductance of 1·29 H, taking a current of 30 mA at 15·5 volts and having a power factor of 0·625. When operated with a 800-ohm non-inductive shunt the signal-wire contact is absolutely sparkless. This relay will operate on lines having a resistance up to 420 ohms and, by adjustment, on a line with an insulation resistance of only 120 ohms. One type of d.c. 25-volt bell has normally a resistance of 50 ohms and a non-inductive shunt of 50 ohms across the contact. Another type has a resistance of 30 ohms, with a protective winding also of 30 ohms. Either of these can be operated with bare wires without visible sparking at the wires. With regard to lighting, I quite agree with the author's proposals. My idea of a lighting system would be a series of 100-watt to 200-watt transformers, solid compounded into the cable boxes of the main supply cables, supplying a number of 10-watt to 20-watt automobile-type lamps at, say, 25 volts. The filaments of lamps of this size would be less than 2 mm in diameter and being of tungsten would not ignite methane. The reactance of these transformers could be made such that the short-circuit current would not exceed 20 amperes. For 20 years we have been experimenting with lamps which would give instant indication of the presence of gas. If the lamp shown is a success it will be a factor in the safety of mines for many years to come. I should like to know what percentage of methane was present in Fig. 5 and what was the frequency in Fig. 6. The earth plate is an excellent one, and I should like to know if the author has any data as to its possible life.

Mr. Ll. Hughes: The paper should help to remove any existing mistrust of the application of electricity to mining work. It is necessary to find means of reducing high working costs in mines to a minimum, and we must look forward to electrical and mechanical methods of getting and transporting coal. I think that the majority of us will agree with the author that electricity is the ideal medium for conveying energy underground, but it has its limits and we must look to its application underground with a good factor of safety. The author says that if the human element of carelessness could be for ever removed there is for each possibility of electrical risk a simple and effective preventive. The Association of Mining Electrical Engineers are doing good work in removing the human element fault, by means of lectures and papers. The small percentage of electrical accidents in the South Wales coalfield confirms that statement. If we recognize the advantages of electricity for underground purposes it is our duty to make full use of the author's investigations in regard to its safe application. I agree with the author that more fixed lighting could, with advantage, be adopted for underground roadways. Most of the colliery pit bottoms are at present lit by electricity. The dispatch of full and empty trams cannot be dealt with at the same rate with ordinary safety lamps, and these improvements to transport will increase with the extension of fixed lighting, if the safe voltage can be determined. The 25-volt a.c. lighting has been installed in the pit bottom at the Treharris colliery for a number of years. The only objection to this voltage is that if a long distance has to be covered by this system the cables have to be sufficiently large to allow for the voltage drop. The author's experiments to show the effect of falls on cables installed underground should be the means of inspiring confidence in those who have any doubt of the ability of the trip-gear of a modern mining switch to deal with such conditions.

The curves on pages 486 and 487 are of interest, especially Fig. 5 which shows the influence of frequency on the ignition of methane. The results of the investigations point towards low-voltage alternating current at high frequency. The practical application of such a system to underground purposes in conjunction with existing systems, offers some problems. Schemes for districts a mile or two inbye, to provide for coal-face lighting as suggested on page 489, will call for much consideration. The statement on page 490 that the space above the oil must be thoroughly ventilated, does not agree with the design of the best type of mining switch in use to-day, in which the space above the oil is not ventilated. This space should be as little as possible, and where possible all spaces should be filled solid with compound. Referring to the earthing system described on page 490, I prefer the earthing clamp to be above the surface of the ground so that it can be inspected easily.

Mr. C. Lewis: I was rather disappointed with the experiment in connection with the miner's lamp in the gas chamber. If it had been carried out more slowly one could have obtained a better idea of the "caps" at various percentages of gas. As a matter of fact the lamp went out all at once. The author advocates high-frequency alternating current for lighting, and I should like to know what minimum frequency should be applied and what maximum frequency would be practical. The author appears to be prejudiced against bitumen cable; why does he say that bitumen cables should be prohibited?

Prof. W. M. Thornton (*in reply*): In reply to Mr. Jones, non-inductive circuits were used for three reasons. First, the influence of self-induction was worked out in 1910 for direct currents and again in the investigation on signalling bells. The influence of added inductance on ignition can be predicted in the case of direct currents once that for non-inductive circuits is known. It is not so well-defined in the case of alternating currents on account of the difficulty of breaking a circuit at a given point in the wave, and to obtain certainty as to the maximum voltage conditions at the moment of break when working with alternating currents it is necessary to use in these researches circuits that are non-inductive. Secondly, by so doing the outside limit of current is found; inductance always lowers it. Thirdly, the singular variations in the curves expressing the experimental results are complicated by inductance. For road-lighting a cable at medium pressure with small straight-through transformers would be the most convenient and economical. For face-lighting it might be better to transform at a gate end and carry 25 volts or less inbye for lighting at 150 frequency. Details of this are under consideration.

In reply to Major David, the essential feature of a safe circuit is a low time-constant. If the inductance is relatively high the resistance in series with it must also be increased. In every case the effect of inductance on ignition can be counteracted by shunts across the magnet windings. The question of better lighting at the face as a means of relieving any sense of uncertainty as to the state of things from moment to moment can in my opinion be dealt with best by a combination of the portable electric lamp and a low-tension cable, to which it may be flexibly connected by a safety interlocking attachment.

I agree with Mr. Hughes that an entirely satisfactory method of carrying electricity far inbye for coal-face lighting will call for much more investigation before it can be adopted. All that the work described in the paper does is to indicate possible lines by which the solution may be reached.

Mr. Lewis is, I think, under some misapprehension as to the test with the "dropper" type of oil safety-lamp in the gas chamber. The essential point of that lamp is that it goes out, or nearly so, before any percentage capable of forming a visible cap when the flame is high could be formed. The lamp gives warning that 2½ per cent of gas is present without any lowering of the wick, so that men can continue in full work feeling sure that full warning will be given when it is necessary to leave the place on account of gas. With regard to bitumen cables, they give off, when overheated, large quantities of methane, hydrogen and sulphuretted hydrogen, all inflammable gases, and they are, or were, rather subject to water faults on direct-current systems.

THE SHAPE OF POLE-SHOE REQUIRED TO PRODUCE A SINUSOIDAL DISTRIBUTION OF AIR-GAP FLUX DENSITY.*

By B. HAGUE, M.Sc., Associate Member.

(*Paper first received 29th April, and in final form 18th July, 1924.*)

SUMMARY.

Considerable interest has recently been shown in the complete elimination of all harmonics from the induced E.M.F. wave-form of an alternator. The methods usually employed in practice for the purification of the wave-shape fall into two classes: (*a*) in which certain harmonics are removed by proper choice of the characteristics of the armature winding, and (*b*) in which an endeavour is made to attain the desired end by producing a sinusoidally distributed flux round the air-gap. The object of the present paper is to give the theory of a commonly used method of the second class, in which the reluctance of the gap from point to point is adjusted to the value proper to the sinusoidal flux by shaping the pole-face to give a gap of varying length, longer at the tip than at the centre of the pole. The problem is solved for the case of a smooth-core armature, or for one in which the slots have been closed by means of magnetic wedges, such as would be used in a wave-form standard. Flat and circular armatures with any number of poles are dealt with, the shape of the pole-shoes and the permeance of the gap being determined in each case. The paper concludes with a numerical example illustrating the theory given in the text.

INTRODUCTION.

In discussing the elementary theory of the alternator it is usual to assume that the magnetic field in which the armature conductors are situated is distributed round the air-gap according to a sine law, so that the wave-form of the electromotive force induced in the armature winding may be sinusoidal. Since the use of impure wave-forms in alternating-current circuits gives rise to a number of technical troubles, the sine-wave alternator represents an ideal to which modern design practice is tending to attain. Indeed, the permissible variation of the voltage wave from the sine form is often stated in specifications for alternators, and an endeavour is now being made to set up a criterion by which the purity of the wave-form can logically be judged. The subject of the purity of the voltage wave of alternators has recently been considerably studied in connection with the important problem of the interference between supply networks and neighbouring telephone circuits.

In connection with the telephone interference problem it has been suggested that a small alternator might be designed to give an exact sine wave of terminal voltage, the machine being intended for laboratory use as a reference standard. Such a wave-form standard would embody all the means known to the designer to suppress all harmonics from the voltage. To this end, a smooth core with a distributed winding would be used, the pole-shoes being empirically shaped so that the flux distribution is approximately sinusoidal. Machines of a similar type have already been constructed for purposes of measurements in telephonic research.

Whether the alternator under construction is for use in ordinary engineering practice or for some special purpose such as that just mentioned, there are numerous methods available to the designer in his endeavour to secure a pure wave-form. Among these are the following:—

(1) Distribution of the armature winding in such a way as to cut out certain harmonics by the reduction of winding factors to zero. Alteration of the phase-spread or the coil-span, interlinking of the phases, the use of wave windings, and other similar devices may be employed. Unless the distribution of the gap flux is sinusoidal, it is not possible to remove all harmonics by alteration of the characteristics of the winding alone.

(2) Skewing of the armature slots or of the pole-shoes.

(3) The use of closed slots or of slots filled at the mouth with a wedge of magnetic material. In small machines slots are dispensed with entirely and a smooth core is used.

(4) Application of a system of poles which will produce a sinusoidally distributed magnetic field. Two methods are used in practice. In the first the axial width of the pole-face is so adjusted that with an air-gap of constant length an approximately sinusoidal distribution is produced.* In the second, the axial width of the pole-shoe is constant but the face of the shoe is shaped to give an air-gap longer at the pole-tip than at the pole-centre, the intention being again to produce a sine wave of flux density. This device is very commonly used for improving the flux distribution, the shoe being shaped empirically.

It is the object of the present paper to examine theoretically the last-named method, i.e. to find what shape would be given to the air-gap in a salient-pole dynamo so that the flux shall be distributed sinusoidally over the armature surface.

To solve the problem by simple mathematical methods it is necessary to lay down certain fundamental conditions, which can now be briefly stated:—

(*a*) The normal distribution of field strength over the surface of the armature core is postulated to be sinusoidal.

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

* W. T. MACCALL: "Alternating-current Electrical Engineering" (1923), p. 172.

(*b*) The armature surface is supposed to be smooth, so that the flux distribution is steady.

(*c*) The iron parts are assumed to have infinite permeability, so that both the armature core and the pole-face can be taken as equipotential surfaces.

Two cases will be considered :—

(i) Where the armature has a plane surface ; and

(ii) Where the surface is a right circular cylinder.

As will be shown at a later stage, multipolar machines approximate closely to case (i). To simplify still further the details of the problem the machine is supposed to have a very great axial length, attention being confined to a portion of unit length situated at a considerable distance from the ends of the machine. The distribution of the magnetic field in the portion under consideration is then sensibly two-dimensional.

In either case the method to be adopted is the same. With the given armature surface and the assumed flux distribution over it, an endeavour is made to find the natural system of equipotential surfaces due to these given conditions. A pole-shoe coinciding with any one of these equipotentials will then give the desired flux distribution on the core. Briefly, the process consists in finding a function Ω specifying the magnetic potential at points external to the armature core. If $\partial\nu$ be an element of length in a given direction the magnetic field-strength in that direction is, from the well-known definition of potential, given by

$$H_\nu = -\frac{\partial\Omega}{\partial\nu}$$

Ω must be chosen so that H_ν has specified values on the armature surface. The choice of a suitable form for Ω is suggested by experience and is determined by the nature of the surfaces bounding the field. Ω must, however, satisfy Laplace's equation of continuity, expressed in suitable co-ordinates. The following sections will show the procedure applicable to the present problem.

Armature with Plane Face.

In Fig. 1 let XOX be the plane surface of the infinitely permeable armature core. Further, let the surface be at zero magnetic potential and let the magnetic field strength normal to the surface be

$$H = H_1 \sin\frac{\pi x}{X} \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where X represents the pole-pitch. It is now required to find the resulting magnetic potential, Ω, at a point P external to the plane core.

It is easy to show from a consideration of the continuity of the flux passing P that the potential must satisfy Laplace's partial differential equation

$$\frac{\partial^2\Omega}{\partial x^2} + \frac{\partial^2\Omega}{\partial y^2} = 0 \quad . \quad . \quad . \quad . \quad (2a)$$

Moreover, since XOX is an equipotential surface the entire magnetic field strength on it must be normal to the surface and equal to the assumed field. The potential must be such, therefore, that the boundary conditions

$$\left(-\frac{\partial\Omega}{\partial y}\right)_{y=0} = H_1 \sin\frac{\pi x}{X} \quad . \quad . \quad (2b)$$

and
$$\left(-\frac{\partial\Omega}{\partial x}\right)_{y=0} = 0 \quad . \quad . \quad . \quad . \quad . \quad (2c)$$

are simultaneously satisfied.

From these boundary conditions experience indicates that the appropriate form for the potential is

$$\Omega = YH_1 \sin px$$

wherein Y is a function of y only and p is a constant coefficient to be determined.

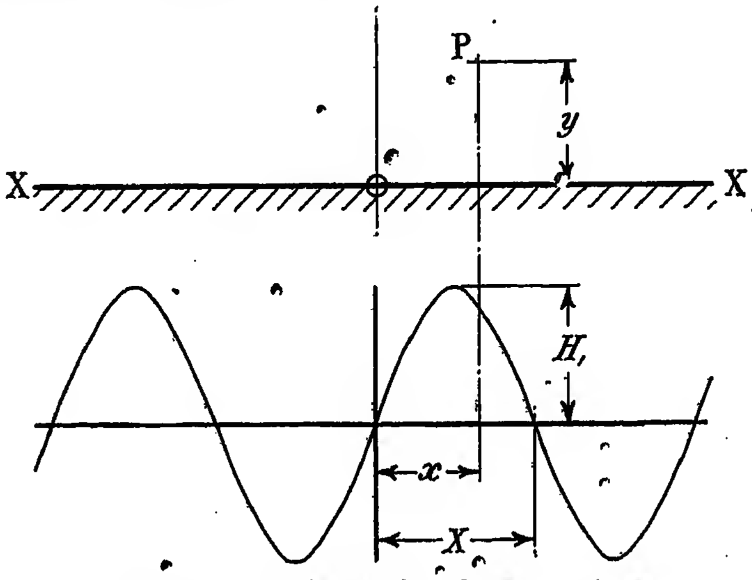

Fig. 1.—Co-ordinates for plane armature.

Inserting the assumed form for Ω in Equation (2*a*) gives

$$\frac{d^2Y}{dy^2} = p^2 Y$$

the solution of which is

$$Y = A\epsilon^{py} + B\epsilon^{-py}$$

A and B being constants. Hence

$$\Omega = H_1(A\epsilon^{py} + B\epsilon^{-py}) \sin px \quad . \quad . \quad (3)$$

Differentiating Equation (3) with respect to y and then making $y = 0$ gives

$$\left(-\frac{\partial\Omega}{\partial y}\right)_{y=0} = -H_1 p(A - B)\sin px = H_1 \sin\frac{\pi x}{X}$$

[from Equation (2*b*)]

Comparison of coefficients makes

$$p = \frac{\pi}{X}$$

and
$$p(A - B) = -1$$

whence
$$A = B - \frac{X}{\pi}$$

Next differentiating Equation (3) with regard to x, making $y = 0$, and comparing with Equation (2*c*), gives, on insertion of $p = \pi/X$ and $A = B - (X/\pi)$,

$$\frac{\pi}{H_1 X}\left(2B - \frac{X}{\pi}\right)\cos\frac{\pi x}{X} = 0$$

From this and the preceding relation,

$$A = -\frac{X}{2\pi} \quad \text{and} \quad B = \frac{X}{2\pi}$$

Finally, putting these values of A and B in Equation (3), we get

$$\Omega = -H_1\frac{X}{\pi}\sin\frac{\pi x}{X}\sinh\frac{\pi y}{X} \quad . \quad . \quad . \quad (4)$$

Natural equipotentials and lines of force.—On an equipotential Ω is constant; writing $C = -\pi\Omega/H_1X$ as a parameter, we get

$$\sin\frac{\pi x}{X}\sinh\frac{\pi y}{X} = C \quad . \quad . \quad . \quad . \quad (5a)$$

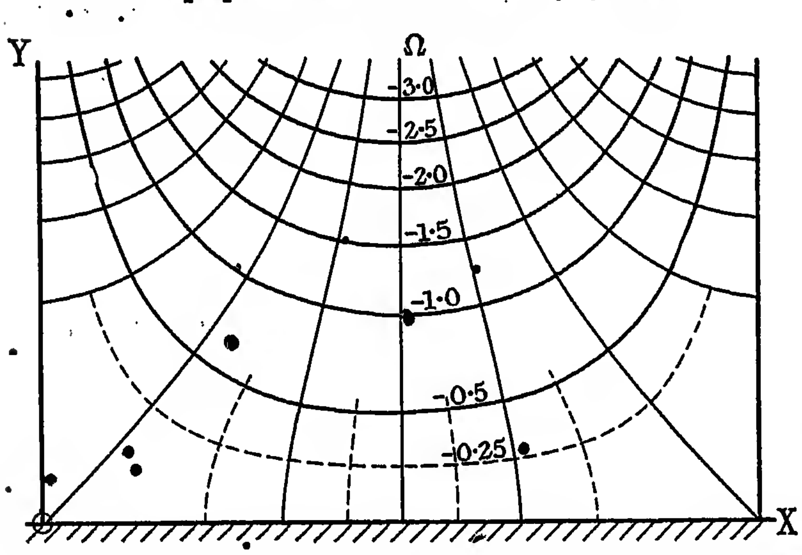

Fig. 2.—Equipotentials and lines of force near plane armature plotted from Equations (5*a*) and (5*b*).

as the equation to the equipotentials natural to the sinusoidal field distribution. These are plotted from $x = 0$ to $x = X$ in Fig. 2 for various positive values of C, i.e. for negative values of Ω.* The equipotentials facing this portion of the plane armature are thus south poles, as is otherwise obvious when it is remembered that flux is leaving the armature (H positive) between 0 and X.

From Equation (5*a*) we obtain by differentiation

$$\frac{dy}{dx} = -\tanh\frac{\pi y}{X}\cot\frac{\pi x}{X}$$

The lines of force cut the equipotentials at right angles, so that the slope on them must satisfy the equation

$$\frac{dx}{dy} = \tanh\frac{\pi y}{X}\cot\frac{\pi x}{X}$$

which on integration gives

$$\cos\frac{\pi x}{X}\cosh\frac{\pi y}{X} = D \quad . \quad . \quad . \quad . \quad (5b)$$

as the equation to the lines of force, D being a parameter. These are also plotted in Fig. 2.

Shape of pole-shoes.—In Fig. 2 the ordinates through the points 0 and $\frac{1}{2}X$ are axes of symmetry. Choosing a definite numerical value equal to C, let the equipotential surfaces given by Equation (5*a*) be traced for $+ C$, giving south poles, and for $- C$, giving north poles. This is done in Fig. 3. It is now clear that a system of alternate north and south poles having the shapes of these equipotential surfaces and having magnetic potentials determined by $\mp C$ will give rise to a sinusoidal field along the armature surface XOX.

It is obvious from the shape of these poles that the leakage between successive north and south poles will be infinitely great and that there is, moreover, no provision for a magnetizing coil to maintain the poles at their appropriate potentials. These objections and their practical significance will be referred to later in dealing with the more important case of a machine with a circular armature core.

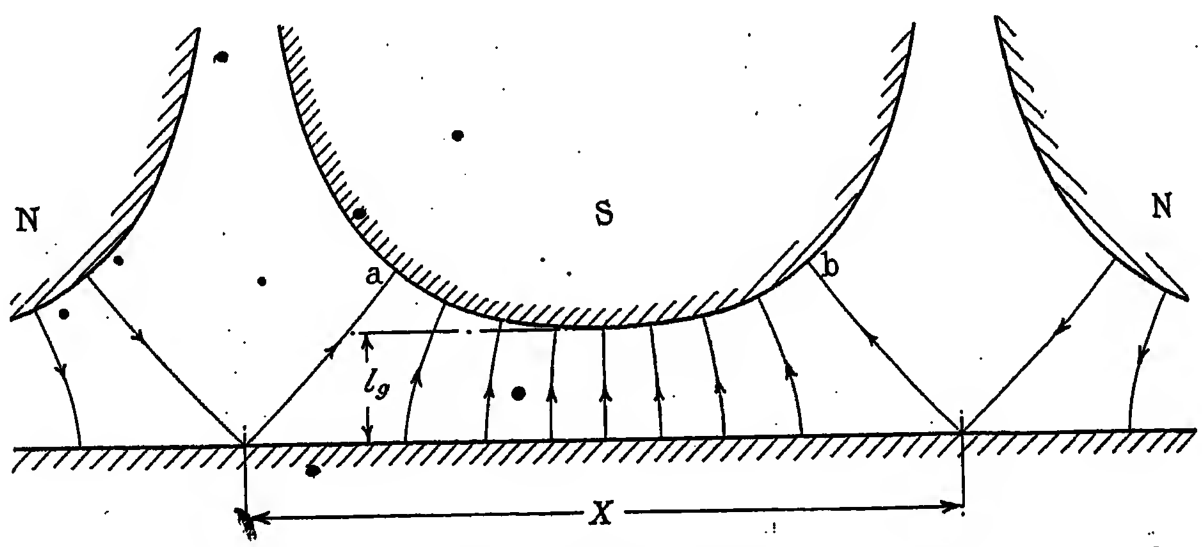

Fig. 3.—Pole-shoe form required to produce sinusoidal flux distribution on the surface of a plane armature. Useful arc of pole is "ab."

Permeance.—Assuming the poles to have the ideal shape indicated in Fig. 3, it is of interest to examine the permeance of the air-gap field, this being emitted by the arc "ab" of the pole.

Since the field at the armature face is given by $H = H_1 \sin(\pi x/X)$, the flux per pole is

$$F = \int_0^X H dx = \frac{2}{\pi}XH_1 \text{ per cm axial length}$$

* For a similar diagram see R. Rüdenberg: "Über die Verteilung der magnetischen Induktion in Dynamoankern und die Berechnung von Hysterese- und Wirbelstromverlusten," *Elektrotechnische Zeitschrift*, 1906, vol. 27, p. 109. The matter is also dealt with by F. Emde: "Sinusrelief und Tangensrelief in der Elektrotechnik" (1924), p. 93.

Let the chosen equipotential pass through a point of which the co-ordinates are $(\frac{1}{2}X, l_g)$; then from Equation (5a) the appropriate value of the potential of the shoe will be given numerically by $(H_1X/\pi)\sinh(\pi l_g/X) = \Omega'$ say. Then if α = least gap length/pole-pitch $= l_g/X$, the permeance of the gap field per unit axial length is

$$\mathbf{P} = \frac{F}{\Omega'} = \frac{2}{\sinh \alpha\pi} \quad . \quad . \quad . \quad . \quad (6)$$

which is plotted in Fig. 4.

It is important to compare the permeance given by Equation (6) with that calculated by Carter * for a

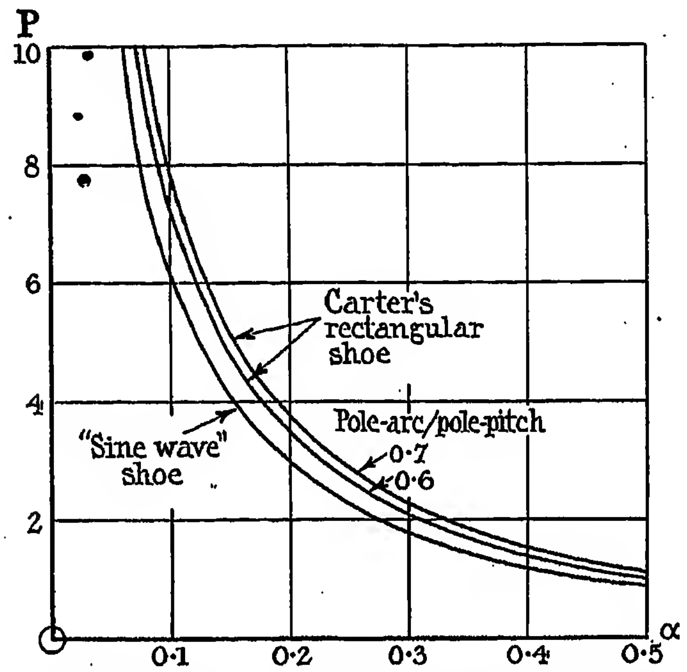

FIG. 4.—Permeance of air-gap between pole and armature. The ordinate gives **P**, the permeance per pole for 1 cm axial length; the abscissa is the ratio α = least gap length/pole-pitch.

plane armature opposite which is placed a system of alternate north and south poles with infinitely deep rectangular shoes. Carter shows that the permeance may be expressed as

$$\mathbf{P} = \frac{b}{l_g} + 2\lambda$$

where b is the pole-arc,

l_g the gap length, and

$$\lambda = \frac{2}{\pi}\left[\frac{c}{l_g}\arctan\frac{l_g}{c} + \frac{1}{2}\log_e\left\{\frac{1}{4}\left(1+\frac{c^2}{l_g^2}\right)\right\}\right]$$

in which $c = \frac{1}{2}(X - b)$. This expression for the permeance has been plotted for comparison in Fig. 4 for two values of pole-arc/pole-pitch, corresponding to certain proportions of pole used in practice. The designer will see that the adoption of the "sine-wave" shoe only results in a small loss of permeance when compared with a "rectangular" shoe having the usual practical ratio of arc to pitch.

ARMATURE WITH CIRCULAR SURFACE.

Attention will now be directed to the solution of the more practical problem in which the surface of the armature is a right circular cylinder, represented by the circle of radius a in Fig. 5. Let the circle be at zero magnetic potential so that the magnetic field is normal to it and can be represented by

$$H = H_1 \sin p\theta \quad . \quad . \quad . \quad . \quad . \quad (7)$$

p being the number of pairs of poles in the machine.

The magnetic potential at a point P at which the polar co-ordinates are (r, θ) must satisfy Laplace's equation expressed in cylindrical polars, namely

$$\frac{\partial^2\Omega}{\partial r^2} + \frac{1}{r}\cdot\frac{\partial\Omega}{\partial r} + \frac{1}{r^2}\cdot\frac{\partial^2\Omega}{\partial\theta^2} = 0 \quad . \quad . \quad . \quad (8a)$$

In addition, Ω must be such that the normal component of field on the circle $r = a$ is the given value of H and the tangential component is zero; that is

$$\left(-\frac{\partial\Omega}{\partial r}\right)_{r=a} = H_1 \sin p\theta \quad . \quad . \quad . \quad (8b)$$

and

$$\left(-\frac{1}{r}\cdot\frac{\partial\Omega}{\partial\theta}\right)_{r=a} = 0 \quad . \quad . \quad . \quad . \quad (8c)$$

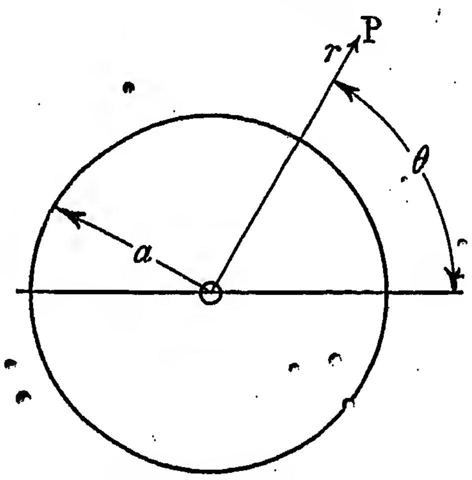

FIG. 5.—Co-ordinates for circular cylindrical armature.

To solve Equation (8a), assume that the form of Ω is

$$\Omega = R \sin n\theta$$

where R is a function of r only and n is a coefficient. Then substitution in Equation (8a) yields

$$r^2\frac{d^2R}{dr^2} + r\frac{dR}{dr} - n^2R = 0$$

This equation is of the homogeneous form, the trial solution of which is $R = r^m$. Inserting this gives

$$m^2 - n^2 = 0,$$

or

$$m = \pm n$$

Thus the value of R is

$$R = Ar^n + Br^{-n}$$

A and B being constants to be found. Hence

$$\Omega = (Ar^n + Br^{-n})\sin n\theta \quad . \quad . \quad . \quad (9)$$

Differentiating Equation (9) with respect to r, making $r = a$ and comparing with Equation (8b), gives

$$\left(-\frac{\partial\Omega}{\partial r}\right)_{r=a} = -n(Aa^{n-1} - Ba^{-n-1})\sin n\theta = H_1 \sin p\theta$$

Comparison of coefficients shows that

$$\left.\begin{aligned} n &= p \\ H_1 &= -n(Aa^{n-1} - Ba^{-n-1}) \end{aligned}\right\} \quad . \quad . \quad (10a)$$

* F. W. CARTER: "Note on Air-gap and Interpolar Induction," *Journal I.E.E.*, 1900, vol. 29, p. 925.

Again, differentiating Equation (9) with respect to θ, making $r = a$ and using Equation (8c), we get

$$\left(-\frac{\partial\Omega}{r\partial\Omega}\right)_{r=a} = -n(Aa^{n-1} + Ba^{-n-1})\cos n\theta = 0$$

from which

$$A = -Ba^{-2n} \quad . \quad . \quad . \quad . \quad . \quad (10b)$$

potential Ω is constant; writing $C = -2p\Omega/(H_1a^{p+1})$ as a parameter we get

$$\left(\frac{r^p}{a^{2p}} - \frac{1}{r^p}\right)\sin p\theta = C \quad . \quad . \quad . \quad (12a)$$

as the equation to the natural equipotentials.* These have been plotted in Fig. 6 for two cases, namely when

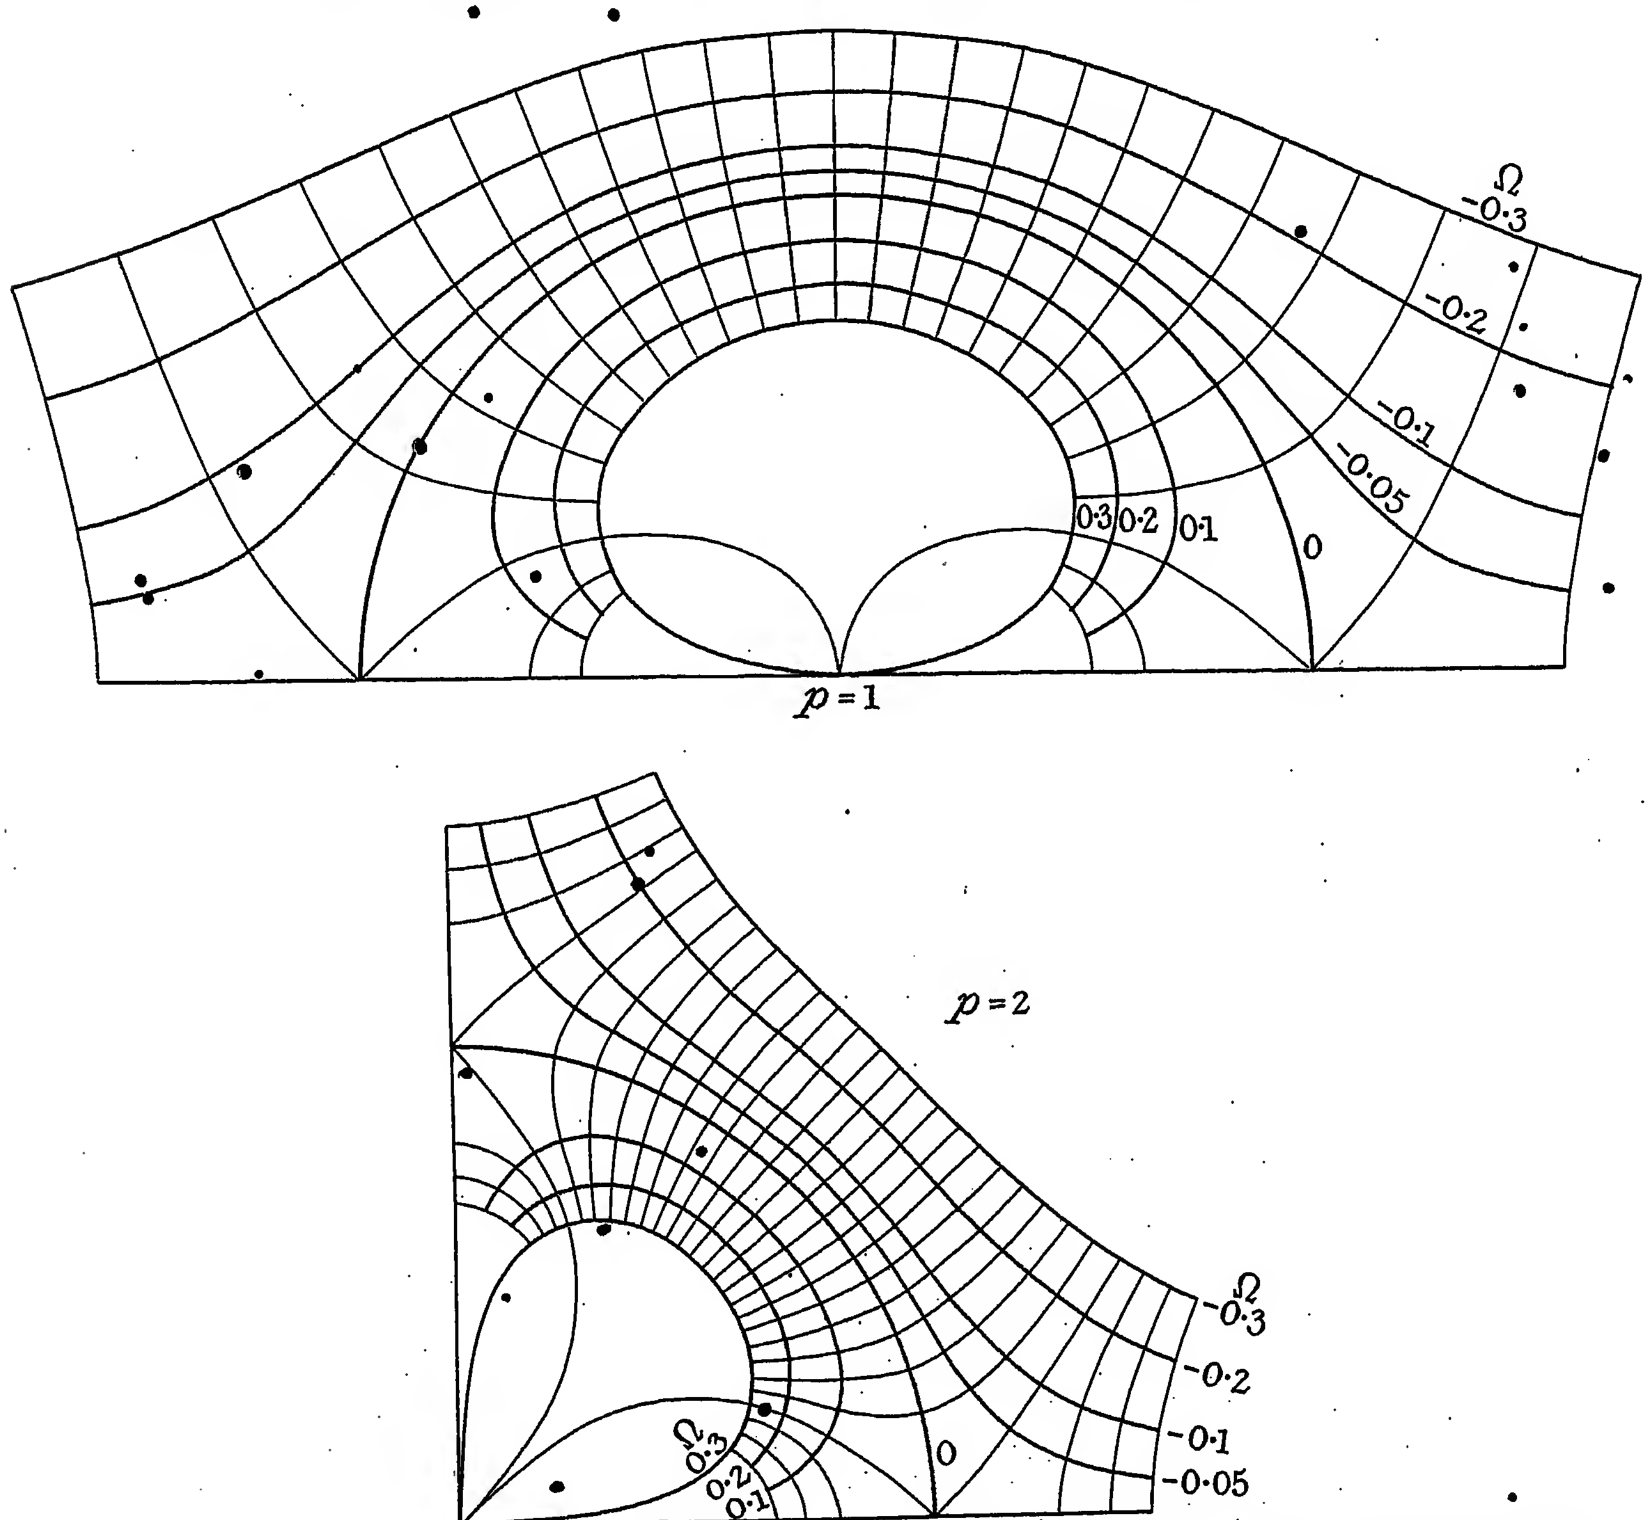

FIG. 6.—Equipotentials and lines of force near circular cylindrical armature plotted from Equations (12a) and (12b) for $p = 1$ and $p = 2$.

Solving Equations (10a) and (10b) makes

$$A = -\frac{H_1}{2p}a^{-p+1} \quad \text{and} \quad B = \frac{H_1}{2p}a^{p+1}$$

which on insertion in Equation (9) gives for the magnetic potential,

$$\Omega = -\frac{H_1a^{p+1}}{2p}\left(\frac{r^p}{a^{2p}} - \frac{1}{r^p}\right)\sin p\theta \quad . \quad . \quad (11)$$

Natural equipotentials and lines of force.—On an equi-

$p = 1$ and $p = 2$. In this diagram it has been assumed that $a = 1$ unit and that $H_1 = 1$. In each case one pole has been drawn; the diagram must be repeated

* The equation to the equipotentials has been given by Dr. J. F. H. DOUGLAS, *Transactions of the American Institute of Electrical Engineers*, 1915, vol. 34, p. 1067, in the case of a two-pole machine. Putting $p = 1$ in Equation (12a) gives $\left(\frac{r}{a^2} - \frac{1}{r}\right)\sin\theta = C$; transforming from polar to rectangular co-ordinates by writing $r^2 = x^2 + y^2$, $\sin\theta = \frac{y}{r}$, $Ca = \frac{y}{a} - \frac{ay}{x^2 + y^2}$ is the equation to the equipotentials in a two-pole machine, as is shown by Dr. Douglas. In the case of multi-polar machines it is simpler to retain the polar form of the expressions.

$2p$ times round the circle, the sign of Ω marked thereon being reversed at each repetition.

Differentiating Equation (12a) gives

$$\frac{d\theta}{dr} = -\frac{r^{2p} + a^{2p}}{r^{2p} - a^{2p}} \times \frac{\tan p\theta}{r}$$

Since the lines of force cut the equipotentials at right

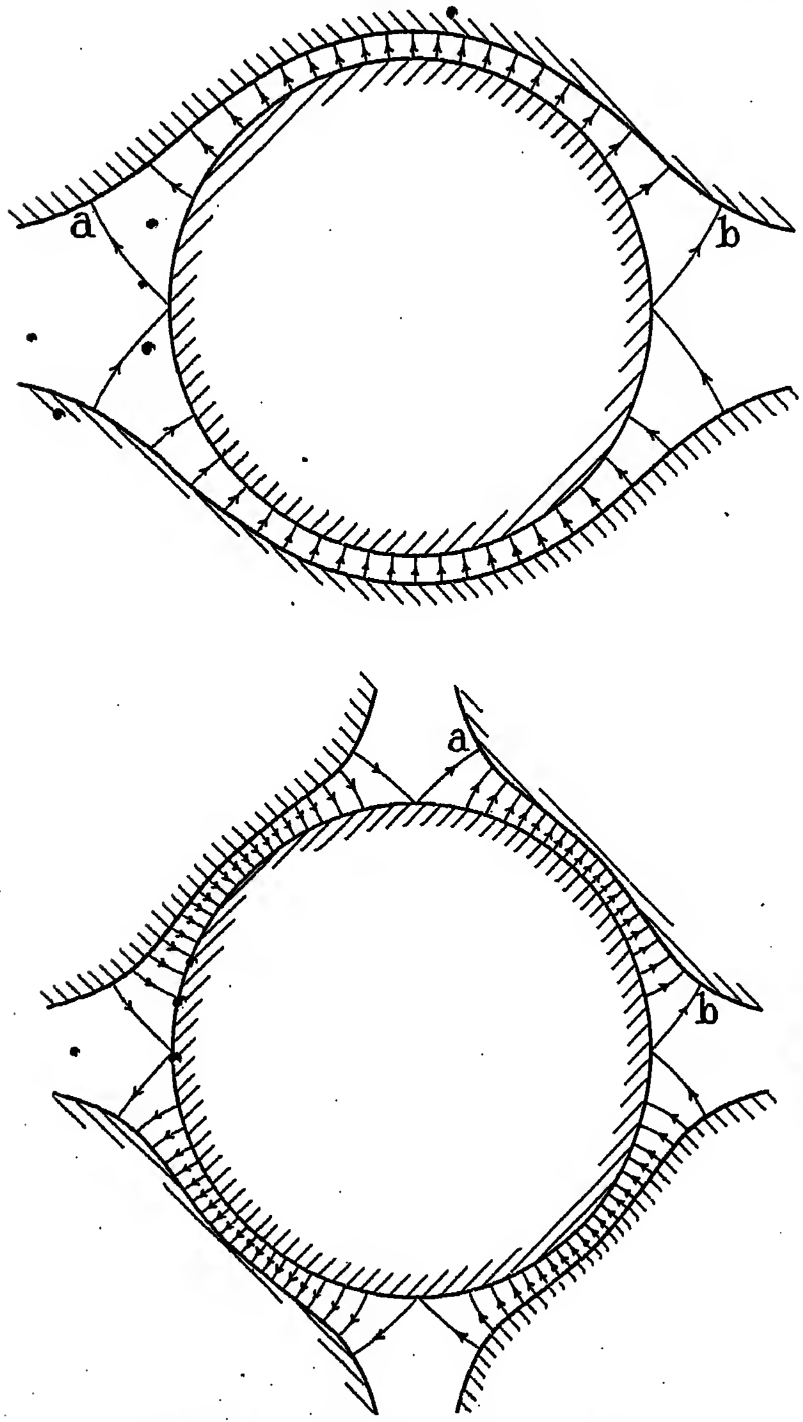

FIG. 7.—Pole-shoe form required to produce sinusoidal flux distribution on the surface of a circular cylindrical armature for two-pole and four-pole, smooth-core machines with external poles. Useful arc of pole is "ab."

angles the slope $d\theta/dr$ on them must satisfy the equation

$$\frac{1}{r^2} \cdot \frac{dr}{d\theta} = \frac{r^{2p} + a^{2p}}{r^{2p} - a^{2p}} \times \frac{\tan p\theta}{r}$$

which on integration gives

$$\left(\frac{r^p}{a^{2p}} + \frac{1}{r^p}\right) \cos p\theta = D \quad . \quad . \quad . \quad (12b)$$

as the equation to the lines of force. These have been plotted in Fig. 6 in such a way that the flux per pole is divided into 20 tubes of force of equal strength.

Shape of pole-shoes.—In the same way as before, the pole-shoes should be chosen to coincide with the equipotential surfaces of alternate south and north polarity defined by $+ C$ and $- C$ in Equation (12a). Typical instances are adapted from Fig. 6 and are shown in Figs. 7 and 8. Fig. 7 shows two-pole and four-pole machines with external poles; Fig. 8, on the other hand, depicts the corresponding internal-pole machines. In both diagrams the gap lines of force are indicated.

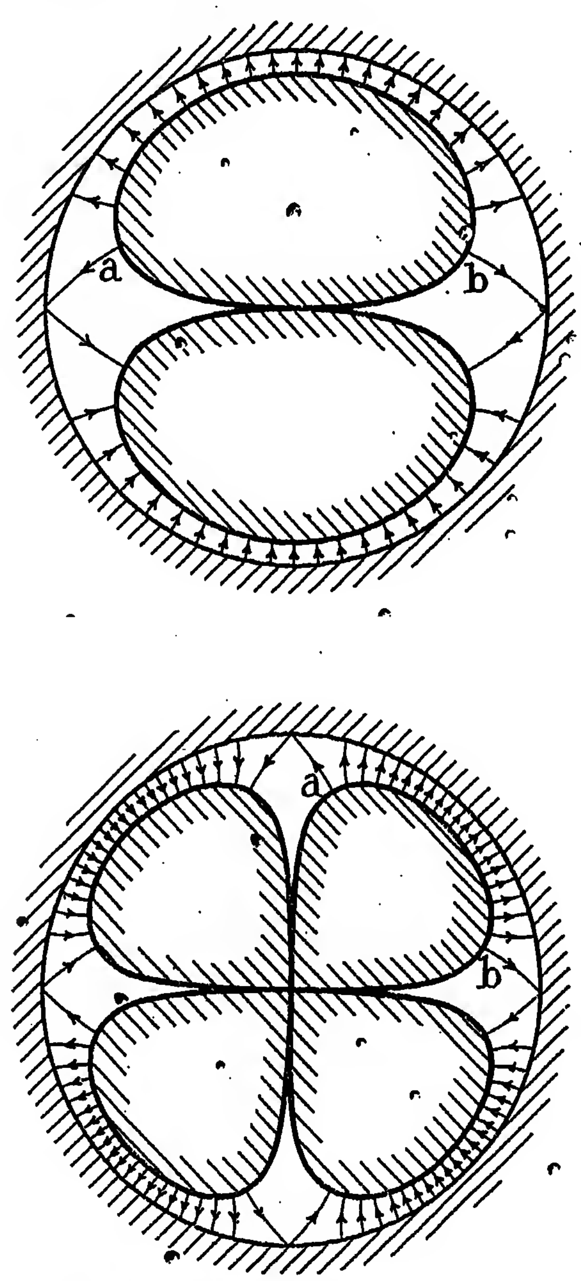

FIG. 8.—Pole-shoe form required to produce sinusoidal flux distribution on the surface of a circular cylindrical armature for two-pole and four-pole, smooth-core machines with internal poles. Useful arc of pole is "ab."

It is interesting at this stage to note an important practical fact. In a sine-wave generator the armature winding is bound upon the surface of the core; hence the conductors lie upon the core at a mean radius greater than a—assuming a machine with external poles. Inspection of Equation (11) shows that $\partial\Omega/\partial r$ is proportional to $\sin p\theta$ for *any* value of r, i.e. on any circle concentric with the core the radial component of the field is still sinusoidally distributed round the

periphery. The conductors will thus still remain in a sinusoidal field even though they are above the core surface. A similar argument and result can easily be seen to apply to the flat-core problem, as an inspection of Equation (4) will show, since $\partial\Omega/\partial y$ is proportional to sin $(\pi x/X)$ for all values of y.

The shapes of poles shown in Figs. 7 and 8 cannot be completely realized in practice, owing to the fact that a practical pole possesses a core upon which a magnetizing coil is wound. This core is provided with a shaped shoe facing the armature. The results of this paper can be very approximately utilized in practice by arranging that the shoe face is cut to fit the arc marked ab of the chosen equipotential. Since the rest of the pole does not coincide with the remainder of the equipotential, the interpolar leakage will be considerably altered, and with it to some extent the distribution of the flux influence of the magnetizing coil and the core of the pole on the distribution of the air-gap flux will be small if the breadth of the core is not great in comparison with that of the shoe. The field in the gap is then screened by the shoe from the stray field of the magnetizing coil and from the effects of the modified interpolar leakage. In these circumstances the results of this paper should apply with a high degree of accuracy, and any remaining discrepancy could be compensated by the artifice shown in Fig. 9 for the case of a two-pole machine. Cut out the pole-shoe to conform to two of the theoretical equipotentials and attach it to a small pole-core in the manner just suggested. Since the iron of the shoe has a high permeability, both surfaces of the shoe will be approximately equipotentials and will not be much influenced by stray fields from the main coil. Now put on the tips of the shoe an auxiliary winding

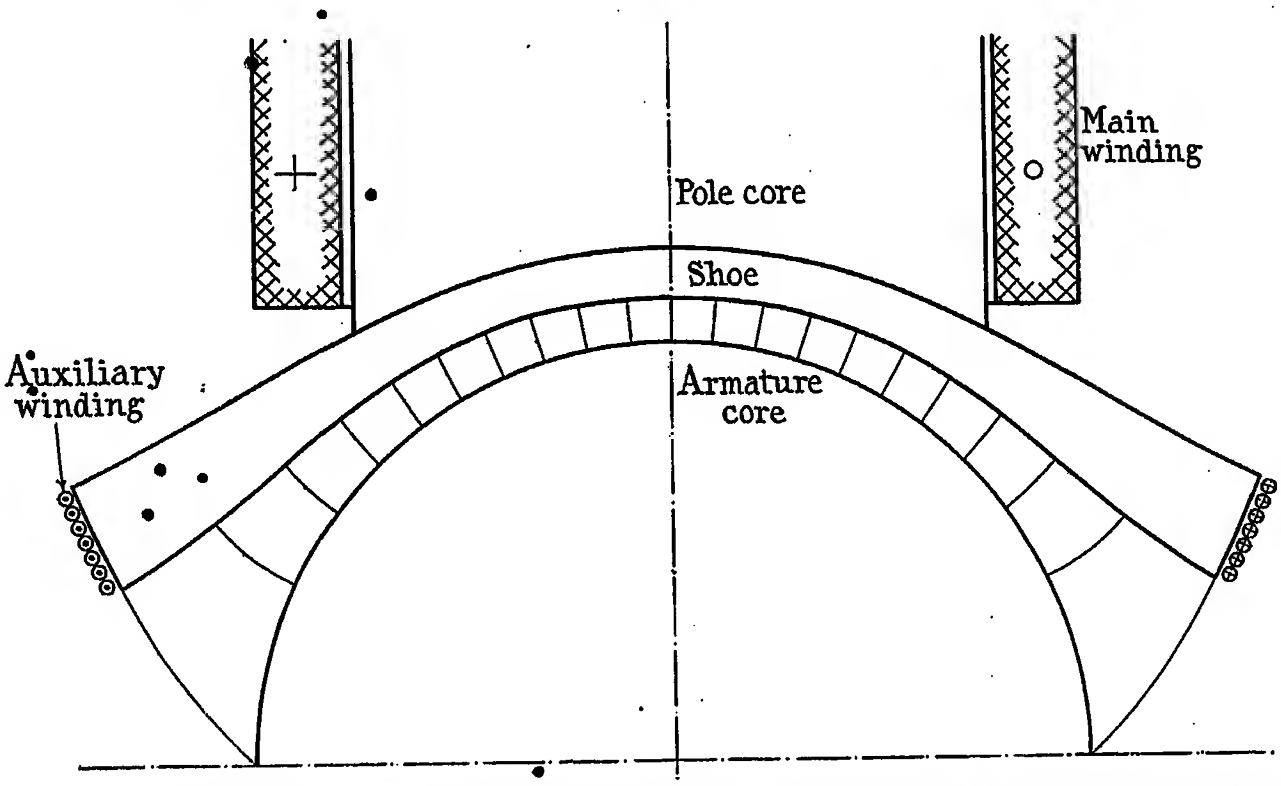

FIG. 9.—Detail of pole-shoe in two-pole machine, showing auxiliary winding arranged to compensate for the effects of the main field winding and the pole-core on the air-gap flux distribution.

which leaves the corners of the shoe. To restore the sinusoidal flux distribution on the armature core the pole-tips would require to be slightly reshaped. The precise amount of shaping could, in any given case, be found by a process of trial and error using any suitable experimental or graphical method.*

Mr. S. Neville has pointed out to the author that the opposing the main winding and such that the drop of magnetic potential along the edge of the shoe is equal to the difference of potential between the chosen equipotentials. This device might be necessary in wave-form standards where absolute purity of flux distribution is desired.

Permeance.—The gap permeance when the shoe has the ideal shape is easily found. Let F be the flux per pole, then

$$F = \int_0^{\pi/p} H a d\theta = H_1 a \int_0^{\pi/p} \sin p\theta d\theta = \frac{2H_1 a}{p}.$$

When $\theta = \pi/(2p)$ and the pole-shoe is formed by the equipotential passing through a point at a radius $r = b$ the numerical value of the potential thereon is, from Equation (11),

$$\Omega' = \frac{H_1 a^{p+1}}{2p}\left(\frac{b^p}{a^{2p}} - \frac{1}{b^p}\right) \doteq \frac{H_1 a}{2p} \cdot \frac{(b^{2p} - a^{2p})}{a^p b^p}.$$

* The Kirchhoff current method is one of the most convenient experimental methods for the purpose. Two electrodes, one shaped to represent the pole-shoe and the other the armature, are clamped upon a sheet of tinfoil and are maintained at a constant difference of potential. The equipotential lines in the sheet correspond to the required magnetic equipotentials, and are easily plotted by means of potential contacts and a galvanometer. The method has been used by Dr. Douglas in the paper cited. Another convenient method makes use of electrodes of appropriate forms immersed in an electrolyte, the equipotential lines being plotted out. This method, apparently originally used by W. G. ADAMS (*Proceedings of the Royal Society*, 1875, vol. 23, p. 280) has been employed by a number of investigators in Germany and America; it has recently been employed by A. A. AHMED (*Journal I.E.E.*, 1924, vol. 62, p. 801) with considerable improvements and has been put on a sound experimental basis as a result of his work.

The best graphical process is that of Richardson. This depends on the fact that the lines of force and the equipotentials in the space between given bounding surfaces divide up that space into a series of curvilinear squares. These can be sketched in freehand and the shape of each adjusted by eye until correct, using a process of trial and error. The method is much used by German and other Continental designers and writers, who always refer to it as Lehmann's method.

The permeance per unit axial length is thus

$$\mathbf{P} = \frac{F}{\Omega'} = \frac{4a^p b^p}{(b^{2p} - a^{2p})} = \frac{4a^p b^p}{(b^p - a^p)(b^p + a^p)}$$

The minimum air-gap is $b - a$; if $b > a$ the machine has external poles, if $b < a$ the poles are internal. This result can be put into a more convenient form; let β = radius at pole-centre/radius of armature $= b/a$, then

$$\mathbf{P} = \frac{4\beta^p}{(1 + \beta^p)(1 - \beta^p)} \text{ numerically} \quad . \quad (13)$$

from which the shape of the pole-face in any given case can be approximately found. To illustrate this the following numerical example will be of service. Take the case of a two-pole, smooth-core, sine-wave alternator with external poles, the radius of the armature core being $a = 15$ cm. If the minimum length of the air-gap be 1 cm, the radius to the pole-centre will be $b = 16$ cm. Let the maximum flux density be $H_1 = 6\,000$ lines per cm^2, so that the flux per pole for 1 cm axial length is

$$2H_1 a = 2 \times 6\,000 \times 15 = 180 \text{ kilolines.}$$

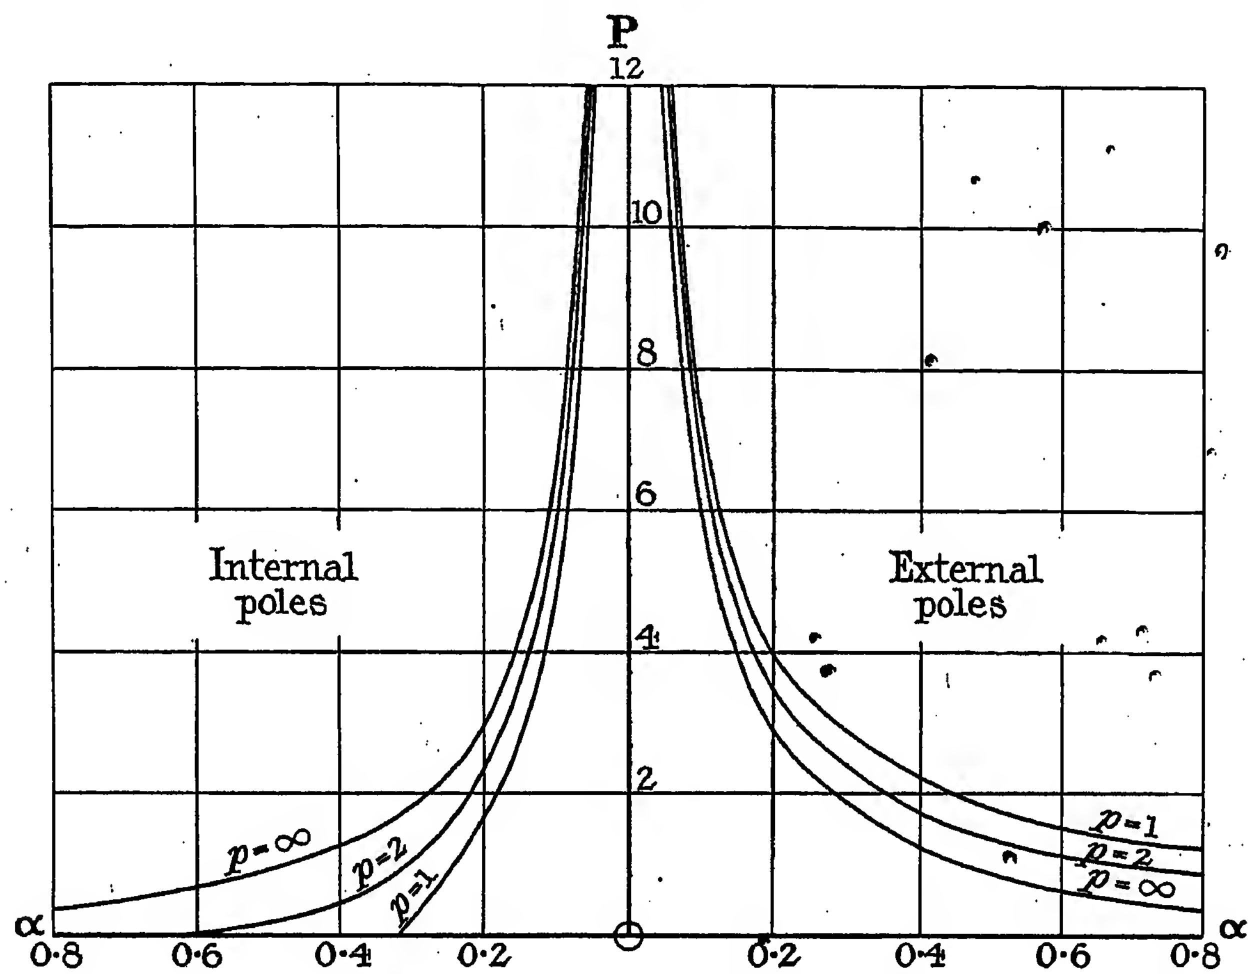

FIG. 10.—Permeance of air-gap between pole and armature. The ordinate gives P, the numerical value of the permeance per pole for 1 cm axial length; the abscissa is the ratio α = least gap length/pole-pitch, the latter being measured at the armature surface.

By a simple change of variable these results can be compared with the permeance curve for a flat armature. Thus

$$\frac{p}{\pi}(\beta - 1) = \frac{p}{\pi}\left(\frac{b}{a} - 1\right) = \frac{(b-a)}{\pi a/p} = \frac{\text{minimum gap}}{\text{pole-pitch}} = \alpha$$

Equation (13) is plotted in Fig. 10 to a base of α, the curve of Fig. 4 for a flat armature being included for comparison. It will be seen that multipolar machines tend to approximate closely to the result found for a flat armature.

CONCLUSION.

The formulæ developed in the paper and the curves plotted therefrom will provide the designer with data

Referring to Equation (11) and putting $p = 1$, $r = b$, $\theta = \frac{1}{2}\pi$ gives for the potential of the shoe

$$\Omega' = \frac{H_1}{2b}(b-a)(b+a) = \frac{6\,000}{2 \times 16} \times 1 \times 31$$
$$= 5\,810 \text{ C.G.S. units.}$$

Inserting this value in Equation (12*a*) makes

$$C = -\frac{2\Omega'}{H_1 a^2} = -\frac{2 \times 5\,810}{6\,000 \times 15^2} = -0{\cdot}0086$$

so that the equation to the pole-face is

$$\left(\frac{r}{225} - \frac{1}{r}\right)\sin\theta = -0{\cdot}0086$$

in which $r > 16$. By choosing values of r, θ can readily

be calculated and the curve set out on polar co-ordinate paper. To determine the useful arc of the curve—the arc "ab" of Fig. 7—it is necessary also to set out the critical line of force emanating from the armature surface at the point $r = a$, $\theta = 0$. Putting this in Equation (12*b*) gives $D = 2/a$, so that the equation to the critical line limiting the arc is

$$(225 + r^2) \cos \theta = 30r.$$

The ampere-turns required for the gap are

$$\Omega'/0 \cdot 4\pi = 5\,810/0 \cdot 4\pi = 4\,640$$

and the permeance per cm axial length is

$$\mathbf{P} = 180\,000/5\,810 = 31.$$

In conclusion the author wishes to thank Professor G. W. O. Howe and Mr. S. Neville for their valuable advice and criticisms during the preparation of the paper.

SOME NOTES ON INSULATING PAPERS.

By A. I. MACNAUGHTON, B.Sc., STUDENT.

(ABSTRACT *of paper read before the Scottish Students' Section, 14th December*, 1923.)

INTRODUCTION.

During recent years considerable attention has been given to insulating papers, and the author hopes that the following notes may prove of value, as no clear appreciation of the possibilities and limitations of such papers can be obtained without a knowledge of what paper is and how it is made.

Paper is usually defined to be " a deposit of vegetable fibres from aqueous suspension," and these fibres belong to one or other of chemical groups known as " cellulose."

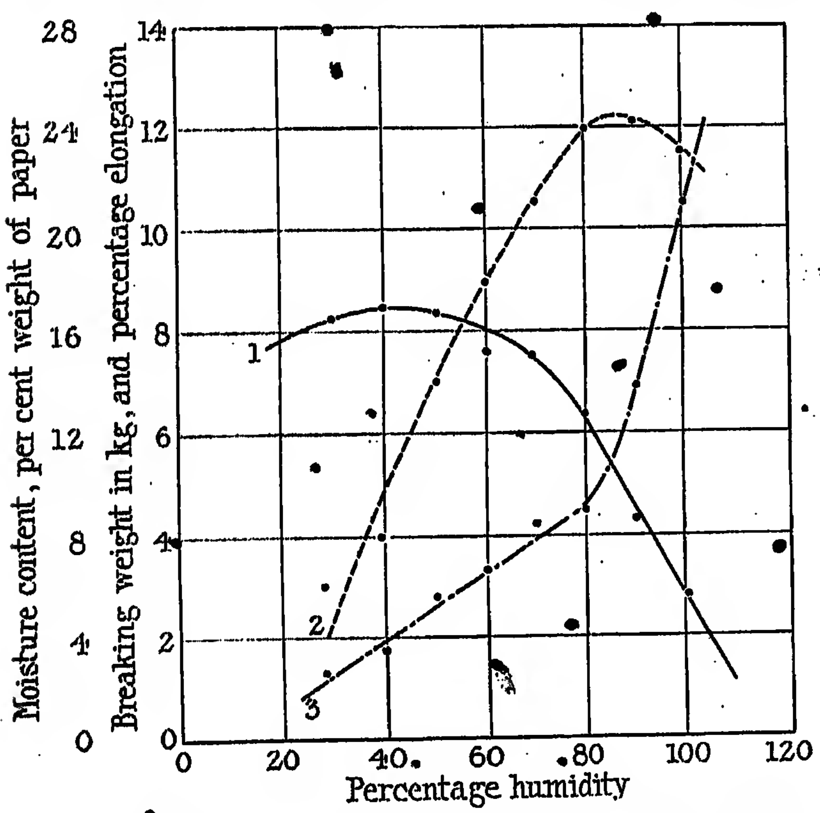

FIG. 1.—Relation between humidity, moisture and strength.

Only two celluloses are considered here: (*a*) Normal cellulose, which is contained in cotton, linen and hemp, and (*b*) cellulose obtained from other vegetable origins, which is more highly oxidized than that already referred to. There are many forms of this latter class, but the exact constitutional differences are not understood, though, proportional to their degree of oxidation, they are more liable to attacks from acids and atmospheric conditions. Another property common to all types of cellulcse is "water of condition," and this varies for each cellulcse. This water content varies directly as the humidity for any constant temperature, and it greatly affects the tensile strength (see Fig. 1).

MANUFACTURE OF PAPER.

In the preliminary treatment all impurities have to be removed from the raw material, which may be rags, jute bagging, old manilla ropes, etc. They are picked

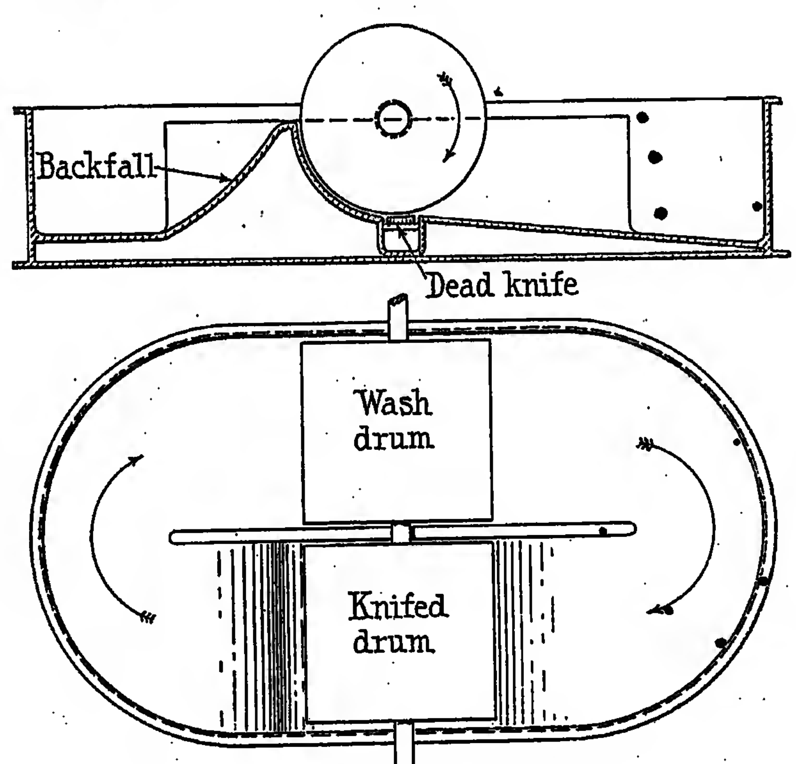

FIG. 2.—Diagram of hollander.

by hand to remove all pieces of metal, etc., after which the material is dusted and partially disintegrated by cutting in special machines. After this treatment it is passed into large rotating boilers where it is boiled with an alkaline solution for a period of about 6–10 hours under a steam pressure of 10–60 lb./sq. in.

Wood pulps are prepared in the same way, i.e. the

"soda" and "sulphate" group of pulps are prepared by digesting the wood with an alkaline lye of caustic soda, and the "sulphite" pulps by boiling with an acid solution of hydrogen sulphites of calcium or magnesium, the difference being that while in the former group the resin is unaffected, in the latter it is dissolved.

When the wood—or rags, as the case may be—is completely digested, the liquor is run off and the pulp washed with a copious supply of water.

After this preliminary treatment the pulp has to be resolved into its elementary fibres, and the fibres themselves cut to lengths of from 4 to 1·5 mm. This is carried out in a "breaker" or "hollander" (Fig. 2), which consists essentially of an oval trough containing two revolving drums, one on either side. One drum is fitted with longitudinal blades which cut the fibres to their desired length, while the other, a framework covered with fine wire cloth, carries off the dirty water, clean water being added to the trough until the pulp, or "half-stuff," is thoroughly cleaned. The "half-stuff" is then fed into the "beater," which is similar to a "breaker" except that it has no wash drum. Here the fibres are again cut or bruised and fibrillated, according to whether absorbent or non-absorbent paper is required. When the fibres are bruised they become coated with a slimy hydrated cellulose film. Non-absorbent paper is stronger than absorbent paper. To make the paper thoroughly non-absorbent, size must be added. This is prepared by treating melted resin with sodium carbonate and then diluting with water, the resulting solution being added to the beater. The addition of alum again precipitates the resin, which forms a coating on the paper, making it waterproof.

Paper Machine.

The only paper machine described by the author is the "Fourdrinier" paper machine.

After the pulp leaves the beaters it is led into the store tank or "stuff-chest," from which it is pumped continuously, through sand traps and strainers, until it is fed evenly on to the whole width of an endless band of wire gauze. The consistency at this point is about 1 per cent (i.e. 1 lb. of dry pulp to 99 lb. of water). The wire gauze is supported on suitable rollers and moves forward in a horizontal plane (Fig. 3), the pulp being prevented from overflowing by means of a pair of endless rubber belts which rest on, and run with, the wire. The water separates from the pulp by dropping through the wire gauze, this action being accelerated by suction boxes over which the wire is passed. The pulp, which is now wet paper, is further dried by passing between heavy rollers. The paper web, supported on an endless band of felt, is passed through two or more sets of press rollers, and then through a series of steam-heated drying cylinders, the web being maintained by the felt in close contact with the cylinders.

Thus stated, the action of the "Fourdrinier," machine is quite simple, but in practice it presents some difficulties. First, the whole wire belt has imparted to it a lateral motion termed the "shake" in order to assist to "felt" the sheet together. This shake, as it plays a very important part in determining the strength of the finished product, must be controllable both as regards frequency and travel. Secondly, the paper shrinks as it dries on being passed over the drying cylinders, and so the drying cylinders must be run at a progressively lower speed as the paper proceeds down the machine. This variation in speed must also be controllable since different papers shrink according to the materials used in their manufacture.

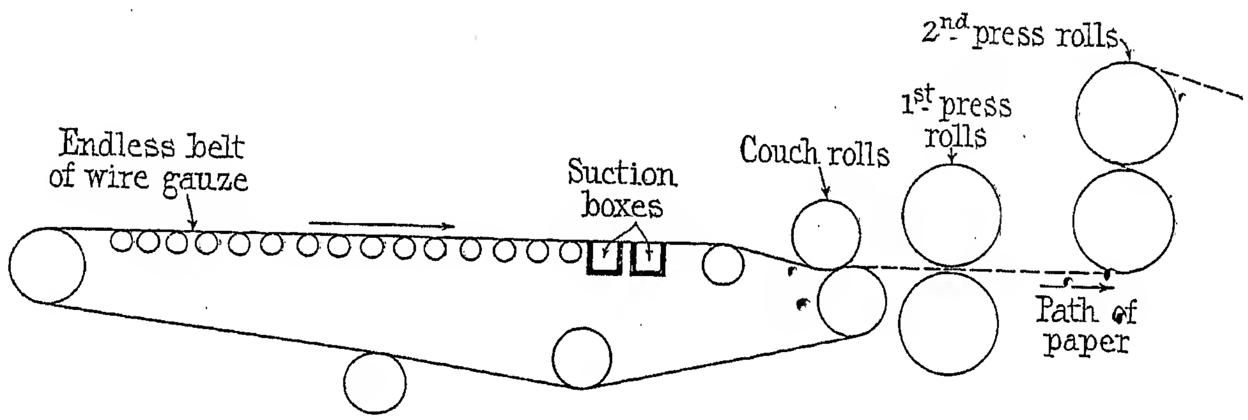

Fig. 3.—Line diagram of paper machine wire.

No matter how the pulp is cleaned, certain impurities are always present in paper. In the original paper a list of these impurities, which include (1) free acids, (2) sulphur, and (3) metals, was given, their effect on the quality of the paper was stated, and the methods used to detect and eliminate them were detailed. In addition, the physical tests to which paper can be submitted were given and described. These include: (*a*) Thickness, (*b*) tensile strength, (*c*) bursting strength, (*d*) folding, (*e*) pinholes, and (*f*) porosity. These tests are all carried out in accordance with the specification of the Electrical Research Association.

Insulating Papers.

(*a*) *General.*—For papers used for the insulation of machine slots, bolt-holes in yokes or to form cores for coil windings in transformers, where the electrical pressures between adjacent conductors are not large, mechanical strength is the determining factor, and papers made from sulphite wood pulp, and glazed, are found satisfactory. Tissue papers used for condensers must be free from pinholes and are usually made from linen

rags which are grass bleached, i.e. bleached by the sun and atmosphere.

(b) *Cable papers.*—Papers for insulating cables must be very pure, both chemically and physically, free from all metallic inclusions, and must also be able to absorb varnish, a fact which may diminish their strength. Owing to the excessive cost of manilla ropes, "composite papers" are sometimes used for this purpose and are compositions of several types of varnishes were given in the original paper.

DRY-CORE CABLES FOR TELEPHONE WORK.

These are insulated with unimpregnated paper made from manilla. In the original paper a list of clauses in the suggested Research Association type of specification

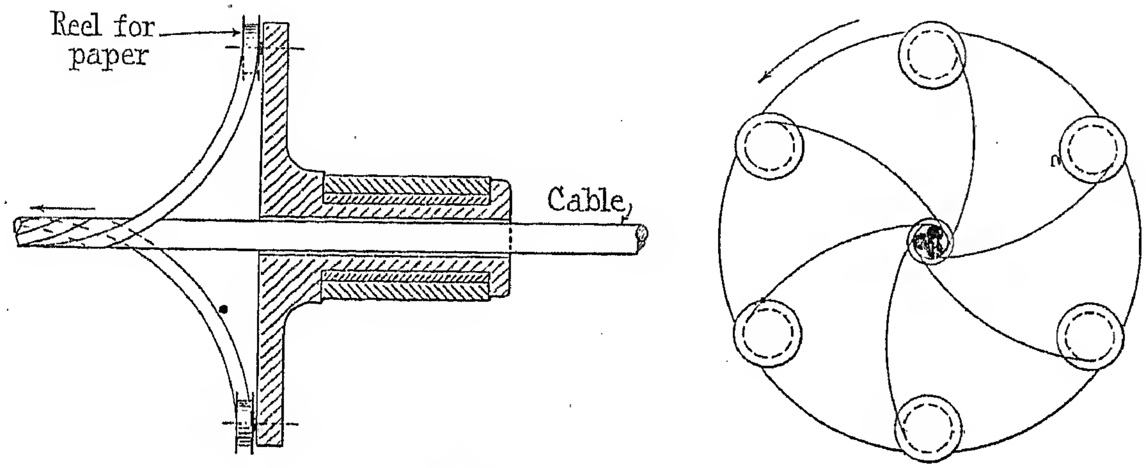

FIG. 4.—Cable-winding cage.

made from jute and soda wood. The paper is laid on to the cable by means of a "cage." This carries the paper reels (see Fig. 4), and as it revolves it wraps the paper around the cable. The cable is dried under vacuum at about 275° F. for 12–30 hours, and is then impregnated at 240° F. with varnish for 4–30 hours, after which it is led direct to the bitumen forcing machine. The

was set out. This specification is given in the *Journal* (1923, vol. 61, p. 982), and embodies the following clauses: Condition, Thickness, Density, Tensile Strength, Bursting Test, Tearing Test, Porosity, Absorption Test, Moisture Loss, Acidity and Alkalinity, Mineral Ash Test, Resinous Material, Nitrogenous Material, Metallic Particles, Flash Test and Microscopical Examination.

ELECTRIFICATION SCHEMES IN RUSSIA.

By B. L. METCALF and O. MORDUCH, Students.

(ABSTRACT *of paper read before the* NORTH-WESTERN STUDENTS' SECTION, *25th February*, 1924.)

SUMMARY.

The importance of foreign markets for the electrical industry of Great Britain and the characteristics of Russia as a prospective market for electrical goods are discussed, a brief account being given of general Russian economics.

The possibilities of electrification in Russia, and projects of various electrification schemes are then described, and an outline of results achieved and work done is included.

1. INTRODUCTION.

The future of the electrical industry in Great Britain is becoming increasingly dependent upon its export trade. It is important, therefore, that all engineers, even though they may belong to a purely technical branch of their profession, should take a broader, more open-minded, view of the problems facing their industry. The beneficial results to be obtained from research departments are now fully recognized by most of the big manufacturing concerns in this country, but in these research departments the amount of time devoted to commercial research is disproportionately small. The British electrical industry, although comparatively young, has gained an honourable place among the electrical industries of other countries, and can now safely compete anywhere with regard to the quality and wide range of its products, but the problem is how to find a regular demand for these products, a demand which will maintain the industry in a healthy state and in addition help it to expand and develop. The needs of the home market are insufficient, consequently a voluminous and permanent export trade must be built up—and this as energetically as possible if the good start that has been made is not to be lost. In line with these special considerations there is the national problem of widespread unemployment which calls for the earnest attention of all sections of the community. The need for commercial research, therefore, to discover and develop new markets, and to assist in the disposal of finished products, seems to be a very urgent one and worthy of more active attention than it has received up to the present. Due recognition must be given to the good work that has been, and is being, done in connection with Empire development, and to the attempt to create a single self-supporting unit out of the British Empire; but the results so far obtained in this direction have been inadequate, and the depression at home is still very acute. The indication is that the trade of Great Britain must continue to be world-wide and must not limit itself to any one particular region.

2. SEARCH FOR NEW MARKETS.

To attempt to find a new field for commercial development, the guiding factors are:—

(1) Large natural resources.
(2) Accessibility of these resources.
(3) Political or legal, and physical considerations.
(4) Backward state of development.

Keeping these ideas in mind, the country which presents itself most forcibly and which appears to satisfy the above considerations to a marked degree is Russia. Russia is the largest potential market in Europe, possessing enormous mineral and agricultural wealth. Yet it is practically undeveloped, as may be seen from Fig. 1. The shaded area represents the

Regions at present commercially developed.
Regions capable of development, but as yet undeveloped.

FIG. 1.

regions as yet undeveloped, but capable of development, and is seen to cover practically the whole of Russia, with the exception of a small industrial area in the extreme west, and a narrow belt following the route of the Siberian Railway. The extreme north and the plains of Siberia are incapable of development at present.

3. STATE OF ELECTRICAL INDUSTRY AND DEVELOPMENT IN 1914.

The following works existed in Russia in 1914:—

A. *Electrical machinery.**—Russian Dynamo Co.'s works in Moscow, employing 1 000 hands. Volta works in Reval, employing about 500 hands. A.E.G. (Russian) works in Riga, employing over 1 000 hands.

* The manufacture of electrical machinery in Russia was not sufficient to cover the requirements of the home market, over 60 per cent of this having to be imported from abroad. The output of the above works for 1913 was—besides other electrical machinery—14 300 dynamos and motors, with a total power capacity of 311 000 kW, making an average of about 22 kW. In the case of cable production, practically all the needs of the Russian market were covered by the output of the works named.

Siemens-Schuckert works in Petrograd, employing about 1 000 hands.

B. *Cable works.*—Union Cable works in Petrograd. Kolchooghno Cable works north of Moscow. Russian Cable and Rolling Mill Co. in Moscow (associated with the Russian Dynamo Co. and the B.T.H. Co. in England). Shamshin and Alexieff in Moscow.

C. *Power supply.*—The power supply in Russia before the war was in a very unsatisfactory state, the demand being met chiefly by a number of small stations which were for the most part privately owned.

D. *Industrial application.*—Electricity was not employed to a great extent in the Russian factories. Only some of the larger works had their machinery electrically driven, but even in these works the electric drive was far from being universally adopted.

4. Erection of New Power Stations.

The main idea underlying the plan for erection of these stations is their development parallel to the

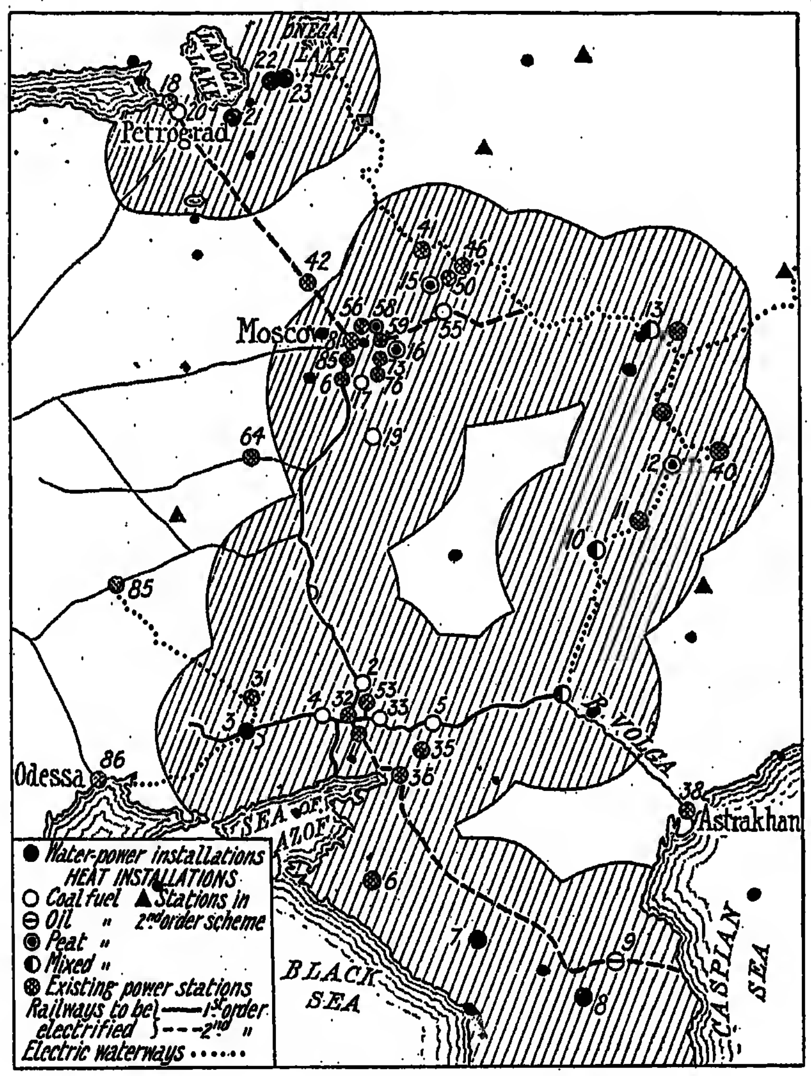

Fig. 2.—Electrification of Russia.

growth of the load. The electric load on the power stations has been steadily increasing since 1919–20, when it reached its minimum. At present the lighting load, having almost reached (on the average) its pre-war magnitude, will henceforth continue to grow rather slowly. On the other hand, the power load is as yet very much below its pre-war value, but is increasing and is expected to continue to grow rather rapidly. Accordingly, the stations are designed to deal with these existing and prospective loads. The shaded part of Fig. 2 represents the area within which the stations are to be erected. It will be seen from this map that Siberia has been left out of this scheme altogether, but that the electrification of European Russia is planned on a fairly extensive scale. The aggregate power capacity of these stations is under 2 000 000 kW, which is a comparatively modest figure, particularly so, if it is remembered that this aggregate will be reached only towards 1935. The whole of the electrification work will be divided into districts, viz. Petrograd, Moscow (Central Industrial), South-West, Ural, Caucasus, Donec Basin, Volga and Turkestan.

The following are some of the stations to be erected:—

A. *Hydro-electric stations.*

Volchov.—The ultimate capacity of this station is to be 200 000 h.p.

Svir.—Three power stations are to be erected, of a total capacity of 500 000 h.p.

Dneipr.—The maximum output of the proposed Dneipr station is to be 330 000 kW.

Water-power stations in Turkestan.—A 7 500-kW station at Troizkoe and a 27 000-kW station on the River Tchirtchik.

Ural.—(*a*) Tchoosavaia, 4 280 000 h.p. available.
(*b*) A canal contemplated between the Rivers Kama and Tobol would furnish a considerable amount of water power in the locks.

Caucasus.—Both on the Goktcha Lake and on the River Terek, 120 000 h.p. are available.

B. *Power stations working on fuel.*

Utkina Zavod.—A power station near Petrograd to be worked mainly on peat. The maximum output is to be 30 000 kW.

Shatura.—This station is situated about 70 miles south of Moscow. The ultimate capacity of the station will be 60 000 kW. This was one of the first stations to be built, and is one of the largest worked on peat.

Summary.—Thirty central stations are to be erected, with a total power capacity of 1 740 000 kW. This means an average capacity per station of about 60 000 kW.

The maximum individual capacity of any one station (the water-power station on the River Dneipr) will be 300 000 kW.

The stations may be classified as follows:—

A. *Water power.*—Ten stations, total capacity 640 000 kW.

B. *Fuel.*—Twenty stations, total capacity 1 000 000 kW.

(*a*) Coal: ten stations, total capacity	..	540 000 kW
(*b*) Oil: two stations, total capacity	..	70 000 kW
(*c*) Peat: four stations, total capacity	..	210 000 kW
(*d*) Mixed fuel: four stations, total capacity		180 000 kW

These stations are to be completed and their ultimate capacity is to be reached before 1935.

5. Railway Electrification.

The lines put down for electrification before the war were the following (see Fig. 3):—

(1) Petrograd–Oranienbaum in the north-west. The scheme included one power house, somewhere midway between Petrograd (Baltic station) and Oranienbaum, and two substations at the above places. The project was quite completed and contracts were already placed, a considerable part coming to this country. The war, however, prevented the carrying out of this scheme.

(2) Plans on a larger scale and of greater importance were made in connection with the Moscow district; there the work had been seriously started on a section of the Moscow–Kazan railway about 40 miles long, the transmission system being 11 000 volts, three-phase, and the distribution being direct current at 1 500 volts. Here, again, the war stopped the work.

(3) A scheme for an underground railway in Moscow, connecting all the main-line terminals (seven in number) and the business centre of the town was seriously considered. The principal advantage of this scheme was the possibility of running the main-line trains from one terminus to another right through the city.

(4) Other, more indefinite schemes existed for the electrification of lines from Moscow to Kursk, down south through the Crimea, as far as Tsaritzino; the Sevirnaia line (up north) and the Alexander line (to Warsaw) as far as Golitzino. On all these lines it was the intention to electrify comparatively short sectors to begin with.

Other schemes in existence were the coastal railway

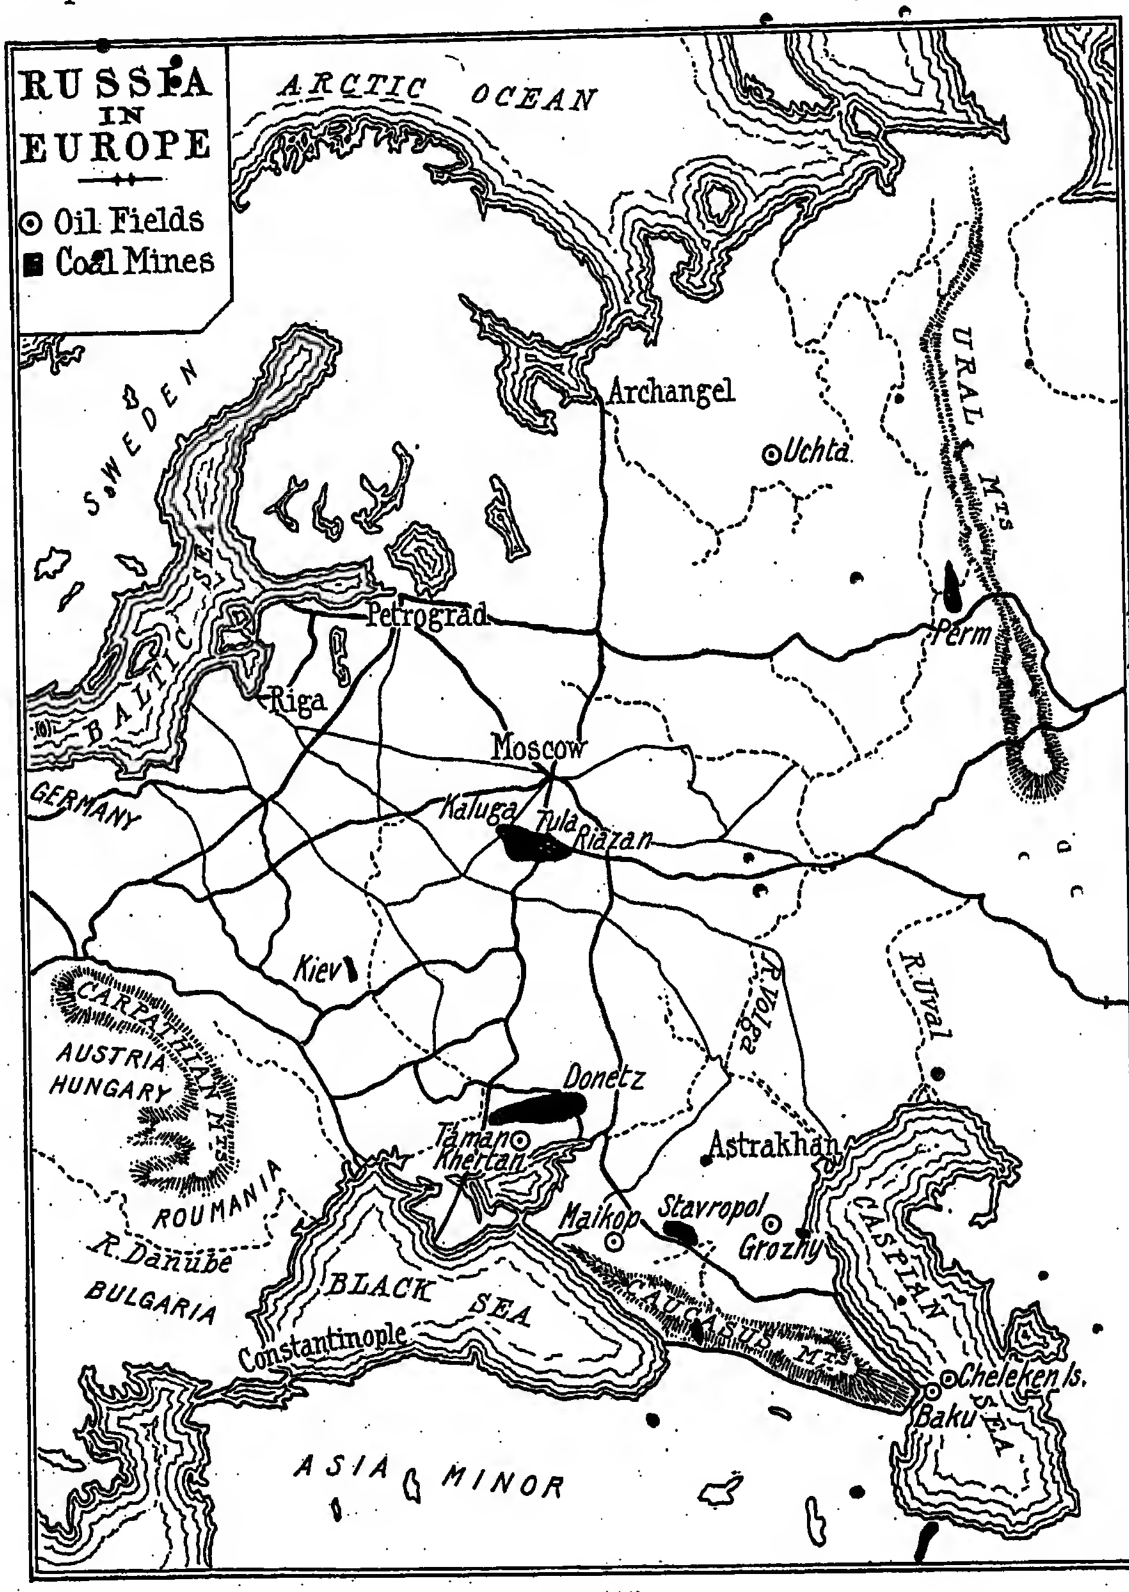

Fig. 3.

in the Crimea from Sebastopol to Yalta, and a series of mineral railways in the Caucasus, viz. Armavir–Tuapse; Saramis–Karaklis; Quiriky–Michailovo; and Vladikavkaz–Tiflis. Up to the present, however, nothing has been done to further these schemes.

This inactivity is temporary and is entirely governed by considerations of an economic nature. It seems, however, that the eventual electrification of the railways will proceed along lines quite different from those adopted in the main scheme, which has been briefly outlined in the preceding paragraphs. There, the immediate object was the long main-line electrification. The present schemes put forward are concerned, not with the main-line electrification, but with the electrification of railways according to a district basis. As soon as the erection of the power stations has been started in certain districts, it is suggested that the electrification of the railways in these districts will achieve two objects at the same time, viz. provide the stations with a load, and enable the railways to obtain sufficient power for their present needs.

It is suggested that the electrification of railways should take place in three districts, viz. Moscow, Petrograd and Donec, the railways near Moscow being in a particularly favourable position because of the close proximity of their power stations. Four very powerful stations, viz. the Electro Transmission, the Moscow, the Kashira and the Shatura stations could supply energy for these railways. These four stations will towards 1930 have a total capacity of not less than about 200 000 kW, and the following network of railways could be supplied from them:—

Moscow–Tula	Moscow–Riazan
Moscow–Kashira	Moscow–Vlagimir
Moscow–Shatura	Moscow–Pushkino

and the Moscow Circle Railway (see Fig. 4).

The total mileage of the last-named is about 700 miles, taking into account the 140 miles of suburban railways. It is suggested that towards 1930 these railways could take 50 000 kW, but with further development they would require up to 200 000 kW, by which time it is hoped that the power capacity of the stations will be increased correspondingly. The erection of several other stations near Moscow will allow of an expansion of the electrified area. The financial strain of such a scheme on the State is much lighter than would be that of long-line electrification, since in district electrification the whole work can be spread over a long period and need not necessarily be completed at once. If 80 to 100 miles of lines be electrified yearly, the whole electrification of the Moscow district would be completed by 1933 and would involve an expenditure

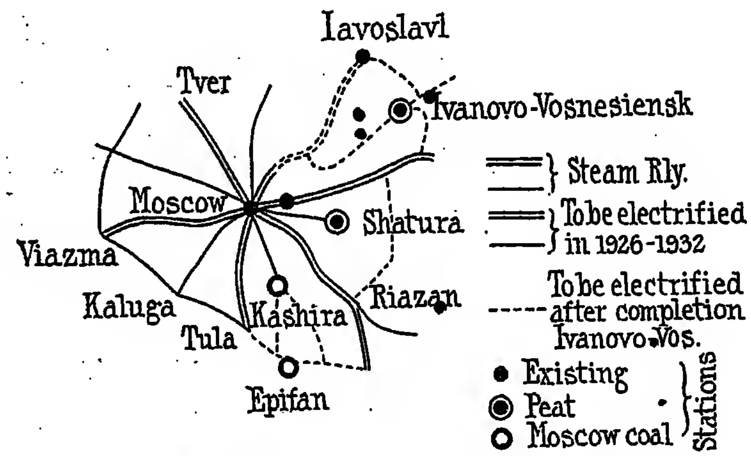

FIG. 4.—Railway electrification of Moscow.

of about £4 000 000; in other words, a yearly expenditure of, say, half a million sterling.

CONCLUSION.

An attempt has been made to give an outline of Russian economics with special reference to the question of electrification, and of the present state and existing tendencies of electrical developments. There seems to be an enormous amount of work to be done in Russia, and no doubt this will be accomplished sooner or later.

The Russian industry is not at present capable of satisfying all the demands of the Russian market. However rapidly the industry grows, for a considerable time to come a large proportion of the electrical requirements of Russia will have to be imported into the country. Apart from that, a tremendous amount of purely technical work will have to be done inside Russia, and this will require the services of a considerable number of technically trained engineers, far in excess of those to be found in that country.

The British electrical industry has definitely become an exporting one, and its future success will greatly depend upon the volume of such work. The interest in foreign markets should, therefore, be a natural one to those concerned with this industry.

The possibilities to be found in Russia should be of overwhelming interest to British electrical engineers, and if such interest has been stimulated by this paper the authors will feel that it has served its purpose.

DIRECTIONS FOR THE STUDY OF ELECTRICAL INSULATING VARNISHES, PAINTS AND ENAMEL PAINTS.*

[REPORT (REF. A/S9) RECEIVED FROM THE BRITISH ELECTRICAL AND ALLIED INDUSTRIES RESEARCH ASSOCIATION.]

CONTENTS.

PREFACE.

The difficulty of carrying out suitable tests on varnishes to determine whether they are satisfactory for use in electrical machinery has been experienced by those who have attempted such investigations. These Directions have been developed with a view to the study of the more important properties of varnishes intended for electrical insulating purposes.

In view of the need for this Publication it has been decided to issue it in its present form, although the most satisfactory methods for carrying out certain of the tests have not been settled.

It is hoped that all those who have occasion to test electrical insulating varnishes will adopt the methods suggested herein, so that results obtained by different investigators may be strictly comparable, and that the essential characteristics of this class of varnishes may be determined.

The Director of the E.R.A. will welcome comments and criticism from those who use this Publication.

I. INTRODUCTION.

The tests described herein are intended for varnishes, etc., that are applied by brushing, dipping or spraying, and are primarily employed for the purpose of providing electrical insulation.

In the clauses describing the methods of test the term "varnish" includes paint, enamel, binder and impregnating material.

II. DEFINITIONS.

1. INSULATING VARNISH.

The term "insulating varnish" denotes a liquid that yields on drying a protective insulating film.

(a) *Spirit varnish.*

The term "spirit varnish" denotes a liquid made with a base of resin or gum dissolved in a spirit, drying only by the evaporation of the solvent relatively quickly at atmospheric temperature, and yielding a protective insulating film.

NOTE.—A lacquer is a thin, quick-drying protective varnish, and is generally applied to a metal surface.

(b) *Oil varnish.*

The term "oil varnish" denotes a drying oil, generally with resin or gum, that yields on drying a protective insulating film.

2. PAINT.

The term "paint" denotes a mixture of pigment with a liquid vehicle.

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

(*a*) *Oil paint.*

The term "oil paint" denotes a mixture of pigment with a drying oil.

(*b*) *Enamel paint or enamel.*

The term "enamel paint" or "enamel" denotes a mixture of pigment with a varnish.

NOTE.—An enamel generally contains less pigment than an oil paint.

3. PIGMENT.

The term "pigment" denotes the fine solid particles used in the preparation of paint, and substantially insoluble in the vehicle.

4. BITUMINOUS ENAMEL.

The term "bituminous enamel"—stoving or air-drying—denotes a liquid made with a bituminous base that yields on drying a smooth protective film.

This class of enamel contains no pigment.

NOTE.—The term "japan" has been discarded in view of the confusion existing in the use of this term.

5. BINDER OR BOND.

The term "binder" or "bond" denotes any substance employed as an adhesive between the several layers of built-up laminated insulating material.

6. IMPREGNATING MATERIAL.

The term "impregnating material" denotes any substance employed to impregnate the interstices of a porous mass of winding or insulation.

7. BASE.

The term "base" denotes the film-producing or impregnating substance from which the materials defined above are made. The base remains behind or undergoes some physical and/or chemical change after the volatile constituent, if any, has disappeared.

8. VOLATILE THINNER.

The term "volatile thinner" denotes the liquid employed to reduce the viscosity of the materials defined above.

III. TESTS.

9. SPECIFIC GRAVITY.

The specific gravity at 20° C., referred to water at the same temperature, shall be determined either by a standard pyknometer specific gravity bottle, specific gravity balance, or hydrometer. All usual precautions as to standardization of vessels shall be adopted by checking against distilled water. The temperature of the varnish shall be between 15° C. and 25° C. when tested, and the specific gravity shall be corrected to 20° C.

10. VISCOSITY.

The viscosity shall be determined at a temperature of 20° C. in accordance with the British Standard Method for the determination of Viscosity in Absolute Units, British Standard Specification No. 188.

11. FLASH POINT.

The closed flash point shall be determined in the Abel or the Pensky-Martens apparatus.

12. FIRE POINT.

The fire point shall be determined as specified in the American Society for Testing Materials (A.S.T.M. Method D92–21T, Tentative Standards 1922).

13. DRYING.

(*a*) *Drying of surface film.*

The test shall be carried out on either Japanese Gampi tissue paper approximately 1 mil thick, or on sheet copper or brass about 5 mils thick. The dimensions of the specimen shall be approximately 8 inches long and 6 inches wide.

(i) *Preparation of specimens.*

The density of the varnish to be employed for the drying test shall be so adjusted by trial with the thinner recommended by the varnish manufacturer that the thickness of the varnish film on each side of the paper or metal sheet shall be not less than 3 mils, and not more than 3·5 mils, in the vicinity of the centre of the specimen.

To obtain the required thickness of film the varnish shall be diluted with the solvent recommended by the varnish manufacturer, and the paper or metal shall be varnished as follows:—

To determine the correct density of the varnish, strips of paper or metal shall be dipped in samples of diluted varnish containing amounts of thinner ranging from 5 per cent to 50 per cent (by volume). After draining for 30 minutes at room temperature, approximately 20° C., the specimen shall be dried as specified in (ii) below. Each specimen shall then be dipped again in varnish of the same density as before, drained for 30 minutes at room temperature, and dried as specified in (ii) below. During the draining, care shall be taken that the specimens remain stationary. When being dipped, drained and dried the second time the specimens shall be suspended in the opposite direction to that employed for the first film. The depth of the varnish in which the specimen is dipped shall be about ¾ inch, and the specimen shall be immersed completely for approximately 1 minute, care being taken to remove all froth. The specimen shall be drawn through the varnish at the same rate as the excess of varnish slips from the surface of the specimen.

NOTE.—If none of the specimens is of the specified thickness, the required density of the varnish may be obtained by interpolation.

(ii) *Method of drying.*

Six specimens coated with air-drying varnish shall be dried in free air at a temperature from 20° C. to 25° C.

Six specimens shall be dipped in baking varnish as specified in (i) above and allowed to drain for 30 minutes at room temperature, approximately 20° C., and then dried in an oven heated externally at a temperature from 95° C. to 100° C., unless the varnish manufacturer

recommends a higher temperature. The air content of the oven shall be changed completely not less than three times per hour. After the first coat has been dried the specimens shall be removed from the oven and allowed to cool to air temperature, approximately 20° C.; they shall then be dipped a second time and drained and dried as before. When being dipped, drained and dried the second time the specimens shall be suspended in the opposite direction to that employed for the first film.

The first specimen shall be tested as specified in (iii) below, 30 minutes before the expiration of the time stated by the varnish manufacturer, and thereafter further specimens shall be tested similarly at intervals of 10 minutes.

(iii) *Time of drying.*

The varnish shall be considered dry when a circular piece of No. 4 Whatman filter paper 1⅝ inch diameter does not adhere to the varnish when it is pressed on the surface of the varnish for one minute by a cylindrical weight of one pound, one inch in diameter. The filter paper shall be applied in the vicinity of the centre of the specimen. The test shall be carried out at a temperature from 15° C. to 25° C.

(*b*) *Drying throughout a mass of winding.*

The test to determine the drying property of a varnish throughout a mass of winding shall be carried out on coils of double cotton covered copper wire. The coil employed for the test shall be of circular section, approximately 2 inches internal diameter and 2 inches long. The coil shall be wound with wire 0·036 inch diameter, double cotton covered, and the depth of the winding shall be approximately ½ inch.

The time required for the varnish to dry satisfactorily shall be determined as follows:—

Several specimen coils shall be provided which shall be thoroughly dried in a hot vacuum oven and immediately immersed for ten minutes in a bath of the varnish at the density recommended by the manufacturer, or other trial density. After draining, the coils shall be baked at different temperatures and for different periods of time, the varnish maker's recommendations being taken as an initial guide. When cold, the coils shall be sawn through and the several layers and turns separated. The baking conditions necessary to obtain effective adhesion between the cotton covered wires throughout the mass of the winding shall be recorded.

14. Electric Strength.

The electric strength test shall be carried out on either varnished Japanese Gampi tissue paper or varnished sheet copper or brass. The paper employed for the test shall be approximately 1 mil thick and the metal sheet about 5 mils thick.

The paper or metal sheet shall be varnished and dried as specified in Clause 13 (*a*).

Sufficient specimens shall be varnished to enable ten tests to be carried out at each of the temperatures given below.

The electric strength tests shall be carried out at a temperature from 20° C. to 25° C. and at a temperature from 90° C. to 95° C. within 24 hours of the completion of the drying of the second coat of varnish.

The electrodes shall make contact with the varnish in the vicinity of the centre of the specimen.

The potential difference shall be raised from zero, in steps of not more than 250 volts, at the rate of 30 kilovolts per minute until breakdown occurs.

In other respects the electric strength test shall be carried out in accordance with Technical Publication Ref. L/S2, Tentative Directions for the Determination of the Electric Strength of Solid Dielectrics, except where otherwise specified in this Clause.

In each test the thickness of the varnish film shall be determined from the mean of three measurements of thickness taken as close to the point of puncture as practicable.

The puncture voltage, the total thickness of the specimen and the net thickness of the varnish film shall be stated for each of the ten tests at each temperature, and the maximum, minimum and mean values of the volts per mil of the varnish film shall be given.

15. Waterproof Tests.

The waterproof properties of the varnish shall be determined by the following tests:—

(*a*) *Resistance to moisture.*

The ability of the varnish to resist moisture shall be determined by carrying out the electric strength test specified in Clause 14 after the specimen has been subjected to an approximately saturated atmosphere (relative humidity not less than 95 per cent) for 3 days. The electric strength test shall be carried out whilst the specimen is in the moist atmosphere at a temperature from 20° C. to 25° C.

(*b*) *Water permeability test.*

This test shall be carried out as follows:—

A clean smooth copper or brass sheet approximately 10 inches square and 5 mils thick shall be coated on one side only either by spraying or pouring the varnish over the sheet. The density and viscosity of the varnish shall be adjusted in accordance with conditions specified by the varnish maker.

The thickness of the film shall be measured at 20 points equally spaced over the area of the sheet. The thickness at any point shall not vary from the mean value by more than 1 mil, and the mean value shall be taken as the thickness of the varnish film. In each quarter of the sheet a ring of wax approximately 2½ inches internal diameter and ⅛ inch deep shall be made on the varnish. The four rings shall be filled with distilled water and left for a period of 24 hours. The water shall then be removed as far as possible with a pipette, the remainder being absorbed by blotting paper or similar material. The sheet shall be left for 5 minutes to dry off at a temperature from 20° C. to 25° C. The electric strength of the varnish shall then be determined at two positions in each quarter of the sheet, one inside the ring of wax and the other outside, but as close to the ring as possible, care being taken that the varnish surface on which the electrode is placed is entirely free from wax.

The upper electrode shall be a solid cylinder of brass $1\frac{1}{2}$ inches long and $1\frac{1}{2}$ inches diameter. The electric strength test shall be carried out at a temperature from 20° C. to 25° C. The electric strength test shall be carried out in accordance with Technical Publication Ref. L/S2, Tentative Directions for the Determination of the Electric Strength of Solid Dielectrics, except where otherwise specified in this Clause.

Comparison shall be made between the mean values of the four puncture voltages inside and outside the rings respectively, and the percentage decrease computed on the mean outside value shall be stated.

16. Ageing.

The ageing test shall be carried out on Japanese Gampi tissue paper on specimens varnished and dried as specified in Clause 13 (*a*). After removing not less than $\frac{1}{2}$ inch from one edge, six strips each $\frac{3}{4}$ inch wide shall be cut from that edge.

The strips shall be placed in a uniformly heated oven at a temperature from 100° C. to 105° C. A strip shall be removed at the end of 50, 100, 200, 300, 400 and 500 hours respectively and shall be tested at room temperature, approximately 20° C., as specified below, between half-an-hour and one hour after removal from the oven.

Each strip shall be bent double under a weight of one pound, the dimensions of the base of which shall be 1 inch square, and the effect on the varnish at the bend shall be noted. The number of hours that the varnish has been heated when it first cracks in the bending test shall be stated.

17. Effects of Acids and Alkalies.

The ability of the varnish to withstand acids and alkalies shall be determined at a temperature between 15° C. and 25° C. by the following tests:—

(*a*) A number of copper rods each approximately $\frac{1}{4}$ inch diameter and about 6 inches long, one end being rounded and the other having a suitable terminal, shall be brightly burnished, washed clean with dilute alcohol and then dried in warm air; whilst still warm they shall be dipped carefully without agitation into the varnish and dried as specified in Clause 13 (*a*).

When dry the rounded end of each rod shall be coated with paraffin wax to a distance of approximately 2 cm.

A zinc rod, such as is used in Leclanché batteries, shall be well amalgamated with mercury, and immersed centrally into a vessel containing an aqueous solution of sulphuric acid, specific gravity 1·182 at 15°/4° C. (25 per cent by weight of H_2SO_4); the lower end of the zinc rod shall dip into a small cup containing mercury (to maintain the amalgamation), whilst the copper rods shall be spaced round the zinc rod at a radius of 5 cm. The zinc rod shall be connected to one terminal of a millivoltmeter, while each of the copper rods shall be successively connected up and the potential difference noted.

The millivoltmeter used shall have a range of 1 500 millivolts and a resistance of 60 ohms (plus or minus 10 per cent) at 20° C. If an instrument of lower resistance be used, then a resistance shall be inserted in series to make up the difference, and the readings multiplied by a correction factor to give the millivolts across the instrument and external resistance. If an instrument of higher resistance be used it shall be shunted with a suitable resistance.

It is important that no difference of potential is indicated at the commencement, and should any occur the rod shall be rejected and a fresh one put in its place. The rods shall be tested every hour for the first few hours to study the effect, and then at intervals of 6, 12 or 24 hours.

(*b*) The varnish shall be tested as described in (*a*) except that the solution in which the rods are immersed shall be a 10 per cent solution of caustic soda (NaOH) prepared with distilled water (specific gravity equals 1·13).

(*c*) A standard Soxhlet thimble, approximately 2 cm by 8 cm (as made by Whatman, or similar thimble) shall be coated with two coats of the varnish under test either by dipping or brushing and shall then be dried in accordance with Clause 13 (*a*). It shall be filled to within $\frac{1}{2}$ inch of the top of the varnish film with a 10 per cent solution of caustic soda (NaOH). It shall be then supported by suitable means in a freshly prepared solution of phenol phthalein in distilled water, dipping to the same level as the alkali inside. The time expressed in minutes taken for the solution in the immediate vicinity of the thimble to turn pink in colour due to the alkali shall be noted.

(*d*) The following tests shall be carried out on sheet copper specimens about 5 mils thick and $\frac{3}{4}$ inch wide. The specimens shall be varnished and dried as specified in Clause 13 (*a*).

The specimens shall be immersed in the reagents given below at a temperature from 15° C. to 25° C. for approximately 16 hours, and suspended in an air oven at atmospheric temperature for the remainder of the 24 hours. This procedure shall be carried out for six days consecutively, and the effect of the reagents on the varnish shall be stated.

Reagents :

- Sulphuric acid, specific gravity 1·4.
- Hydrochloric acid, specific gravity 1·1.
- Nitric acid, 5 per cent solution.
- Picric acid, 2·5 per cent aqueous solution.
- Ammonia (0·88), 10 per cent solution.
- Mixture of ammonium chloride and sulphate, a saturated aqueous solution.
- Caustic soda, specific gravity 1·13 (10 per cent NaOH).

18. Effect of Oil.

The ability of the varnish to withstand hot oil shall be determined by the following tests:—

(*a*) Specimens of Rope paper shall be varnished and dried as specified in Clause 13 (*a*). The paper shall be in accordance with the Rope paper defined in Technical Publication Ref. A/S5, Directions for the Study of Electrical Insulating Papers (Unvarnished) for Purposes other than the Manufacture of Cables.*

The effect of oil on the varnish shall be determined

* *Journal I.E.E.*, 1923, vol. 61, p. 982.

by immersing a number of varnished specimens in the oils specified below at a temperature from 115° C. to 120° C. The specimens shall be examined at intervals, and the period required for the varnish to be affected by the oils shall be determined. The effect on the varnish shall be stated, for example, by the formation of sludge on the varnish.

(i) Transformer oil complying with B.S.S. No. 148—1923 for light grade oil.

(ii) Lubricating oil, which shall consist of a mineral oil with 20 per cent of blown rape oil, and shall comply with the following specification:—

Specific gravity at 60° F. (15·6° C.)	0·92 (approximately).
Closed flash point	Not less than 370° F. (188° C.).
Viscosity (time of outflow of 50 cm^3 in Redwood viscometer)	75 seconds at 200° F. (93° C.); 38 seconds at 300° F. (149 °C.).
Acidity, calculated as oleic acid	Not more than 1 per cent.
Loss in 2 hours at 212° F. (100° C.) (determined as described below)	Not more than 0·3 per cent.

The oil shall be free from mineral acid.

The loss at 212° F. (100° C.) shall be determined by heating 9 grammes of oil in a flat-bottomed porcelain dish approximately 2½ inches diameter and ¾ inch deep.

(*b*) The test for the effect of oil shall be carried out on a coil of cotton covered copper wire. The coil employed for the test shall be of circular section approximately two inches internal diameter and two inches long. The coil shall be wound with wire 0·036 inch diameter double cotton covered, and the depth of the winding shall be approximately ½ inch. Before the application of varnish to the coil, it shall be dried for six hours in an oven at a temperature from 95° C. to 100° C. The coil shall then, whilst still hot, be dipped in the varnish under test, and allowed to remain immersed for a minimum period of 5 to 10 minutes or until such time as all bubbling ceases. It shall then be removed from the varnish, allowed to drain, and placed in a drying oven for 18 hours at a temperature from 95° C. to 100° C., unless the varnish manufacturer recommends a higher temperature. The coil shall then be again dipped for a further period of about five minutes, and the drying operation carried out as before.

The effect of oil on the varnish shall be determined by immersing coils in the oils specified in (*a*). The test shall be carried out as specified in (*a*), and the effect on the varnish shall be stated, for example, by the formation of sludge on the varnish and by the loss of adhesion between the turns of the coil.

19. Effect of Varnish upon Copper.

Note.—Electrical insulating varnishes, other than those of the synthetic resin type, usually contain organic acids.

The ordinary tests for acidity do not furnish sufficient information to determine whether a varnish is likely to have an injurious effect on copper.

This subject is under consideration with a view to the development of a suitable test.

20. Effect of Corona Discharge.

Note.—A test to determine the effect of corona discharge on varnish is under consideration.

21. Effect of Producer Gas.

Note.—A test to determine the effect of producer and similar gases on varnish is under consideration.

22. Permanence of Coloured Enamels (used for Marking and not for Insulating Purposes).

Note.—An investigation is in hand with a view to the development of suitable tests.

INDUCTIVE INTERFERENCE WITH COMMUNICATION CIRCUITS.*

By Dr. ALEXANDER RUSSELL, F.R.S., President.

(*Paper received* 15*th August*, 1924.)

SUMMARY.

The paper discusses interference between power circuits and telegraph and telephone circuits. A distinction is made between "radiation" and "induction." The former cause produces both electric and magnetic effects and is used in radio-telegraphy. The conductivity of the earth, which is not a homogeneous body, should be taken into account. Experiment, however, shows that in radio work we can get approximate solutions by assuming that the earth is a non-conductor and that its inductivity is unity. Making this assumption, it is shown that the intensity of the "radiation" field in simple cases falls off inversely as the distance and inversely as the wave-length. On this assumption also the intensity of the induction field, whether electrostatic or electromagnetic, obeys this law in a few cases. It is pointed out that a balanced three-phase system produces both electric and magnetic rotary fields in its neighbourhood, the amplitudes of which fall off according to the inverse square of the distance. A three-phase four-wire system, however, may produce serious interference with telephone systems even when the phases are balanced. In an appendix an easy method of finding the numerical value of the mutual capacity coefficient between two spheres is given.

When the Secretary of the London Students' Section asked me to give an address to the Section I felt that it was my duty to do so; but I also felt that I should be free to choose the subject for the address. It is expected on these occasions that the President should give some useful advice to those on the threshold of the profession. Last year on a very similar occasion it was put very bluntly to me. The Students wanted to know how best they could utilize in the industrial world the knowledge they had acquired in college. Paraphrased slightly, I took this to mean: What is the easiest way of getting a well-paid job? Although I ventured to say something in this connection last year with the object of interesting my audience, I thought that on this occasion I should say something with the object of interesting myself. Naturally I thought that some mathematical subject would be suitable, although from the eloquent silence of the secretary of the Students' Section I inferred that in his opinion it would not be a happy choice so far as my audience was concerned. I therefore sought for some mathematical subject which would have an immediate practical bearing on industry. I only chose the subject, however, last night after listening to a valuable paper on "Power Circuit Interference with Telegraphs and Telephones" which was read † by Mr. S. C. Bartholomew before the Institution. It seemed to me that a talk on the inductive interference of power circuits with communication circuits would be useful at the present time. There are many problems still to be solved which are of interest to the mathematician and the experimentalist. In what follows I shall attempt to give a survey of the problem from the mathematical point of view in the hope that some Students will amend some of the assumptions which it is necessary to make, and extend or perfect many of the theorems given. In this connection many useful formulæ and some valuable data will be found in Eccles's handbook on "Wireless Telegraphy and Telephony."

So many young engineers are now radio experts that they naturally think that radiation from power lines may be one of the causes of interference. Radiation has been defined as the moving disturbance in the ether, the energy connected with which does not return to the radiator. It is this disturbance which is considered in modern radio-telegraphy.

From the engineering point of view we may discuss radiation as follows: Consider a small electrified body O in infinite space and let it have an electric charge q. The potential v at a point P at a distance x from O is given by

$$v = \frac{q}{x} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

Now if q changes, v changes. But it is against all physical principles to assume that the change takes place instantaneously. We shall adopt Maxwell's theory, and suppose that the electric effects are propagated with the velocity u of light. We can suppose, therefore, that there is a time-lag x/u between the varying charge q and the varying potential at the point P. If q follow the harmonic law, we can write $q = Q \sin \omega t$, where $\omega = 2\pi/T$, T is the periodic time and t the number of seconds since the epoch of reckoning. We shall make the supposition that the potential at P has the retarded value given by

$$v = \frac{Q}{x} \sin \omega\left(t - \frac{x}{u}\right) \quad . \quad . \quad . \quad . \quad . \quad (2)$$

Mathematical reasons can be given for this supposition, but as it is the simplest that could be made we shall adopt it.

By definition, the electric force F at P in the direction OP is given by

$$F = -\frac{\partial v}{\partial x}$$
$$= \frac{Q\omega}{ux} \cos \omega\left(t - \frac{x}{u}\right) + \frac{Q}{x^2} \sin \omega\left(t - \frac{x}{u}\right)$$

* Part of this paper was given in an Address to the London Students' Section on the 11th April, 1924.

† *Journal I.E.E.*, 1924, vol. 62, p. 817.

If λ be the wave-length of the disturbance in the ether, $\lambda = uT$, $\omega = 2\pi u/\lambda$ and, therefore,

$$F = \frac{2\pi Q}{\lambda x} \cos \omega\left(t - \frac{x}{u}\right) + \frac{Q}{x^2} \sin \omega\left(t - \frac{x}{u}\right) \quad . \quad (3)$$

We see, therefore, that one effect of the finite velocity of propagation is to increase the value of F by a term the amplitude of which is $2\pi Q/(\lambda x)$.

Formula (3) shows that the electric force at P, which is in the direction OP, consists of two components. The first component has an amplitude $2\pi Q/(\lambda x)$. This is called the "radiation" component. The second component has an amplitude Q/x^2 and is called the component due to electric induction. When x is small compared with λ the induction component is the more important. When $x = \lambda$, the first component is more than six times greater than the second, and when x is large compared with λ, the "radiation" (and not the "induction") has to be considered. It is customary to consider only the radiation in radio theory, and when discussing interference troubles it is usual to consider only the inductive effects. It is well to bear in mind, however, that both effects are always in action when the electrification is varying.

In what precedes we have only discussed the electric field. But if we had discussed the magnetic field of a small current element of length l and carrying a current I we should have found that the magnetic field H at a point on the equatorial plane at a distance x from the element was given by *

$$H = \frac{2\pi lI}{\lambda x} \cos \omega\left(t - \frac{x}{u}\right) + \frac{lI}{x^2} \sin \omega\left(t - \frac{x}{u}\right) \quad . \quad (4)$$

We see as before that the first term is due to radiation and the second to induction. From Maxwell's theory it follows that in the case of radiation the electric field is always accompanied by a magnetic field, and vice versa. These fields can be regarded as aspects of the same phenomenon and are in a constant ratio to one another. The effects produced in the receiving aerial can be computed by considering either the electric or the magnetic component. Radiation, therefore, cannot be described as exclusively an electric or a magnetic phenomenon. Neglecting absorption and assuming a homogeneous dielectric and a non-conducting earth we see that the electric and magnetic forces fall off inversely as the distance and inversely as the wave-length. This has been roughly verified in certain cases by several experimenters.

The interference produced by low-frequency power circuits in connection with telegraphy and telephony is mainly due to induction. In this case we have to distinguish between electric and magnetic induction, and both have to be taken into account. It seems to me that power engineers lay too much stress on magnetic induction, and telephone engineers on electric induction. In practice both effects take place simultaneously. To calculate them it would be necessary to know both the mutual electrostatic and the mutual electromagnetic coefficients between various kinds of circuits. Several of the latter coefficients are given in textbooks and are fairly easy to compute, but with the exception of the case of two spheres very little has been done towards calculating the mutual electrostatic coefficients of circuits. Personally I have tried to solve several problems of this nature, but with only partial success. It is only possible in this paper to give an introduction to a wide field which wants mathematical and experimental exploration, and to touch in a sketchy way on some of the problems that have to be considered. I hope that some Students will be able to suggest better methods of attacking the problems.

Before proceeding further we must face the question of whether we are going to consider the earth as a conductor or as an insulator for electric currents. If we adopt the former assumption we shall be forced to make the further assumptions that it is a homogeneous conductor and that its conductivity remains constant. As a matter of fact we know that it is a conductor. In certain cases its conductivity in the neighbourhood of buried wires has been measured. We know also that when an alternating potential difference of constant effective value is maintained between a long insulated horizontal wire and the earth, the charging current varies from day to day and in certain cases from hour to hour. It obviously depends on the amount of moisture on the surface of the earth. The earth therefore must be considered as a heterogeneous conductor. This enormously increases the difficulty of getting accurate solutions.

To enable us to get approximate solutions we must either consider the earth to be an insulator the inductivity of which equals unity or that its surface may be considered to be a perfect conductor. If we suppose the small conductor O considered above to be at a distance H above a perfectly conducting plane, and if OP be parallel to the plane and very great compared with H, then for the amplitude of the electric force F of radiation we have, by the method of electric images,

$$F = \frac{2\pi Q}{\lambda x} - \frac{2\pi Q}{\lambda\sqrt{(x^2 + 4H^2)}} = \frac{4\pi Q H^2}{\lambda x^3} \text{ (approx.)}$$

The radiation effect would, therefore, fall off with extreme rapidity, obeying the law of the inverse cube of the distance. So far as radio communication is concerned, the assumption that the earth is an insulator leads to the best results. We shall therefore adopt it in what follows. When we have obtained formulæ assuming the earth to be an insulator, the corresponding formulæ taking the earth as a perfect conductor can be written down at once by the method of images.

We shall consider the electric and the magnetic forces separately. In practice they occur simultaneously, but if we attempted to give a complete solution so many variables occur in it that the formula would be very complicated and therefore of little practical help. We shall first consider electrostatic induction.

Electrostatic Induction.

Let us take the case of two insulated conductors A and B at a considerable distance x apart. Let v_1, v_2

* J. H. Dellinger: Bureau of Standards, Scientific Paper No. 354 (1919).

and q_1, q_2 be the potentials of and the charges on A and B respectively. We see that

$$v_1 = \frac{q_1}{K_1} + \frac{q_2}{x}; \text{ and } v_2 = \frac{q_2}{K_2} + \frac{q_1}{x} \quad . \quad . \quad (5)$$

approximately, where K_1 is the ratio q_1/v_1 when q_2 is zero. K_1 and K_2 are practically, therefore, the capacities of the conductors A and B respectively to earth. If the conductors A and B were spheres, ellipsoids, rings, discs or thin rods the ordinary formulæ show that K_1 and K_2 are very minute compared with x. Solving (5) for q_1 and q_2 we get

$$q_1 = \frac{x^2K_1}{x^2 - K_1K_2} v_1 - \frac{K_1K_2x}{x^2 - K_1K_2} v_2$$

$$= K_1v_1 - \frac{K_1K_2}{x} v_2 \text{ (very approx.)} \quad . \quad . \quad (6)$$

and $$q_2 = K_2v_2 - \frac{K_1K_2}{x} v_1 \text{ (very approx.)} \quad . \quad . \quad (7)$$

when K_1 and K_2 are very small compared with x.

If v_1 were given by $E \sin \omega t$ and the conductor B were earthed ($v_2 = 0$), the current i_2 in the earthing wire of B would be given by

$$i_2 = -\frac{\partial q_2}{\partial t} = \frac{K_1K_2}{x} \omega E \cos \omega t$$

$$= \frac{2\pi K_1K_2u}{x\lambda} E \cos \omega t \quad . \quad . \quad (8)$$

where u is the velocity of light and λ is the wave-length of the radiation ($\omega = 2\pi u/\lambda$).

Hence the current induced in the earthing wire of B when the potential of A varies according to the harmonic law, is proportional to K_1, to K_2 and to the amplitude of the potential. It is also inversely proportional to x and λ.

Let us now consider a very long and thin conducting prolate spheroid. The ellipsoid is considered so long and so thin that it is practically a wire, the foci S and H of the elliptic sections being at its ends. The electrification of a conducting ellipsoid was a problem much studied by mathematicians 50 years ago as exact solutions were obtainable, and many curious properties came to light. For example, all ellipsoids confocal to the given ellipsoid were found to be equipotential surfaces of the given ellipsoid. We suppose that the prolate spheroid is so thin that it practically represents the line SH. It is known that if a wire conductor of this shape be electrified the charge on it per unit length of SH will be the same. It will therefore act like a wire having an electric charge uniformly distributed along it.

If q be the total charge on the prolate spheroid it can be shown that the potential v at any point P is given exactly by

$$v = \frac{2q}{\text{SH}} \text{ arc tanh } \frac{\text{SH}}{\text{SP} + \text{PH}} \quad . \quad . \quad . \quad (9)^*$$

which is a remarkably simple expression.

* Those not familiar with inverse hyperbolic trigonometry may convert the inverse tangent into Napierian logarithms or into algebra by the formulæ

$$\text{arc tanh } x = \tfrac{1}{2} \log_e (1 + x) - \tfrac{1}{2} \log_e (1 - x) = x + \frac{x^3}{3} + \frac{x^5}{5} + \ldots$$

Expression (9) proves at once that the equipotential surfaces round SH are prolate spheroids the foci of which are S and H.

When CP is very great, where C is the middle of SH, we can write SP = PH = CP and $v = q/\text{CP}$. The problem thus reduces to the preceding case.

If SH $= 2a$, CP $= x$ and $\angle$SCP is a right angle so that P lies on the equatorial plane, we have

$$v = \frac{q}{a} \text{ arc tanh } \frac{a}{\sqrt{(a^2 + x^2)}} \quad . \quad . \quad . \quad (10)$$

The electric force F at P in the direction CP is given by

$$F = -\frac{\partial v}{\partial x} = \frac{q}{x\sqrt{(x^2 + a^2)}} = \frac{q}{\text{CP . SP}} \quad . \quad (11)$$

When P lies on HS produced,

$$v = \frac{q}{a} \text{ arc tanh } \frac{a}{x}$$

and thus $$F = \frac{q}{\text{CP}^2 - \text{CS}^2} \quad . \quad . \quad . \quad . \quad . \quad (12)$$

Formulæ (11) and (12) enable us to compute easily the electric force at points on the equatorial plane and along the polar axis.

If the ends of a thin wire in the equatorial plane be at points where the potentials due to SH are different, a current will obviously be induced in the thin wire by electric induction. Similarly a wire placed along the polar axis will have a current induced in it.

When the wire SH is long and the distance of a point P on the equatorial plane from C is not great, CP is practically equal to SP and so

$$F = \frac{q}{a \times (\text{CP})} \text{ (approx.)}$$

In this case also if P be on the polar axis

$$F = \frac{q}{(\text{CP} + \text{CS})(\text{CP} - \text{CS})}$$

$$= \frac{q}{2a \times (\text{SP})} \text{ (approx.)}$$

Thus the electric intensity is greater at a point in the equatorial plane than at a point on the polar axis at the same distance from the wire.

Let us now consider two infinitely long parallel wires at a distance x apart. Let the radius of the cross-section of each of them be a and let q_1, q_2 and v_1, v_2 be the charges per unit length and the potentials of the wires respectively. In this case it is known that

$$q_2 = k_{22}\, v_2 + k_{12} v_1$$

where k_{22} and k_{12} are constants called Maxwell's capacity coefficients. The computation of the values of these constants is difficult, but when the wires are far apart it can be shown that

$$k_{22} = -k_{12} = \frac{1}{4 \log (x/a)} \text{ (approx.)}$$

* A. Russell: *Proceedings of the Physical Society*, 1919, vol. 31, p. 123.

Thus if v_2 be zero and $v_1 = E \sin \omega t$, we find that the current i_2 in the earthing wire is given by

$$i_2 = -\frac{\partial q_2}{\partial t} = \frac{1}{4 \log (x/a)} \omega E \cos \omega t$$
$$= \frac{\pi u E}{2\lambda \log (x/a)} \cos \omega t \quad . \quad . \quad . \quad . \quad (13)$$

As x is great compared with a, i_2 varies very slowly with x.

Electromagnetic Induction.

As a rule, students pay much more attention to electromagnetic induction than to electric induction. Problems in connection with magnetic induction linking circuits together are therefore much more familiar to them.

Let i_1 be the current in the disturbing circuit and let L_{12} be the mutual induction between it and the disturbed circuit. Then we know that the disturbing E.M.F. induced in the latter is $L_{12}(\partial i_1/\partial t)$. This E.M.F. depends on the factor L_{12} and on how the disturbing current varies with the time.

If we have a small current element of length l_1 carrying a current i_1, the magnetic force H at a point P in the plane bisecting the element at right angles will be in this plane and at right angles to the line joining P to the element. If x be the distance of P from the element we have, by Laplace's formula,

$$F = \frac{l_1 i_1}{x^2}$$

Thus the magnetic flux ϕ linked with a small conductor of length l_2 parallel to the element is given by

$$\phi = l_1 l_2 i_1 \int_x^\infty \frac{1}{x^2} \partial x$$
$$= \frac{l_1 l_2}{x} i_1.$$

Hence if $i_1 = I \sin \omega t$, the disturbing E.M.F. e' is given by

$$e' = \frac{\partial \phi}{\partial t} = \frac{l_1 l_2 \omega I}{x} \cos \omega t$$
$$= \frac{2\pi l_1 l_2 u I}{\lambda x} \cos \omega t \quad . \quad . \quad (14)$$

The disturbing E.M.F. therefore varies inversely as λ and as x.

Let us now consider an infinitely long horizontal wire carrying a current i_1. If a plane circular circuit of radius r be in the same plane as the wire and if its centre be at a distance x from the wire, we know that

$$L_{12} = 4\pi\{x - \sqrt{(x^2 - r^2)}\} \quad . \quad . \quad . \quad (15)^*$$

exactly.

If x be large compared with r, then

$$L_{12} = \frac{2A_2}{x} \text{ (approx.)} \quad . \quad . \quad . \quad . \quad (16)$$

* A. Russell: "Alternating Currents," vol. 1, p. 53.

where A_2 is the area of the circle. In general, if A_2 be the area of a small circuit with its plane in the same plane as the wire, then, whatever its shape,

$$L_{12} = \frac{2A_2}{x} \text{ (approx.)} \quad . \quad . \quad . \quad . \quad (17)$$

Let us now suppose that we have a parallel return wire in the same horizontal plane as the first wire and the circuit A_2, and that the distance between the wires is c. Equation (17) now becomes

$$L_{12} = \frac{2A_2}{x} - \frac{2A_2}{x+c} = \frac{2cA_2}{x^2} \text{ (approx.)} \quad . \quad (18)$$

The effect now falls off inversely as the square of the distance. This formula may easily be generalized by theorems given in Russell's "Alternating Currents," vol. 1, chap. 19. Let A_2 be the area of a small circuit of any shape with its plane parallel to the wires and at a great distance x from them. If x makes an angle θ with the plane of the wires, and the plane of the small circuit makes an angle ϕ with the same plane, we can easily show that

$$L_{12} = \frac{2cA_2}{x^2} \cos (2\theta - \phi)^* \quad . \quad . \quad . \quad (19)$$

Let the values of x supposed drawn in a vertical plane perpendicular to the wires from the mid-point between the two wires be plotted out so that at their extremities the magnetic effects produced are the same (L_{12} constant). We have

$$x^2 = \frac{2cA_2}{L_{12}} \cos (2\theta - \phi).$$

If we suppose that ϕ is a constant (zero for instance) we see that the curve is a lemniscate. Radio engineers have a hankering after this curve in connection with the explanation of effects noticed in directive signalling.

Let us next consider two small plane circuits of areas A_1 and A_2 at a great distance x apart. If both circuits are in the same plane, we have

$$L_{12} = \frac{A_1 A_2}{x^3} \text{ (approx.)} \quad . \quad . \quad . \quad . \quad (20)$$

If they are both vertical and opposite one another,

$$L_{12} = \frac{2A_1 A_2}{x^3} \text{ (approx.)} \quad . \quad . \quad . \quad . \quad (21)$$

In general, if the planes of the two circuits make angles θ_1 and θ_2 with x and with x produced, respectively, we have

$$L_{12} = \frac{A_1 A_2}{x^3}\{2 \sin \theta_1 \sin \theta_2 + \cos \theta_1 \cos \theta_2\} \quad (22)$$

If θ_1 remain constant and θ_2 vary, the maximum value of L_{12} is given by

$$(L_{12})_{\max.} = \frac{A_1 A_2}{x^3}\{1 + 3 \sin^2 \theta_1\}^{\frac{1}{2}}$$

Keeping this value of L_{12} constant we get the polar equation to the curve of equal magnetic effect. Simi-

* Notice that when ϕ equals 2θ, L_{12} has its maximum value, and that it vanishes when $\phi = 2\theta - \frac{1}{2}\pi$.

larly, if the planes of A_1 and A_2 are perpendicular to one another ($\theta_2 = 0$) we get

$$x^3 = \frac{A_1 A_2}{L_{12}} \sin \theta_1$$

and if L_{12} is kept constant we get a new polar curve.

Three-Phase Circuits.

It is known that the electrostatic and electromagnetic fields round three-phase circuits sometimes cause interference. It is of importance therefore to consider them. Let us suppose that the axes of the three conductors form the edges of an equilateral prism. Let also the edges be at a distance a from the central line of the prism. Suppose that the currents in the three conductors are $I \sin \omega t$, $I \sin (\omega t - 120°)$ and $I \sin (\omega t - 240°)$. Then if R be the magnetic force at a point P at a great distance x from the central line of the prism, in the direction of x, and T be the tangential force perpendicular to x, we have,* approximately,

$$R = \frac{3aI}{x^2} \sin (\omega t - \theta) \text{ and } T = \frac{3aI}{x^2} \cos (\omega t - \theta) \quad . \quad (23)$$

Thus the magnetic field at P is a rotary field, and therefore the induced E.M.F. in a small circuit whose plane is parallel to the edges of the prism is the same whatever angle it makes with x.

If we had a single-phase circuit consisting of two parallel wires at a distance c apart, then the radial and tangential components of the magnetic force would, by (19), be given by

$$R = \frac{2cI \sin \omega t}{x^2} \sin \theta ; \text{ and } T = \frac{2cI \sin \omega t}{x^2} \cos \theta \quad (24)$$

where $I \sin \omega t$ is the current in the wire and θ is the angle that x makes with the plane of the wires. If $c = 1 \cdot 5a$ it will be seen that the amplitude of the magnetic effects produced would be the same in the two cases. With single-phase circuits the fields are purely oscillatory.

Similarly in the three-phase case it can be shown that the electrostatic field at a distant point P is a rotating one, and that the magnitude of the resultant electric force at P is $3aQ/x^2$, where Q is the maximum value of the electric charge per unit length on each of the three-phase conductors. If f is the frequency of the alternating currents the angular velocities of the rotating electric and magnetic fields at P each equal $2\pi f$.

When the three-phase system is connected in "star" and the star points are connected to another conductor we get a four-wire three-phase system. The disturbing effects are now greatly increased. Let i_1, i_2 and i_3 be the currents in the three conductors. In this case $i_1 + i_2 + i_3$ is not necessarily zero, although the effective values of each of the currents may be the same. The tangential magnetic force at a point P at a great distance x has therefore a component

$$\frac{2(i_1 + i_2 + i_3)}{x}.$$

* A. Russell: "Alternating Currents," vol. 1, p. 478.

Similarly it has a component

$$- \frac{2(i_1 + i_2 + i_3)}{y}$$

where y is the distance of P from the return-conductor.

If $y = x + d$, the tangential magnetic force T is approximately given by

$$T = \frac{2d(i_1 + i_2 + i_3)}{x^2}$$

and the mutual induction between the four-wire system and a small horizontal circuit of area A_2 at P is given by

$$L_{12} = \frac{2dA_2}{x^2}$$

and the induced E.M.F. e' in this circuit is given by

$$e' = \frac{2dA_2}{x^2} \cdot \frac{\partial}{\partial t} (i_1 + i_2 + i_3) \quad . \quad . \quad . \quad (25)$$

Now it is known * that the frequencies of the components into which the current $(i_1 + i_2 + i_3)$ may be divided are $3f$, $9f$, $15f$, . . . $3(2n + 1)f$, . . . In practice, several of these frequencies come within the range of audibility, and disturbing humming noises may ensue in neighbouring telephone circuits.

In this case also the electric force at P will have high-frequency components, and these can produce serious interference.

If the three-phase system be earthed at both ends the earth forms the fourth conductor and the interference will probably be worse than if a fourth wire were used. In a three-wire three-phase system when one of the conductors is out of commission the system reduces to a single-phase system and so the effects can be computed in the way we used previously.

Conclusion.

It will be seen that we have only given approximate solutions for a few simple cases. Yet if these solutions be compared with experimental results interesting conclusions will probably be inferred. We want more experimental data on the effect of the conductivity of the earth on induction. Seeing that this conductivity varies with moisture it should not be difficult to get instructive results.

We have not discussed the problem of what happens to a communication circuit when a current surge occurs in a neighbouring power line. A definite amount of electric power is transferred to the communication circuit, and so possible damage may result. O. Brauns † has stated that when the amount of energy exceeds the hundredth part of a volt-coulomb (joule) dangerous conditions may arise. It seems to me, however, that it must depend on the rate at which the energy is delivered. I can see no justification for a general theorem of this nature.

APPENDIX.

The Mutual-Capacity Coefficient of Two Spheres.

If we have two insulated conductors in infinite space and their charges per unit length are q_1 and q_2, and their potentials v_1 and v_2, the following two equations hold :—

$$q_1 = k_{11} v_1 + k_{12} v_2$$

and

$$q_2 = k_{22} v_2 + k_{12} v_1,$$

where k_{11}, k_{22} and k_{12} are geometrical constants which are difficult to calculate although sometimes easy to measure. These quantities are called capacity coefficients and attempts have been made for over a hundred years to calculate them. Only in the case of two spheres have satisfactory solutions been found.*

If we earth the second conductor ($v_2 = 0$) then the current i_2 in the earthing wire is given by

$$i_2 = -\frac{\partial q_2}{\partial t} = -k_{12}\frac{\partial v_1}{\partial t}.$$

Hence the inductive interference depends on the value of k_{12}, which is called the mutual-capacity coefficient.

* A. Russell: *Proceedings of the Royal Society*, 1920, vol. 97, p. 160.

If the radii of the spheres be a and b, and c be the distance between their centres, it can easily be shown by Poisson's method (*Memoires de l'Institut*, 1812) that

$$-k_{12} = \frac{ab}{c} + \frac{a^2b^2}{c(c^2-a^2-b^2)} + \frac{a^3b^3}{c\{(c^2-a^2-b^2)^2-a^2b^2\}} + \cdots$$

and many other formulæ for k_{12} have been found. When c is great it will be seen that this value of k_{12} is in agreement with the formulæ (6) and (7) given above.

The quickest way of obtaining the numerical value of k_{12} is to utilize the following theorem * :—

The mutual-induction coefficient between two spheres whose radii are a and b, the distance between their centres being c, equals the mutual-induction coefficient between two equal spheres the radius of each of which is $(ab)^{\frac{1}{2}}\{1 - (a-b)^2/c^2\}^{\frac{1}{2}}$ and the distance between the centres of which is $c\{1 - (a-b)^2/c^2\}$. Tables for this case have been given by Kelvin ("Reprint," p. 96) and by A. Russell (*Proceedings of the Royal Society*, 1909, vol. 82, p. 529; and *Journal I.E.E.*, 1912, vol. 48, p. 257).

NOTE ON POLYPHASE HIGH-FREQUENCY ALTERNATORS.*

By Professor SHIGETARO CHIBA, Associate Member.

(*Paper first received 27th February, and in final form 15th April, 1924.*)

Section 1.

Polyphase high-frequency alternators should find many practical applications. As an example, they might be employed with a group of antennæ for the purpose of directive transmission. Each phase of the alternator supplies a high-frequency current to one of the antennæ placed at a certain definite distance apart. For example, a three-phase alternator would be employed for supplying high-frequency currents to three antennæ separated by a distance equal to $\frac{1}{3}\lambda$. It is easily seen that the radiation from such a set of antennæ has a directive characteristic; in one direction the radiation will be very strong, while in others it will be feeble. The interchanging of any two of the three phases in such a set will permit of sending in the opposite direction.

It is well known that, in the ordinary type of machines for a given speed and voltage, polyphase machines can develop a greater output than single-phase machines of the same size, the reason being that the armature periphery is better utilized. Also for high-frequency alternators, when the tooth widths in the stator and the rotor are suitably chosen so as to bear a certain relation to each other, we arrive at the conclusion that the utilization of the armature or stator periphery is inherently far better in polyphase than in single-phase machines. This is shown in the calculations given below.

Let us take the case of a homopolar high-frequency alternator provided with polyphase windings, as shown diagrammatically in Fig. 1.

Let τ_t = rotor tooth width,†

τ_s = rotor slot width,

τ = pole pitch, i.e. distance between centres of two adjacent teeth in the rotor,

$= \tau_t + \tau_s$,

τ'_t = stator tooth width,

τ'_s = stator slot width,

τ' = distance between centres of two adjacent teeth in the stator,

$= \tau'_t + \tau'_s$.

In high-frequency alternators we take

$$\tau_s = \tau_t = \tfrac{1}{2}\tau \quad . \quad . \quad . \quad . \quad . \quad (1)$$

When the peripheral speed, V, of the rotor is given, the frequency, f, of the current produced by the alternator may be expressed by

$$f = V/\tau \quad . \quad . \quad . \quad . \quad . \quad (2)$$

The slot width and the tooth width of the rotor are then determined if this frequency f is given. The dimension of the stator slots and teeth for this polyphase alternator may be found from the relation

$$2p\tau' = (2p \pm 1)\tau \quad . \quad . \quad . \quad . \quad (3)$$

where p is the number of phases of the alternator.

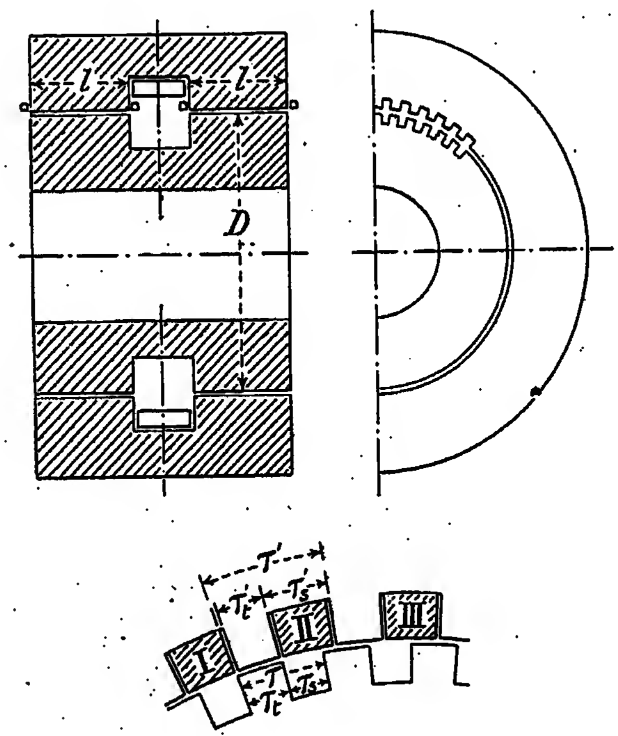

FIG. 1.

Since the number of slots n_r, n_s in the rotor and stator respectively are related to τ and τ' by the equation $n_r\tau = n_s\tau' = \pi D$, where D is the diameter of the rotor, we have, instead of (3),

$$\begin{cases} n_r = (2p \pm 1)m \\ n_s = 2pm \end{cases} \quad . \quad . \quad . \quad . \quad (4)$$

where m is any integer.

When using the relation $2p\tau' = (2p - 1)\tau$, it is preferable to choose τ'_s so that

$$\tau'_s = \tfrac{1}{2}\tau \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

and
$$\tau'_t = \tau' - \tau'_s = \frac{p-1}{p} \times \frac{\tau}{2} \quad . \quad . \quad . \quad (5a)$$

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

† All quantities are expressed in C.G.S. units (electromagnetic) unless otherwise stated.

If we use the relation $2p\tau' = (2p+1)\tau$, τ'_t should be chosen so that

$$\tau'_t = \tfrac{1}{2}\tau \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

and
$$\tau'_s = \tau' - \tau'_t = \frac{p+1}{p} \times \frac{\tau}{2} \quad . \quad . \quad . \quad (6a)$$

(*a*) *The case when* $2p\tau' = (2p-1)\tau$.—For the sake of simplicity let us assume that in the stator teeth the flux density is zero for that part not facing the rotor teeth. We then see that the flux in stator teeth 1, 2, 3, . . . p, . . . $2p$ (Fig. 2) is

$$\frac{p-1}{p}B_m l\tau_t,\ \frac{p-2}{p}B_m l\tau_t, \ldots$$
$$\frac{1}{p}B_m l\tau_t,\ 0,\ 0,\ \frac{1}{p}B_m l\tau_t \ldots \frac{p-1}{p}B_m l\tau_t \quad . \quad (7)$$

where B_m is the maximum flux density in the air-gap, and l is the axial length of the slots (see Fig. 1).

The flux between the two conductors, 1–1, of the same phase is then

$$\left(\frac{p-1}{p} + \frac{p-2}{p} + \frac{p-3}{p} + \ldots + 0\right)B_m l\tau_t$$

When the rotor moves by the amount $\frac{1}{p} \times \frac{\tau}{2}$, this flux becomes

$$\left(\frac{p-2}{p} + \frac{p-3}{p} + \ldots + 0 + 0\right)B_m l\tau_t$$

and with another displacement $\frac{1}{p} \times \frac{\tau}{2}$ of the rotor it becomes

$$\left(\frac{p-3}{p} + \frac{p-4}{p} + \ldots + 0 + \frac{1}{p}\right)B_m l\tau_t$$

and so on.

Hence we see that the minimum value of this flux is

$$\phi_1 = \left(\frac{q}{p} + \frac{q-1}{p} + \frac{q-2}{p} + \ldots \right.$$
$$\left. + 0 + 0 + \frac{1}{p} + \frac{2}{p} + \ldots + \frac{q-1}{p}\right)B_m l\tau_t$$
$$= \left\{2\left(0 + \frac{1}{p} + \frac{2}{p} + \ldots + \frac{q-1}{p}\right) + \frac{q}{p}\right\}B_m l\tau_t$$

when $p = 2q + 1$ (odd)

$$\phi_1 = \left(\frac{q-1}{p} + \frac{q-2}{p} + \ldots \right.$$
$$\left. + 0 + 0 + \frac{1}{p} + \frac{2}{p} + \ldots + \frac{q-1}{p}\right)B_m l\tau_t$$
$$= 2\left(0 + \frac{1}{p} + \frac{2}{p} + \ldots + \frac{q-1}{p}\right)B_m l\tau_t$$

when $p = 2q$ (even)

If from this position of minimum flux the rotor be displaced by the amount $\frac{1}{2}\tau$, we obtain the maximum value

$$\phi_2 = \left\{2\left(\frac{q+1}{p} + \frac{q+2}{p} + \ldots + \frac{p-1}{p}\right) + \frac{q}{p}\right\}B_m \tau l_t$$

(when $p = 2q + 1$)

$$\phi_2 = 2\left(\frac{q}{p} + \frac{q+1}{p} + \frac{q+2}{p} + \ldots + \frac{p-1}{p}\right)B_m l\tau_t$$

(when $p = 2q$)

The difference between the maximum and minimum values is

$$\phi_m = \phi_2 - \phi_1 = \frac{2(p-q)q}{p}B_m l\tau_t \quad (8)$$

and in both cases $p = 2q + 1$ and $p = 2q$.

Now consider the conductors 1–1 which interlink this flux. We see that the loop "ab" formed by these conductors links the maximum flux $\phi_2 - \phi_1 = \phi_m$ at a certain position of the rotor. After the rotor has been displaced by $\frac{1}{2}\tau$ the loop is interlinked by the same amount of the flux ϕ_m but in the opposite direction.

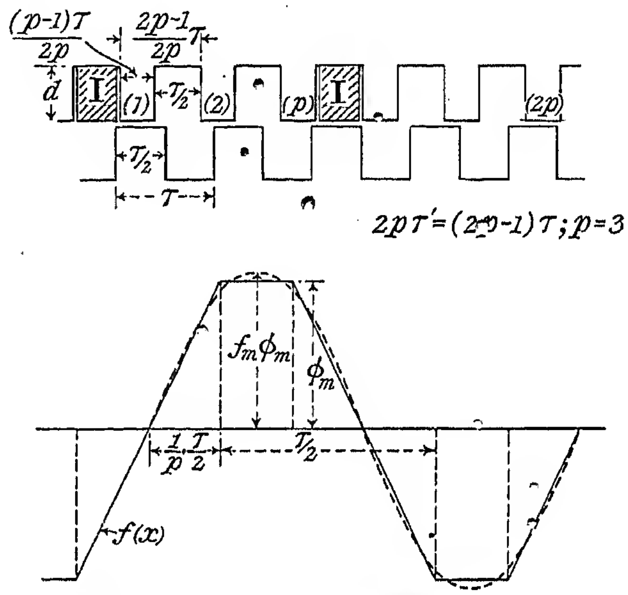

FIG. 2.

Between these two positions the flux changes in the manner shown in Fig. 2. This graph is obtained by plotting the values of the flux corresponding to every displacement $\tau/(2p)$ of the rotor. Considering only the fundamental of this curve, we can express the wave-form of the flux by

$$f_w\phi_m \sin\left(\frac{2\pi}{\tau}x\right) = f_w\phi_m \sin\left(\frac{2\pi}{\tau}Vt\right)$$
$$= f_w\phi_m \sin 2\pi f t$$
$$= f_w\phi_m \sin \omega t$$

where f_w is the ratio of the amplitude of the fundamental harmonic to the maximum amplitude ϕ_m of this flux $f(x)$.

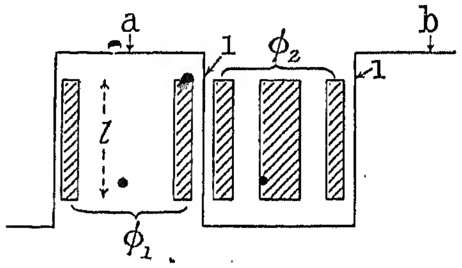

FIG. 3.

Hence the E.M.F. induced in the loop "ab" is

$$e_{ab} = \frac{d}{dt}(f_w\phi_m \sin\omega t)10^{-8} = \omega f_w\phi_m \cos\omega t \times 10^{-8}$$
$$= \omega f_w \frac{2(p-q)q}{p}B_m l\tau_t \cos\omega t \times 10^{-8} \text{ volts} \quad (9)$$

The number of the conductors in the stator periphery is

$$n_s = \frac{\pi D}{\tau'} = \pi D \frac{2p}{(2p-1)\tau}$$

and

$$\frac{n_s}{p} = \frac{2\pi D}{(2p-1)\tau} \text{ per phase} \quad . \quad . \quad . \quad (10)$$

Therefore the E.M.F. induced in one half of the stator is

$$e_{AB} = \frac{n_s}{2p} e_{ab} = \frac{2\pi D}{(2p-1)\tau} \times \frac{(p-q)q}{p} w f_w B_m l \tau_t \cos \omega t \times 10^{-8}$$

$$= \frac{\pi D}{(2p-1)} \times \frac{(p-q)q}{p} w f_w B_m l \cos \omega t \times 10^{-8} \text{ volts}$$

Since the stator is composed of two parts (see Figs. 1 and 4) and the conductors of the same phase in these

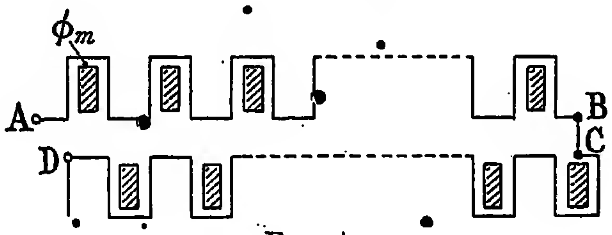

FIG. 4.

half parts are connected in series so that their induced E.M.F.'s are added, we have

$$e_{AD} = 2e_{AB} = \frac{2\pi D}{(2p-1)} \times \frac{(p-q)q}{p} w f_w B_m l \cos \omega t \times 10^{-8} \text{ volts} \quad . \quad (11)$$

E.M.F.'s of the same magnitude will be induced in the coils formed by the conductors 2–2, 3–3, 4–4,

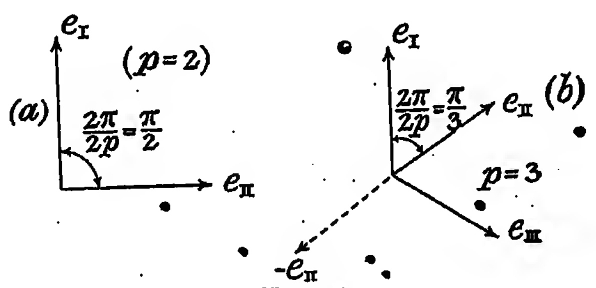

FIG. 5.

etc. But it can be seen from Fig. 2 that the E.M.F. induced in the conductors 2–2 lags behind the induced E.M.F. in the conductors 1–1 by the angle $(2\pi)/(2p) = \pi/p$, and the E.M.F. in 3–3 by the angle $2(2\pi)/(2p) = 2(\pi/p)$, and so on. When p is less than 3, these E.M.F.'s constitute p-phase voltages in the ordinary sense of the words. For example, when $p = 2$ the E.M.F.'s are related as shown in Fig. 5. When $p = 3$ the E.M.F.'s can be represented as in Fig. 5 (b), and become symmetrical polyphase E.M.F.'s if the terminals of the E.M.F. e_{II} are reversed.

When p is greater than 3, these E.M.F.'s are no longer symmetrical p-phase voltages, since the phase angle between them is now π/p instead of $2\pi/p$. The machine may be termed a $2p$-phase machine, as the E.M.F.'s e_1, e_2, e_3 . . . in one half of the stator, together with the E.M.F.'s e_1', e_2', e_3' . . . in the other half, constitute $2p$-phase voltages. In such cases we can, however, obtain symmetrical p-phase voltages if we connect the conductors in series in such a manner that the E.M.F.'s e_1 and e_2, e_3 and e_4, e_5 and e_6, etc., are added as shown in the vector diagram, Fig. 6. Hence instead of (11) we shall have

$$e_{AD} = \frac{2\pi D}{(2p-1)} \times \frac{(p-q)q}{p} w f_w B_m l \cos \frac{\pi}{2p} \cos \omega t \times 10^{-8} \text{ volts} \quad . \quad (11a)$$

when $p > 3$.

When there are currents in the stator slots, the M.M.F.'s due to these currents will modify the distribution of the flux. The induced E.M.F. on load will be different from the induced E.M.F. on no load, both in magnitude and in its phase relation to the position of the rotor. This reaction of the stator current will be considered later. For the time being we

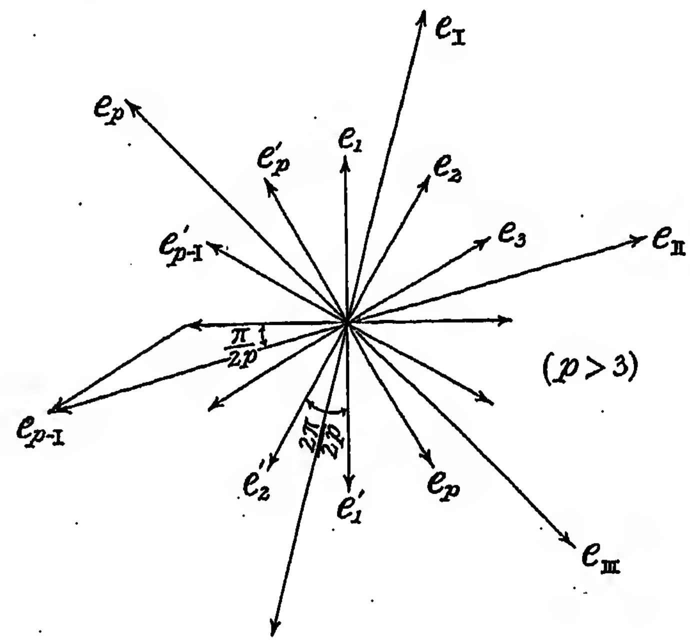

FIG. 6.

shall suppose that the induced E.M.F. remains the same independent of the load.

As the current is generally adjusted to be in phase with the induced E.M.F., we have

$$i = \delta d(\tau_s' - e) \cos \omega t = \frac{\delta d}{2} \tau (1 - \sigma) \cos \omega t \text{ (amperes)} \quad . \quad (12)$$

where δ = current density in the conductor (amps./cm²),
d = depth of the stator slot,
e = twice the thickness of insulation on the conductor,
$\sigma = 2e/\tau$.

When $p < 3$ the power developed is

$$\frac{1}{T}\int_0^{2\pi/\omega = T} e_{AD} i dt = \frac{\pi D}{(2p-1)} \times \frac{(p-q)q}{4p} (1-\sigma) w f_w (B_m \delta) d l \tau \times 10^{-8} \text{ watts per phase,}$$

and the total power of this machine will be

$$P = \frac{p}{T}\int_0^T e_{AD} i dt = \pi D \frac{(p-q)q}{4(2p-1)} (1-\sigma) w f_w (B_m \delta) d l \tau \times 10^{-8} \text{ watts} \quad . \quad (13)$$

The power output per unit length of the stator periphery is

$$\frac{P}{\pi D} = \frac{(p-q)q}{4(2p-1)}(1-\sigma)\omega f_w(B_m\delta)dl\tau \times 10^{-8}$$
$$= kf_w(B_m\delta)dl\tau f \times 10^{-8} = kf_w(B_m\delta)dlV \times 10^{-8} \text{ watts per cm} \quad . \quad (14)$$

where $$k = \tfrac{1}{2}\pi\frac{(p-q)q}{(2p-1)}(1-\sigma) \quad . \quad . \quad . \quad (15)$$

and $p = 2q + 1$ or $p = 2q$.

From (11*a*) we see that when $p<3$ this factor k becomes

$$k = \tfrac{1}{2}\pi\frac{(p-q)q}{(2p-1)}(1-\sigma)\cos\frac{\pi}{2p} \quad . \quad . \quad (15a)$$

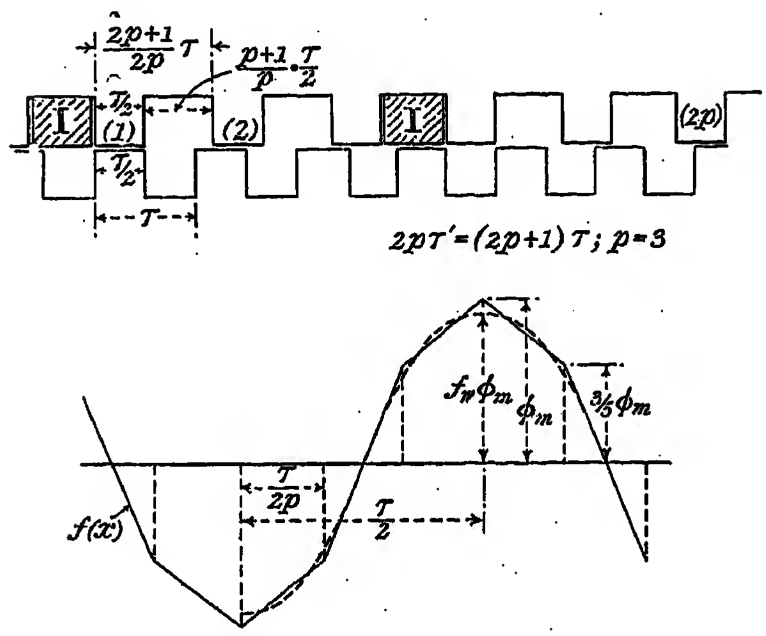

FIG. 7.

(*b*) *The case when* $2p\tau' = (2p+1)\tau$.—The flux in stator teeth 1, 2, 3, . . . p, . . . $2p$ is

$$B_ml\tau_t,\ \frac{p-1}{p}B_ml\tau_t,\ \frac{p-2}{p}B_ml\tau_t \ldots$$
$$\frac{1}{p}B_ml\tau_t,\ 0,\ \frac{1}{p}B_ml\tau_t,\ \frac{2}{p}B_ml\tau_t \ldots \frac{p-1}{p}B_ml\tau_t$$

at the instant shown in Fig. 7.

The minimum value of the flux passing between two conductors 1–1 of the same phase is

$$\phi_1 = \left\{0 + 2\left(\frac{1}{p}+\frac{2}{p}+\ldots+\frac{q}{p}\right)\right\}B_ml\tau_t \quad \text{(when } p = 2q+1)$$

$$\phi_1 = \left\{0 + 2\left(\frac{1}{p}+\frac{2}{p}+\ldots+\frac{q-1}{p}\right)+\frac{q}{p}\right\}B_ml\tau_t \quad \text{(when } p = 2q)$$

The maximum value of this flux will be

$$\phi_2 = \left\{2\left(\frac{q+1}{p}+\frac{q+2}{p}+\ldots+\frac{p-1}{p}\right)+1\right\}B_ml\tau_t \quad \text{(when } p = 2q+1)$$

$$\phi_2 = \left\{\frac{q}{p} + 2\left(\frac{q+1}{p}+\frac{q+2}{p}+\ldots+\frac{p-1}{p}\right)+1\right\}B_ml\tau_t \quad \text{(when } p = 2q)$$

Hence the difference between these two values is

$$\phi_m = \phi_2 - \phi_1 = \left\{1+\frac{2q^2}{p}\right\}B_ml\tau_t \text{ (when } p = 2q+1)$$
$$= \left\{1+\frac{2q(q-1)}{p}\right\}B_ml\tau_t \text{ (when } p = 2q) \quad . \quad . \quad (16)$$

We can now proceed as in the previous case. The calculation for $p = 2q + 1$ is given below.

When $p<3$ the E.M.F. induced in one loop is

$$e_{ab} = wf_w\left\{1+\frac{2q^2}{p}\right\}B_ml\tau_t\cos\omega t \times 10^{-8} \text{ volts} \quad . \quad (17)$$

The number of conductors per phase in the stator periphery

$$\frac{n_s}{p} = \frac{2\pi D}{(2p+1)\tau} \quad . \quad . \quad . \quad . \quad (18)$$

The induced E.M.F. of one phase is, when $p < 3$,

$$e_{AD} = \frac{n_s}{p}e_{ab} = \frac{\pi D}{(2p+1)}\left\{1+\frac{2q^2}{p}\right\}wf_wB_ml\cos\omega t \times 10^{-8} \text{ volts} \quad . \quad (19)$$

The current in the conductor

$$i = \delta d(\tau_s' - e)\cos\omega t$$
$$= \frac{p+1}{p}\delta d\frac{\tau}{2}\left(1-\frac{p}{p+1}\sigma\right)\cos\omega t \text{ amperes} \quad . \quad (20)$$

The total power

$$P = \frac{p}{T}\int_0^T e_{AD}i\,dt = \tfrac{1}{4}\pi D\frac{(p+1)}{(2p+1)}\left\{1+\frac{2q^2}{p}\right\}\left(1-\frac{p+1}{p}\sigma\right)wf_w(B_m\delta)dl\tau \times 10^{-8} \text{ watts} \quad . \quad (21)$$

The power output per unit length of the stator periphery

$$\left.\begin{aligned}\frac{P}{\pi D} &= \frac{p+1}{4(2p+1)}\left\{1+\frac{2q^2}{p}\right\}\left(1-\frac{p}{p+1}\sigma\right)wf_w(B_m\delta)dl\tau \times 10^{-8}\\ &= kf_w(B_m\delta)dlV \times 10^{-8} \text{ watts per cm}\end{aligned}\right\} \quad . \quad (22)$$

where

$$k = \tfrac{1}{2}\pi\frac{(p+1)}{(2p+1)}\left\{1+\frac{2q^2}{p}\right\}\left(1-\frac{p}{p+1}\sigma\right) \quad \text{(when } p = 2q+1) \quad . \quad (23)$$

From (16) we see that this factor k becomes

$$k = \tfrac{1}{2}\pi\frac{(p+1)}{(2p+1)}\left\{1+\frac{2q(q-1)}{p}\right\}\left(1-\frac{p}{p+1}\sigma\right) \quad \text{(when } p = 2q) \quad . \quad . \quad (23a)$$

When $p>3$, we have, instead of (23) and (23*a*),

$$k = \tfrac{1}{2}\pi\frac{(p+1)}{(2p+1)}\left\{1+\frac{2q^2}{p}\right\}\left(1-\frac{p}{p+1}\sigma\right)\cos\frac{\pi}{2p} \quad \text{(when } p = 2q+1) \quad . \quad . \quad (24)$$

$$k = \tfrac{1}{2}\pi\frac{(p+1)}{(2p+1)}\left\{1+\frac{2q(q-1)}{p}\right\}\left(1-\frac{p}{p+1}\sigma\right)\cos\frac{\pi}{2p} \quad \text{(when } p = 2q) \quad . \quad . \quad (24a)$$

Section 2.

It will be seen from the calculations given in the preceding section that for the machine of given dimen-

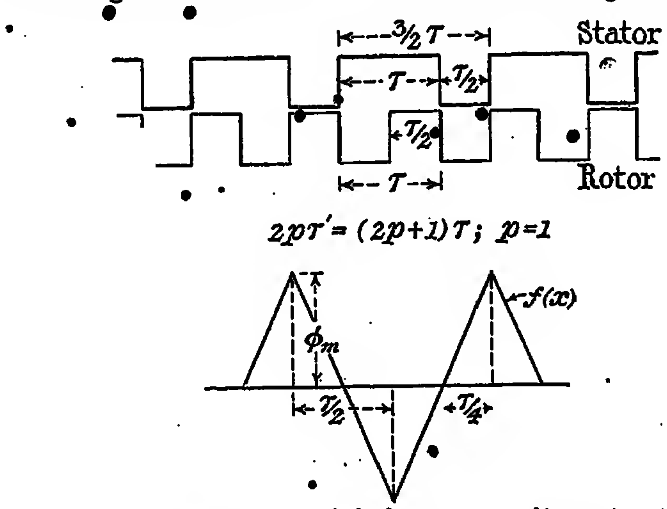

FIG. 8.—Single-phase high-frequency alternator (Société Française Radio-Electrique type).

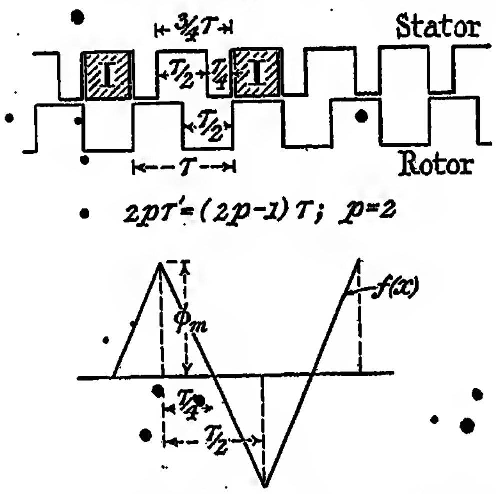

FIG. 9.—Two-phase high-frequency alternator (Latour).

sion with B_m, δ and V fixed, the relative power output may be compared by means of the factor kf_w. In Table 1 these values are given for different values of p. The value of k is calculated by means of one of the formulæ (15), (15a), (23) or (23a), and (24), (24a) for two cases. In the first case we take $\sigma = 0$, i.e. neglect the thickness of insulation on the conductor; in the second case we take $\sigma = 0\cdot1$. The factor f_w

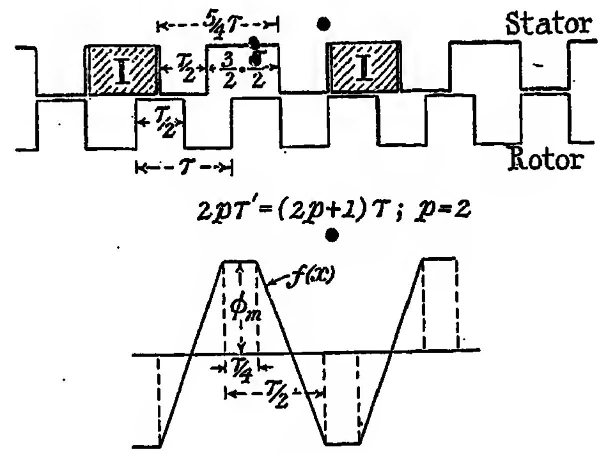

FIG. 10.—Two-phase high-frequency alternator.

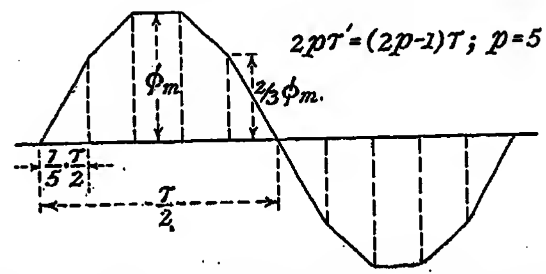

FIG. 11.—$f(x)$ curve for five-phase high-frequency alternator.

given in this table can be easily calculated if the wave-form $f(x)$ of the flux is known.

The table shows that kf_w increases steadily with p. But the number of phases cannot be indefinitely increased in practice, for τ is actually very small in

TABLE 1.

p	$2p\tau' = (2p\pm1)\tau$	f_w	k		$f_w k$		Remarks

	$12\tau' = 13\tau$	1·00 (approx.)	2·46	2·24	2·46	2·24	—

the case of high-frequency alternators and it will be a very difficult matter to construct machines which accurately satisfy the relations

$$2p\tau' = (2p - 1)\tau \quad \text{and} \quad \tau_s' = \tfrac{1}{2}\tau$$
$$\text{or} \quad 2p\tau' = (2p + 1)\tau \quad \text{and} \quad \tau_t' = \tfrac{1}{2}\tau$$

as p increases. The least discrepancy from these conditions for the widths of teeth and slots in both the stator and the rotor will greatly decrease the output of the machine. But if a lower frequency will suffice, we can take a larger value of τ. In such case a five-

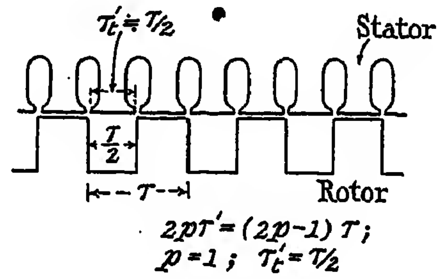

FIG. 12.

phase or six-phase alternator will be of interest, especially the latter which can be used as a three-phase machine. In order to raise the frequency, frequency-changers of saturated iron core may be employed in combination with the alternator.

There is another difficulty in the way of increasing indefinitely the number of phases p. The length of the end connection of conductors will increase, and this means an increase in the volume of copper not actually used in the production of power. At the same time the copper loss increases and the heat dissipation becomes worse. Thus we shall be obliged to reduce the value of δ which was supposed to be constant. Hence we cannot expect to obtain as great an output for large values of p as that indicated by the coefficient kf_w calculated on the simple assumption that δ is constant.

It is to be noted that when $p = 1$ in the case of $2p\tau' = (2p + 1)\tau$, this polyphase alternator reduces to the single-phase high-frequency machine of the S.F.R.* type. The two-phase machine of the type $2p\tau' = (2p - 1)\tau$ has already been proposed and described by Latour in his paper* on the high-frequency alternator of the S.F.R. type.

In the above we have taken the relation

$$\tau_s' = \tfrac{1}{2}\tau, \text{ when } 2p\tau' = (2p - 1)\tau$$
$$\tau_t' = \tfrac{1}{2}\tau, \text{ when } 2p\tau' = (2p + 1)\tau$$

But we can also imagine polyphase machines in which τ_s' or τ_t' is

$$\tau_t' = \tfrac{1}{2}\tau, \text{ when } 2p\tau' = (2p - 1)\tau \quad \ldots \quad (25)$$
$$\tau_s' = \tfrac{1}{2}\tau, \text{ when } 2p\tau' = (2p + 1)\tau \quad \ldots \quad (25a)$$

Calculations of kf_w in these cases show that these types cannot develop as much power as the others. It may here be mentioned that ordinary single-phase homopolar machines may be considered as machines of class (25) (see Fig. 12).

We shall next consider briefly the flux variation in the stator and rotor teeth. The flux variation in the

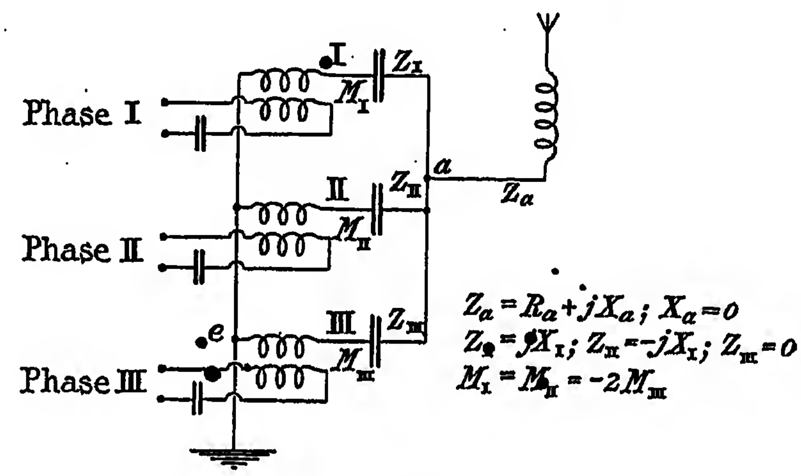

FIG. 14.

stator has a frequency f. Since we have, from (4), the relation $n_s = 2pn_r/(2p \pm 1)$, we see that the flux variation in the rotor teeth has a frequency $2pf/(2p + 1)$ or $2pf/(2p - 1)$, according as $2p\tau' = (2p + 1)\tau$ or $(2p - 1)\tau$. Take, for example, the three-phase alternator of type $6\tau' = 5\tau$. If we suppose, for the sake of simplicity, that the flux density is uniform over the whole cross-section of the teeth—the condition which holds approximately at the bottom of these teeth—then the variation of the flux density in one tooth may be represented by Fig. 13 (a). In this case the frequency of the flux-change in the stator is f, while that in the rotor is $6f/5$.

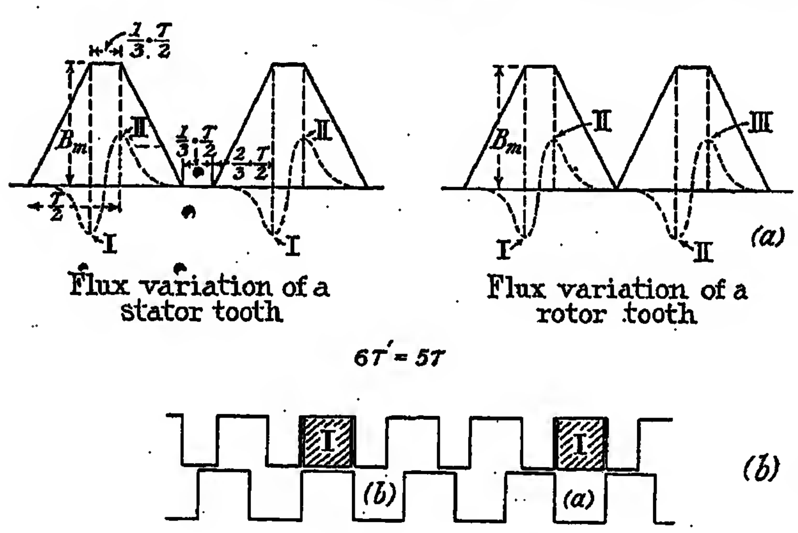

FIG. 13.

In addition to these variations there are the flux variations due to the M.M.F.'s of currents in the slots. When the current is in phase with the induced E.M.F., the stator and the rotor of this three-phase alternator will take the position shown in Fig. 13 (b) at the moment when the current of phase I is a maximum. It is seen that the effect of the M.M.F. due to this current is far greater for a tooth at (a) than for a tooth at (b). Neglecting this reaction of the current on the tooth flux when the teeth are at positions such as (b), the flux-change in the stator and rotor teeth will be somewhat similar to that represented by dotted lines in

* Société Française Radio-Electrique.

* *Radio Review*, 1921, vol. 2, p. 403.

Fig. 13 (*a*). So long as the teeth are supposed not saturated, this flux variation due to the current has no influence on the magnitude of the induced E.M.F., but it will retard its phase to a slight extent. When the current component is in quadrature with the induced E.M.F., the magnitude of the E.M.F. will change at the same time.

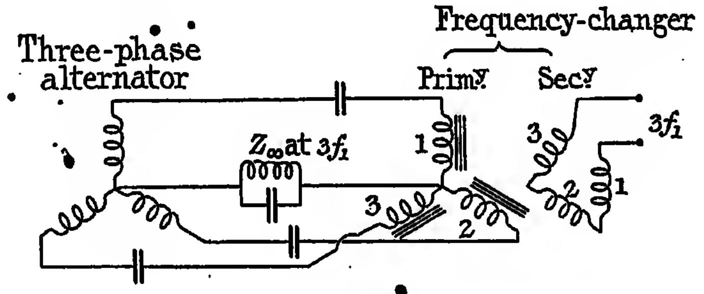

FIG. 15.

We have taken here the case of a three-phase alternator as an example for considering the flux variation in the stator and the rotor. When p becomes greater, this flux variation will be more complicated, especially when p is an odd number. In that case all the teeth in the stator or the rotor will not undergo the same flux variation.

Polyphase machines may also be used for ordinary antennæ. By a certain disposition the polyphase energy can be converted into single-phase energy.* In Fig. 14, the voltages of a three-phase alternator are impressed on the primaries of transformers I, II and III. If the coefficients of mutual inductance of these transformers and of the impedances Z_{I}, Z_{II}, Z_{III} and Z_a are suitably chosen, it is possible to make each phase of the alternator give the same current and power. If we suppose that the circuits aIe, aIIe and aIIIe have no resistance, the conditions for the balanced working of the alternator are as indicated in Fig. 14. It is also assumed here that the primaries of the transformers I, II and III have the same coefficient of self-induction, and that their circuits are adjusted in resonance with the frequency of the alternator.

Polyphase machines are especially adapted to the production of current of higher frequency. To illustrate this, let us take a three-phase alternator supplying three-phase current to the primaries of three frequency-transformers having saturated iron cores (Fig. 15). If the secondaries are correctly connected the voltages of the fundamental frequency disappear completely, but the third-harmonic voltages add together. Thus a current having a frequency three times that of the fundamental may be utilized in the secondary circuit. As the induced E.M.F. in the secondary of such frequency-transformer contains the fifth harmonic in addition to the third, a similar disposition may be adopted for a five-phase alternator to obtain the fifth-harmonic current.

APPENDIX.

Since this paper was written, the author has found that three-phase high-frequency alternators have already been invented by Frank.* Such machines are diagrammatically represented in Figs. 16, 17 and 18. The stator and rotor pitches have the following relations :—

$$\sigma\tau' = 4\tau \quad \text{(Fig. 16)}$$
$$\sigma\tau' = 2\tau \quad \text{(Figs. 17 and 18)}$$

if we adopt the same symbols.

By a method similar to that described in the present paper, the factors k and f_w can be easily calculated for these machines. Let us assume the same maximum flux density B_m in the air-gap (which means a higher density in the stator teeth than was assumed for the machines dealt with in the paper) and the same current

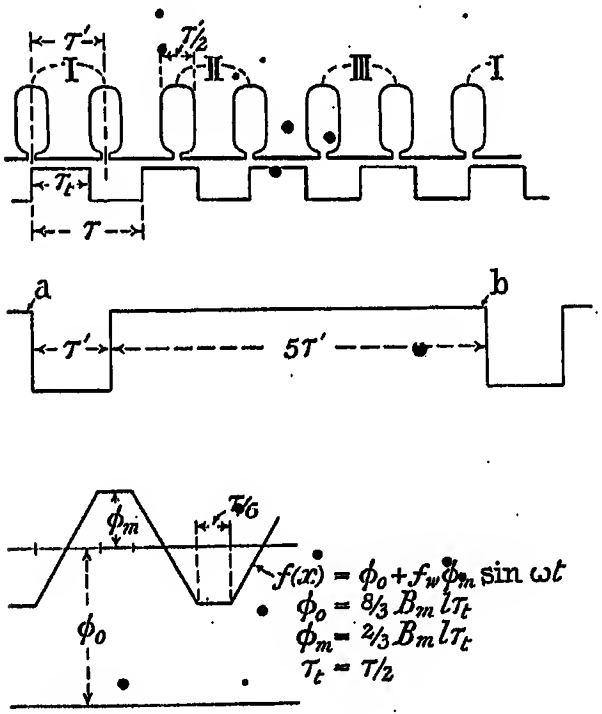

FIG. 16.

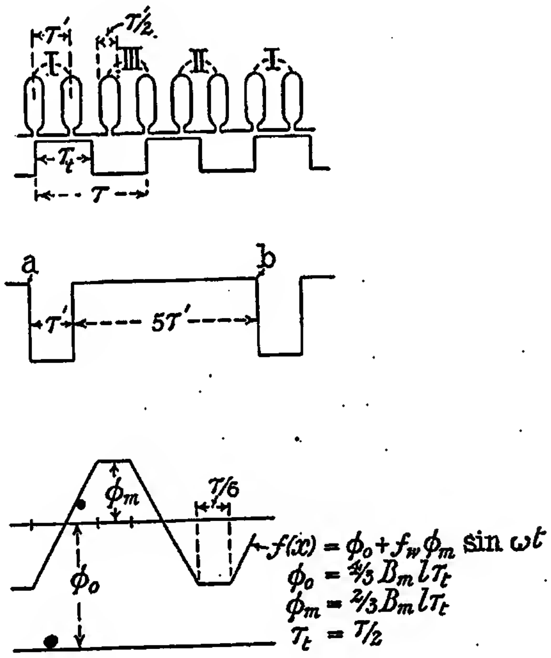

FIG. 17.

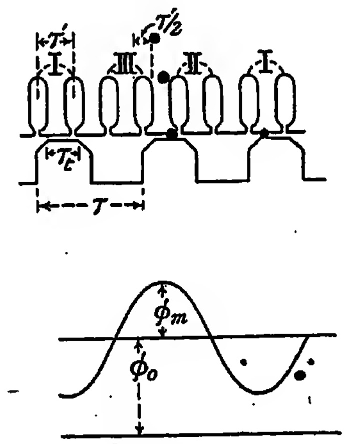

FIG. 18.

* The method adopted in the case of a two-phase alternator is described in Latour's paper (*loc. cit.*).

* *Jahrbuch der drahtlosen Telegraphie*, 1923, vol. 22, p. 44.

density δ. If we take the width of the coil to be equal to half the stator pitch, and neglect the thickness of insulation, we get

$$k = \frac{\pi}{\sigma} = 0\cdot524;\ f_w = \frac{\sigma\sqrt{3}}{\pi^2} = 1\cdot05$$

and
$$kf_w = \frac{\sqrt{3}}{\pi} = 0\cdot550$$

Even the machine in Fig. 12 is better than these machines from the point of view of utilization of the stator periphery, since kf_w is greater.*

This is because the conductors of the same phase in these machines are not arranged at equal distances, so that the flux curve $f(x)$ contains a large amount of constant and idle flux ϕ_0 with relatively small variable and useful flux ϕ_m. The inventor claims that the form of the rotor shown in Fig. 18 improves the wave-shape, but the power developed by the machine is not increased.

* $k = \pi/4 = 0\cdot785$: $f_w = 8/\pi^2 = 0\cdot81$: and $kf_w = 2/\pi = 0\cdot635$.

ELECTRICAL SIGNALLING EQUIPMENT ON RAILWAYS.

By V. Mitchell, Student.

(Abstract *of paper read before the* North Midland Students' Section, 29*th January*, 1924.)

Summary.

This paper is intended, not to give a detailed consideration of a subject upon which it is difficult to theorize, but rather to bring to the notice of engineers, who are mostly engaged on high-power plants, the achievements of a little-known department of all railway companies, the object of the department being to protect moving and stationary vehicles. The paper gives a very brief description of the evolution of the lock-and-block system of signalling and the uses of the track circuit as now employed on the Midland section of the London, Midland and Scottish Railway.

Ordinary Block System.

The expression "block system" may be defined as "A method whereby the traffic on a railroad is so regulated that only one train or vehicle occupies any one section of the line at the same time." To effect this the system must be divided into sections, each section to be termed a "block section."

Under the Regulation of Railways Act, 1899, the adoption of this system by all companies was made obligatory.

The principle of block working is well known; electrical indicators are provided to guide the signalman in the manipulation of the mechanical signals, which in their turn are provided for the guidance of engine drivers.

Three-Wire Single-Needle Block.

This was the first type of instrument used for the operation of the ordinary block; each instrument is capable of giving three indications, i.e. "line blocked" (normal position), "line clear" and "train on line." The signalman in charge of the disposal of the train can, by a single-stroke bell, call the signalman ahead, and by arranged signals inquire if the section ahead is unoccupied; if so, the signalman ahead (by a mechanical arrangement) gives the signalman in charge of the train the indication "line clear." On the train entering the section ahead the indication "train on line" is given. By this arrangement the signalman can tell the state of the section ahead and controls his mechanical signals accordingly.

Interlocking.

The arrangement just considered cannot be said to provide any additional safety for the train, the signalman still being able to work his mechanical signals irrespective of the block indications. This was soon realized, and it was decided to interlock the electrical indicators and the mechanical signals.

The requirements of an interlocking system are :—

(1) That the starting signal must not be lowered until "line clear" is given from the section ahead.

(2) That on placing the block indicator to "train on line" it is locked in that position until the train has passed through the section.

(3) That the signalman can at any time put his signals to danger.

(4) That the starter must be replaced before the indicator can be moved to "line clear."

Single-Needle Interlocking Block.

This was an improvement on the first type mentioned. On moving the indicator to "line clear" an electrical lock on the starting signal in the rear is liberated. On moving the indicator to "train on line" the instrument is locked in that position until the train passes over a contact maker under the rails, inside the home signal. Mechanical arrangements were made to comply with clauses (3) and (4).

Rotary Interlocking Block.

The interlocking block had now brought some degree of protection for the train; this was carried still further by the introduction of the rotary interlocking block. "line clear" position owing to a deviation, or otherwise, of the train concerned. This is obtained by both signalmen simultaneously pressing a cancel button, which picks up a "line clear" cancel lock in the instrument

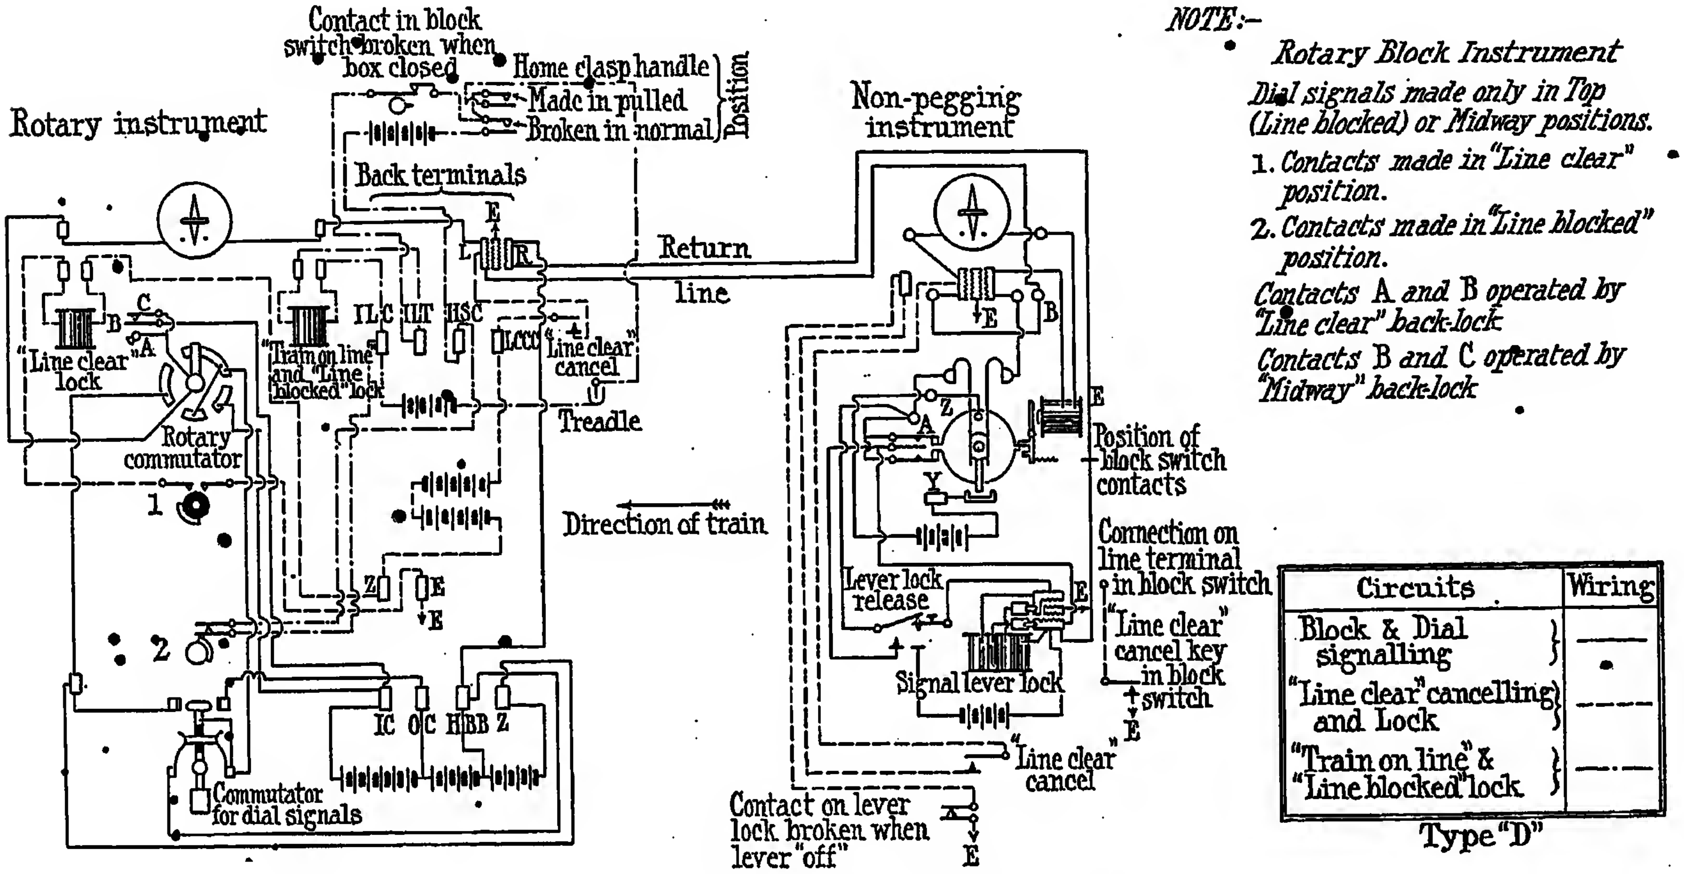

Fig. 1.—Rotary interlocking block.

A complete description of the instrument and the functions of the different parts cannot be given, but much information can be gained from Fig. 1. The indicating handle was changed to a commutator which,

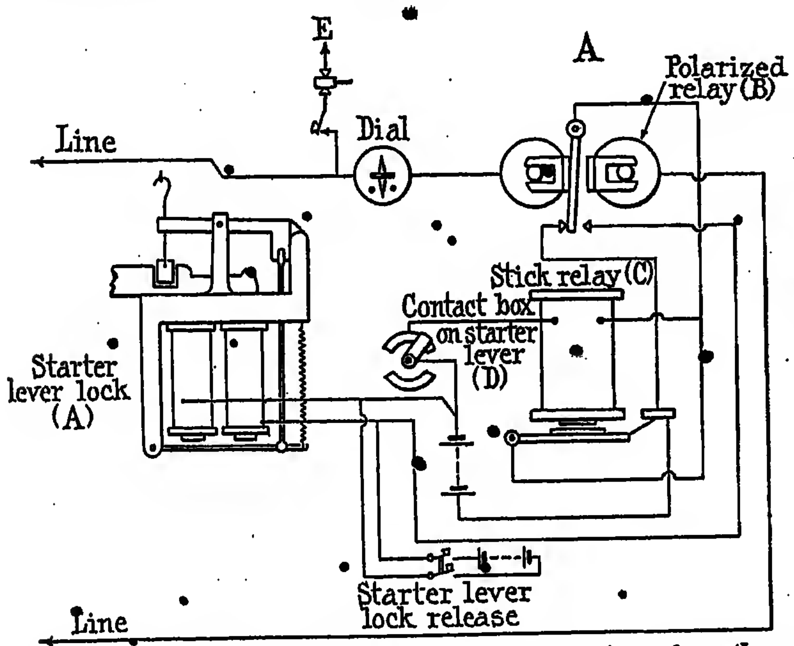

Fig. 2.—Rotary interlocking block; connections for relay working.

except in the "line clear" position, would only rotate in one direction, thus compelling the signalman to carry out the functions in correct sequence. A co-operative cancel is provided should the signalman require to take his handle back to normal from the and allows the signalman to move his handle to the normal position. Cancels are provided to obtain release should the contact maker or treadle fail to pick up the "train on line" lock on the passage of the train through the section; to obtain release the signalman must break a glass cover over the cancel key, which must afterwards be sealed up by the lineman.

A recent addition to the rotary interlocking block is the relay rotary block which is designed for places where signal boxes are closed on Sundays, as many as five block sections being switched to form one long section, the electrical connections being shown in Fig. 2.

Track Circuit.

The methods considered have all been for the protection of moving trains and become useless if no provision is made for vehicles which may have become detached from other trains, or have been left foul inadvertently. They may be standing out of sight of a signal box round a curve, or in a dense fog or tunnel. Indication of the presence of these vehicles is given to the signalman by means of a track circuit. The rails are bonded together with iron or copper bonds to give good conductivity for current from a battery situated at one end of the bonded track. The track is insulated from the rest of the system by means of insulated joints. The battery supplies the holding current for a relay joined across the other end of the track, and this relay controls the signal protecting the track. A train or vehicle standing on the track will

provide a shunt of sufficiently low resistance to drop the relay, thereby breaking the lock circuit for the signal protecting the track. This signal cannot be pulled "off" until the vehicle or train occupying the track has moved from danger (see Fig. 3).

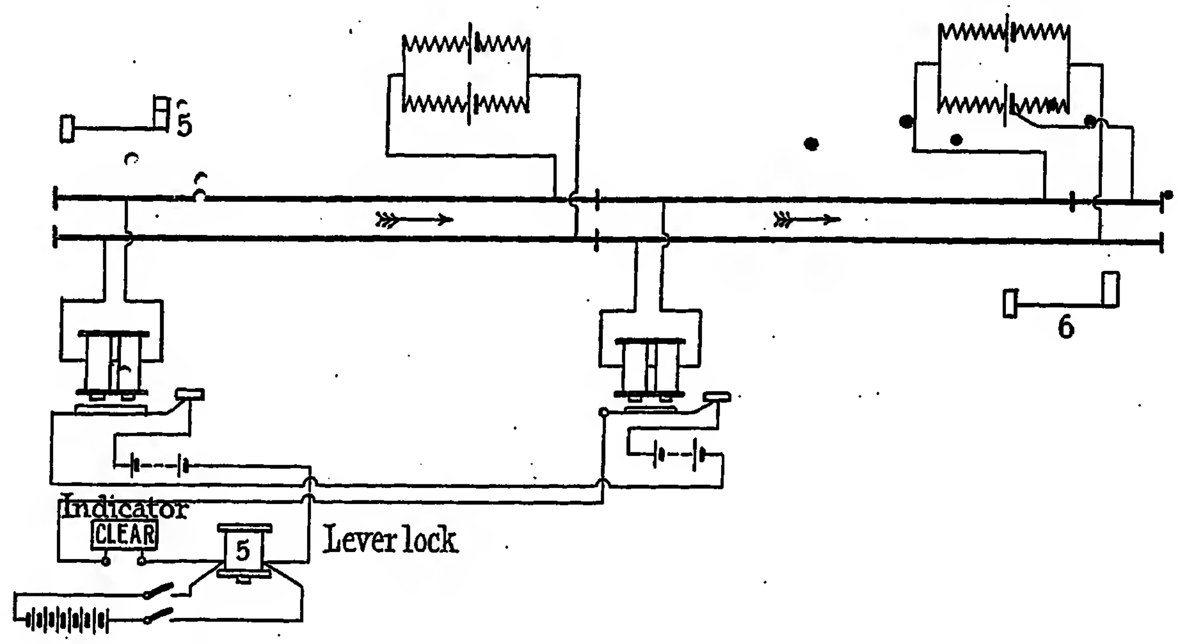

FIG. 3.—Connections for track circuit; two subsections.

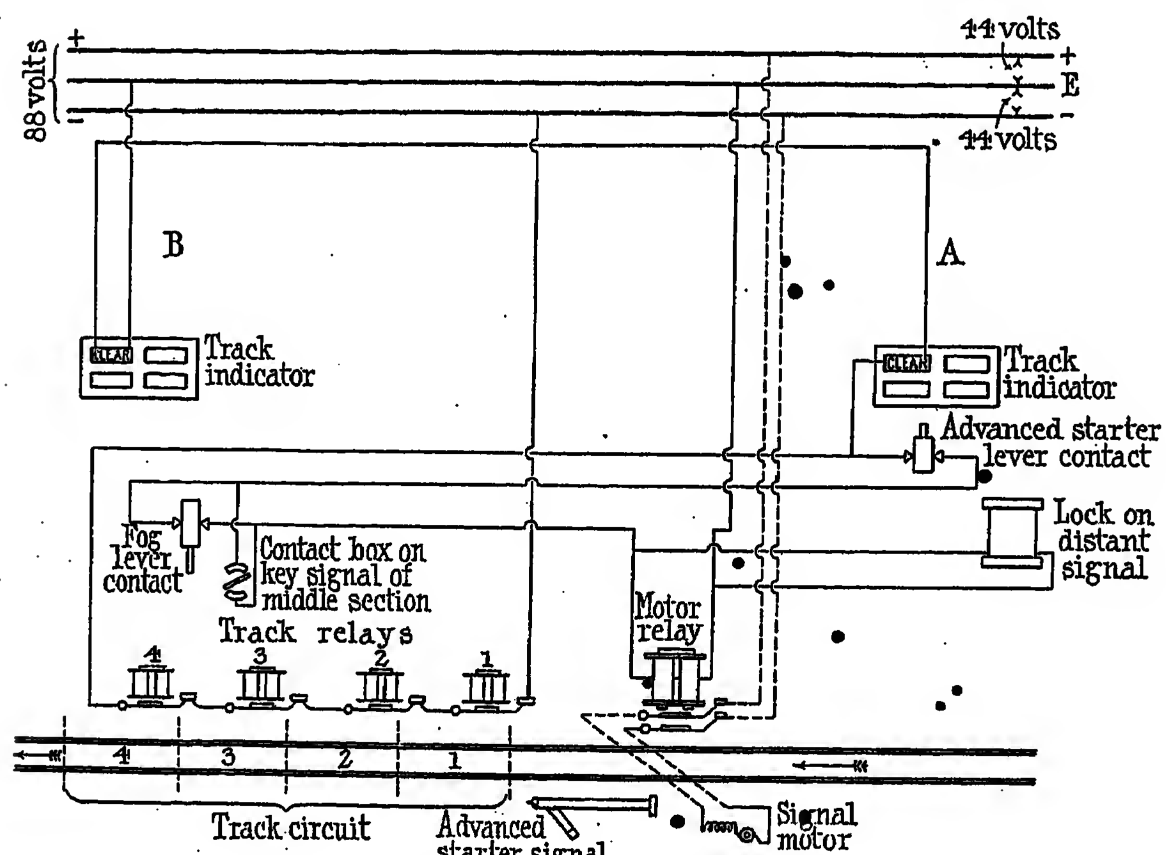

FIG. 4.—One section of semi-automatic signalling connections.

SEMI-AUTOMATIC SIGNALLING.

It was found that where long sections existed between signal boxes on busy lines, delay was caused by the length of time taken by trains to pass one at a time through the block sections. To avoid this delay the track circuit was utilized to spread out the traffic over the long section. Another block section having its own signals controlled by track circuits between two signal boxes, which can under certain conditions be controlled by the signalmen in these signal boxes, is installed, this section taking its share of the distribution of the traffic (see Fig. 4).

THE EFFECT OF THE SHAPE OF THE TRANSMITTING AERIAL UPON OBSERVED BEARINGS ON A RADIO DIRECTION-FINDER.*

By R. L. SMITH-ROSE, Ph.D., M.Sc., Associate Member.

[From the National Physical Laboratory; communicated by permission of the Radio Research Board.]

(*Paper first received 14th June, and in final form 13th August, 1924.*)

SUMMARY.

For the explanation of the variable errors encountered chiefly at night on radio direction-finders, modern theory implies the reception of waves arriving at an appreciable angle of elevation and polarized so that the magnetic field has a horizontal component in the plane of propagation. Previous experimenters have shown that such abnormally polarized waves can be radiated from certain kinds of aerials when situated at a considerable distance from the earth's surface, as in the case of an aeroplane transmitter, and that such waves when arriving at the earth's surface can produce very appreciable errors on a radio direction-finder. The experiments described in the present paper were carried out to determine to what extent the emission of these abnormally polarized waves by aerials of different shapes from a ground transmitting station was responsible for the frequent occurrence of variable "night" errors at a ground direction-finding station. It is concluded that the frequency and magnitude of these errors are independent of the shape of the transmitting aerial, within the limits of this investigation, and that the use of a source of radiation which is, as far as possible, only polarized in the normal manner, in no way diminishes the night effects generally experienced.

1. THE THEORY OF THE ERRORS OF APPARENT BEARINGS OF RADIO DIRECTION-FINDERS.

To account for the variable errors which are experienced under certain conditions in the observed bearings given by the closed-loop type of radio direction-finder, a theory was put forward by Eckersley † in 1920, which ascribed the errors to the reception of an indirect wave arriving at the receiver in a downward direction, the polarization of this wave being such that it possessed a horizontal component of magnetic field in the plane of propagation. The direct wave travels horizontally along the earth's surface and arrives at the receiver polarized with the magnetic field horizontal and at right angles to the plane of propagation.

For the purpose of clarity here and throughout the paper it is desirable to define some of the terms used in connection with the propagation of wireless waves. A wave is considered to be normally polarized when the electric force is contained in a vertical plane. The intersection of this plane with the surface of the earth is the path which is assumed to be taken by the direct wave when it is unaffected by any deviations or distortion. In a normally polarized wave, therefore, the magnetic force will always be horizontal and at right angles to the plane of propagation, whatever may be the actual direction of propagation within this plane. A closed-loop direction-finder rotating about a vertical axis will thus always indicate the true direction of arrival of such a normally polarized wave. If an error in bearing arises with such a wave, it indicates that the plane of travel of the wave is not the meridional plane between transmitter and receiver, i.e. that the wave has been subject to lateral deviation.

For an abnormally polarized wave, however, it is possible, but not necessary, that the magnetic force will have a horizontal component which is *not* at right angles to the plane of travel of the wave. In the extreme case in which the electric force is horizontal and the direction of propagation is inclined to the horizontal, the above component of magnetic force is *in* the plane of propagation. Such a wave arriving alone would evidently give a 90° error on a direction-finder and when it is received together with the direct wave the resultant horizontal magnetic field may give an error of any intermediate value from 0° to 90°, and if the phases of the two waves differ, all the effects connected with rotating fields and elliptical and circular polarization are possible.

Reception during the daytime is assumed to be carried out chiefly or entirely by the direct wave, and the errors in observed bearing on a loop rotating about a vertical axis will consequently be small. At night, however, the effect of the indirect wave is superimposed upon that of the direct wave, and, depending upon the relative magnitudes and phases of the horizontal components of their magnetic fields, errors in apparent bearings up to 90° and the common occurrences of blurred minima can be accounted for. The theory is elaborated in some detail in Eckersley's original paper, and certain experiments are described, the results of which confirm the deductions drawn from the theory.

The indirect wave arriving at the receiver in the vertical plane of propagation but inclined at an angle to the horizontal may have its origin in two causes. In the first case it may be due to the radiation from the unbalanced horizontal portions of the transmitting aerial where this is of the inverted-L type, such radiation being abnormally polarized, so that the magnetic field has a component in a vertical direction. After reflection from the lower horizontal surface of the hypothetical

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

† T. L. ECKERSLEY: "The Effect of the Heaviside Layer on the Apparent Direction of Electromagnetic Waves," *Radio Review*, 1921, vol. 2, pp. 60 and 231.

Heaviside layer this wave would provide at the receiver the necessary component of horizontal magnetic field in the plane of propagation. If, however, the transmitting aerial is symmetrical about a vertical axis, then the radiation will be normally polarized. Such radiation even after reflection from the horizontal surface of an upper ionized layer will always arrive at the receiver with the magnetic field horizontal and perpendicular to the plane of propagation, and can thus never give rise to an error in apparent bearing. To explain any observed errors with the indirect wave polarized in this manner it is therefore necessary to assume that there is a change in the plane of polarization at the reflecting surface, due either to the latter not being horizontal or to some other cause.

In an article published about the same time as Eckersley's a qualitative outline of practically the same theory was given by Bellini,* from which it was concluded that the radiation from the horizontal portions of the transmitting aerial, arriving at the receiver after reflection from the Heaviside layer, would give rise to the errors in bearings experienced. The whole effect is analogous to the reception of waves transmitted from an aeroplane in such a position that it subtends an appreciable angle of elevation at the receiver. Errors in bearing arising from this cause had previously been noted by Adcock and Round,† the sign of the error depending upon the direction of travel of the aeroplane relative to the receiver, and its magnitude only reaching zero for the two cases in which the machine is flying to or from the direction-finder.

A detailed investigation of this effect of the reception of abnormally polarized waves from an aeroplane has been carried out by Baldus and Buchwald.‡ For an aeroplane at a fixed point in space they showed that the errors in apparent bearing at a ground direction-finding station varied with the orientation of the transmitting aerial and might be as great as 60° in certain cases. The magnitude and variations in the error shown by the various experiments carried out are only partially accounted for by the theoretical analysis of the problem carried out by Burstyn.§ In this calculation, however, the earth was taken as a perfect conductor, whereas some of the experiments indicated that the finite conductivity of the earth greatly affected the result.

Quantitative measurements of the intensity of the field in the radiation from an aeroplane have been carried out at a ground station by Baldus and Hase.‖ By comparing the measurements obtained on both vertical and horizontal aerials the abnormal polarization of the waves due to the shape of the aeroplane antenna was demonstrated. In the endeavour to find a form of aeroplane antenna which would eliminate the error at the ground direction-finding station, it was shown that the nearer the aerial approached the form of a vertical Hertzian oscillator the less became the magnitude of the error caused by it. Reciprocal experiments in which the strength of field from a ground transmitting station was measured in the aeroplane were made by Buchwald and Hase,* and these confirmed the shape of the characteristic radiation curves found for the L type of trailing antenna normally employed in aeroplanes.

There appears, therefore, to be experimental evidence in existence which shows: (*a*) that the arrival of an abnormally polarized wave in a direction which is not horizontal will in general give rise to an error in the bearing observed at a ground direction-finding station; and (*b*) that a type of bent-L antenna which contains an unbalanced component of horizontal current will, in free space, emit waves which are in part abnormally polarized. The experiments described in the present paper were carried out with the object of determining whether it was necessary for the waves to be abnormally polarized at the transmitter in order to give rise to the errors included in class (*a*) above.

2. Origin of Investigation and Arrangement of Experiments.

In an investigation of all the errors encountered in wireless direction-finding which has been conducted on a wide scale by the Radio Research Board since 1921, a large amount of data has been accumulated, the work of reduction of which is now well advanced. With a view to ascertaining the effect, if any, of the dimensions and shape of the transmitting aerials, details of these were sought from the authorities responsible for the respective stations whose transmissions had been used for observation purposes. Up to the time of writing, however, details have been received for the British stations only. A graphical representation of the variations in bearing experienced on those stations which have an inverted-L aerial with a long horizontal portion pointing in a known direction, shows that there is no definite relation between the direction of the receiving station relative to the transmitting aerial, and the variations in bearings experienced, whereas such an aerial should not radiate an abnormally polarized wave in its own plane. In other cases, where the transmitting aerial is known to have no unbalanced horizontal portions, very appreciable variations have been experienced during the periods of observation. Although the effects are necessarily somewhat difficult to establish with certainty, owing to the large number of other variables such as distance, geographical features, etc., which accompanied these observations, the only general conclusion which can be drawn is that no evidence is supplied that the errors or variations in observed bearings are in any way dependent upon the radiation of abnormally polarized waves from the transmitter. These observations were made on wave-lengths from 2 to 10 km, employing both damped and undamped waves.

The present experiments originated in a suggestion made by Prof. G. W. O. Howe in 1920 to Committee C of the Radio Research Board, that an experimental transmitting station should be set up at which the conformation of the aerial could be altered and its effect

upon a directional receiver at a distance could be studied. Various considerations precluded the possibility of the erection of an aerial of sufficient vertical and horizontal dimensions for the carrying out of the experiments at long wave-lengths, and 450 m was ultimately selected as the wave-length, damped waves from a spark transmitter being employed. From other observations which had been in progress for some time it was known that the effects observed would not be fundamentally different on any other wave-lengths within wide limits, nor would they differ with the use of undamped waves.

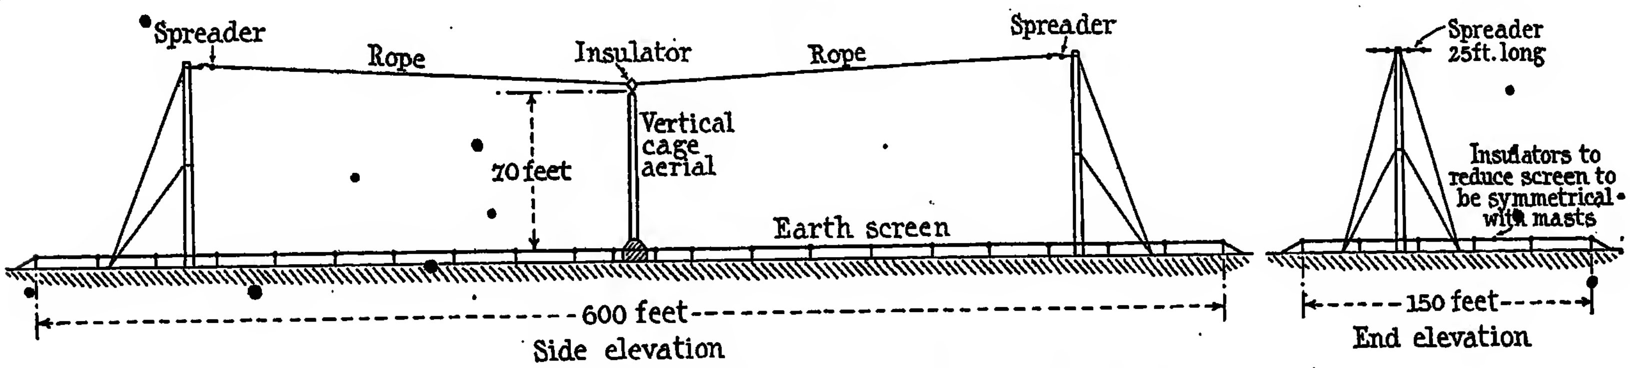

FIG. 1.—Side and end elevations of vertical-aerial arrangement.

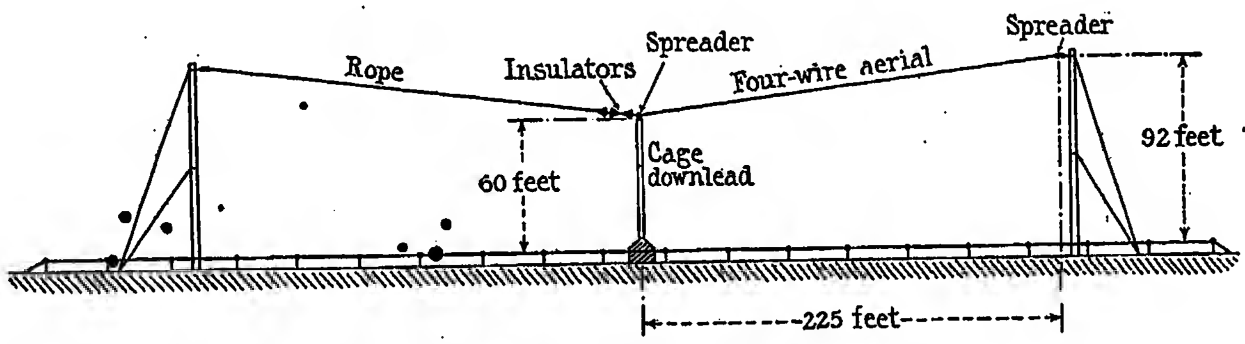

FIG. 2.—Side elevation of inverted-L aerial.

The aerial employed for these experiments at the National Physical Laboratory is slung between two wooden masts 100 ft. high and 450 ft. apart, the guy wires to these masts being split up into short lengths by porcelain insulators. The horizontal portion of the T aerial normally used is formed of four wires equally spaced on 25-ft. spreaders. An earth screen 600 ft. × 150 ft. is employed, being supported on porcelain insulators on wooden posts, the average height of the screen above the ground being about 8 ft. Owing to lack of space the masts were not situated quite symmetrically with respect to the screen, but insulators were provided in the screen wires by which the overhanging portion could be cut off, the width of the screen being thereby reduced to 100 ft.

3. Procedure of Experiments.

The general mode of procedure in this investigation was to set up one type of aerial and then make daily transmissions of special signals for two 2-hour periods, one of which was located near mid-day and the other near midnight. Observations of the apparent bearings were made on these transmissions at the two direction-finding stations at Slough and Orford, which are respectively 11·5 and 93 miles distant from Teddington. With each type of aerial employed this daily procedure was repeated for a fortnight, without making any alteration whatever, so as to obtain a fair average of the observed direction-finding conditions during both day and night periods. The transmissions from Teddington took place at 10-minute intervals and were interspersed with similar transmissions from Orford. At this station the transmitting aerial of the normal T shape was retained throughout the whole of the experiments, and the corresponding observations made at Slough afford what is in the nature of a check on the prevailing direction-finding conditions in the different periods.

The experiments were commenced with a fortnight's test made with the T aerial and the full width of the earth screen. A vertical aerial was then erected in the form of a four-wire cage of 3 ft. diagonal suspended

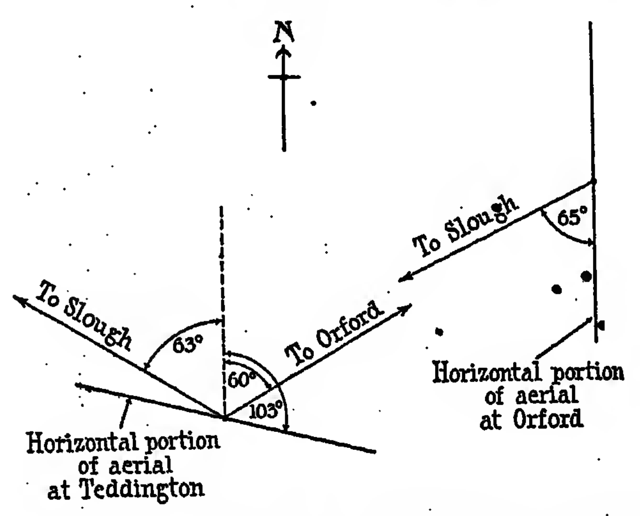

FIG. 3.—Plan of transmitting aerials relative to directions of receivers.

from the centre of two hemp ropes carried between the spreaders slung from the top of the masts. The height of this cage was about 70 ft. from the screen, and the portion above the screen was adjusted as closely vertical

as possible, the lead-in to the transmitting hut being taken below the screen and being only about 4 ft. in length. An elevation of this vertical aerial arrangement is shown in Fig. 1. With this vertical aerial two tests of a fortnight's duration each were carried out, in the second of which the earth screen was reduced in width as mentioned above. This arrangement provided exact symmetry of intersection of the screen by any vertical plane through the aerial. This alteration produced no noticeable effect on the observations made at the receiver, however, and the symmetrical screen was retained in all the remaining experiments. For the inverted-L aerial, one half of the horizontal top of four wires on a 25-ft. spreader was replaced, the other half being retained as rope. The elevation of this aerial is shown in Fig. 2 from which it is seen that the ratio of horizontal spread to vertical lead is 225/92 = 2·45. After a fortnight's test with this arrangement the free end of the aerial was changed over to the other mast,

4. Summary and Discussion of Results Obtained.

Tables 1 and 2 give a summary of the observations obtained at Slough on the transmissions from Orford throughout the investigation. The results are given as weekly summaries, and the day and night periods are separated as stated. A summary of the observations of apparent bearings made at Orford upon the transmissions from Teddington throughout the whole series of experiments is given in Tables 4 and 5. The simultaneous observations made at Slough are summarized in Table 3, the day and night readings being here combined since there was no perceptible difference between them.

Considering Table 1 in the first instance, it will be seen that over the whole period of about six months' working, large numbers of observations show a comparatively small variation in apparent bearing for day transmissions. The extreme values are less than 3° different from the mean and, with one week's exception,

* True bearing of Teddington at Orford = 240·6°.

giving the equivalent of a rotation of the inverted-L aerial through 180° in a horizontal plane. With the completion of observations on the transmission from this type of aerial, a few check readings were taken on transmissions from the original T aerial.

The horizontal portion of the aerial at Teddington was in a direction approximately 103° from true North, and the direction of Orford was 60°, so that the latter direction made an angle of 43° with the horizontal portions of the aerial. At Orford the transmitting aerial was practically due North and South, so that the direction of Slough made an angle of 65° with the horizontal portion of the aerial (see Fig. 3).

The direction-finding stations employed at Orford and Slough were of the standard Marconi-Bellini-Tosi pattern and do not call for any special comment, beyond the statement that the aerial loops were used in the untuned condition throughout.

all the observed readings differ from the mean by less than 2°. The majority of the larger variations recorded, and particularly the reduced average in the week excepted above, were due to the presence of interfering signals at the time of observation. The mean observed bearing shows an average difference of the order of 1° from the true value. Referring to Table 2 it is seen that during the corresponding night periods a totally different state of affairs prevailed. It was the general rule throughout all the periods of observation that the bearings observed were very erratic and in many cases very difficult to obtain. In actual figures it is seen that in the majority of cases a very small percentage of the observed bearings were within 2° of the mean value, and in many cases less than 25 per cent were within 5° of the mean. This greatly reduced accuracy is due to the prevalence of the well-known night conditions in direction-finding, the extreme

flatness of the signal minima and the rapidity with which the apparent bearings changed making it impossible to determine any bearing in from 26 per cent to over 76 per cent of cases.

The observations recorded in Table 3 made on transmissions over the comparatively short distance from Teddington to Slough, show that for both day and night periods the extreme variations are approaching the limits of accuracy of the direction-finding apparatus. Of the total observations made, amounting to nearly 1 000, the maximum deviation is 1°. It will be noted that in this case there is a permanent error of about 3·5° which has been shown by observations on a portable direction-finder to be due to the site of the Slough station.

type of aerial employed. The T and vertical types of aerial, which have no unbalanced horizontal currents, gave rise to errors in observed bearings ranging up to 30·7°, and during the individual weeks' tests it was impossible to obtain a bearing at all in from 43 per cent to 86 per cent of cases. During the four weeks' tests carried out with the inverted-L aerials, the errors recorded were of somewhat larger order and ranged up to 75°. It is doubtful, however, if this is very significant, as the extreme observations which give rise to this figure were taken with very large angles of swing (from 80° to 140°). These figures make the readings very unreliable, and the observations would probably have been better classed with the "no minimum" variety. It should also be noted that the extent of

* True bearing of Teddington at Orford = 240·0°   † Swing of extreme readings = 80°.   ‡ Swing of extreme readings = 140°.

Reverting next to Tables 4 and 5 it is seen that the change of aerials at Teddington produces no distinctive effect on the bearings at Orford. The day readings show a total variation which is of the usual order for propagation over distances approaching 100 miles, and in every case all the readings are within 2° of the mean. The whole summary, in fact, shows a striking resemblance to the corresponding observations made in the reverse direction, viz. from Orford to Slough, and this similarity, as contrasted with the effects observed between Teddington and Slough, appears to indicate that the effects are not local to either transmitting or receiving station, but are due to some variation in conditions over the path of transmission.

In a very similar manner the readings taken during the night periods (Table 5) do not show anything distinctive which can be definitely associated with the variation of Orford's bearings at Slough vary greatly for the different weeks' summaries.

The proportion of readings recorded as missed on account of the above absence of minimum is seen to range from 40 per cent to 65 per cent for the L aerials and is thus quite comparable with the corresponding figures for the T and vertical aerials. With all the types of aerials employed it will be seen that it is comparatively seldom that more than 30 per cent of the readings are within 2° of the mean value, or more than 40 per cent within 5° of the mean.

5. CONCLUSION.

The general conclusion to be drawn from this experimental investigation is therefore that all attempts made to arrange the conformation of the transmitting aerial so as to prevent the emission of radiation polarized in such a manner that the electric field is horizontal and

magnetic field vertical, have been unsuccessful in materially reducing the occurrence of night effects encountered at a distant direction-finding station. If, therefore, Eckersley's theory of night errors is correct, the abnormally polarized component of the downcoming waves would appear to be due either to the reflecting layer not always being horizontal, or to the effect of the earth's magnetic field in causing a rotation of the plane of polarization of the waves on reflection at the upper ionized layer.*

It should be remarked that the intensity of this reflected wave must quite often be greater than that of the direct wave, for it was frequently observed during the tests that the strength of signal in the maximum position of the search coil by day was less than the strength at night when the coil was perpendicular to this. Fading of the received signals at Orford was also noted with all the aerials employed at Teddington.

These experiments were carried out for the Radio Research Board under the direction of the Committee on Directional Wireless, the members of this Committee being as follows:—Mr. F. E. Smith, C.B.E., F.R.S. (*Chairman*); Mr. F. W. Davey; Mr. C. E. Horton, B.A.; Capt. C. T. Hughes, M.C., R.E.; Dr. J. Robinson, M.B.E.; Dr. G. C. Simpson, F.R.S.; Dr. R. L. Smith-Rose; and Mr. O. F. Brown, M.A., B.Sc. (*Secretary*).

The author wishes to acknowledge the valuable services rendered during this investigation by the following assistants:—Petty Officer R. Taylor and Telegraphist G. A. Williams, at Orford; Messrs. R. H. Barfield, M.Sc., S. R. Chapman, B.Sc., and M. G. Bennett, B.Sc., at Slough; and Messrs. E. L. Hatcher and A. C. Haxton, at Teddington.

THE NATURE AND REPRODUCTION OF SPEECH SOUNDS (VOWELS).

By Sir Richard Paget, Bart.

(*Lecture delivered before* The Institution, *20th March*, 1924.)

Human speech forms in a special degree a bond between the physicist and the electrical engineer. Take, for example, the question of the range of human speech. The gibbon can be heard at a range of six miles, whereas under the best natural conditions the range of human speech is only of the order of half a mile. By the art of the telephone engineer, however, the balance has been handsomely redressed, and, in America, the human voice has been heard by cable at a distance of over 5 000 miles, while by wireless telephony transatlantic conversation is beginning to be possible.

The amazing development of the telephone, and of cabled and wireless transmission of speech, has been produced to a large extent without any very close investigation of the mechanism by which the sounds were originally produced. But now, especially in the hands of the Western Electric Company of America, refined analysis of the nature of speech sounds is being made. A more intimate knowledge of the human acoustic mechanism may be of assistance to the electrical engineer, besides affording to the physicist a little relaxation in the course of his strenuous pursuit of the electron.

The first scientific explanation of the differences between the vowel sounds was that given by Willis, of Cambridge, in 1828. Willis showed that each separate vowel sound depended on a characteristic resonance set up in the human mouth. He also reproduced a number of vowel sounds by means of a vibrating reed (corresponding to the human vocal chords) and a tubular resonator. I will demonstrate this effect by means of a tubular resonator with a reed set in a plunger which moves up and down the tube so as to vary the vowel sound produced when air is blown through the reed.

About 1834 Wheatstone at King's College, London, made his talking machine—on the lines of one previously made (about 1760–1770) by de Kempelen, but with various improvements. In this device (exhibited by the courtesy of King's College) Willis's tubular resonator is replaced by a cup-shaped cavity and the vowel sounds are produced by covering the orifice by the hand so as to vary its aperture.

In the sixties of last century Helmholtz further developed Willis's theory, but added the observation that some vowel sounds depended on two characteristic resonances set up in the vocal cavity. He also devised the Helmholtz resonator. The late Lord Rayleigh clarified the whole subject of the resonance of a cavity which was small in comparison with the wave-length of its natural resonance, and he even investigated mathematically the behaviour of two Helmholtz resonators joined in series. The human voice appears to be entirely produced by Helmholtz resonance—not by tubular resonance of the wind-instrument type.

As illustrating the principles of Helmholtz resonators, I have here three egg-shaped resonators, their cubic capacities being 185, 70 and 30 cm^3 and the diameters

of their orifices being 25–26, 15–15·5, and 7·5–8 mm respectively. All three models shown give the same note (512 ∾) when blown as whistles by means of a rubber tube, but the larger resonators produce vibrations of greater amplitude. For this reason men, women and children, with voices of very different pitch (due to the different lengths of their vocal chords), can still speak alike, as far as pronunciation is concerned, in spite of the difference in size of their resonating cavities.

In the English language, at least, the vocal chords are not an organ of speech; they are a vehicle of speech. Practically all the essentials of the English language are found in whispered speech. [The lecturer then whispered the following: "If I put my vocal chords out of action, by separating them as in breathing, so that the air that passes through my vocal cavities is not vibrating but is merely turbulent, I can still speak so as to be understood at a moderate range." The words were clearly heard throughout the lecture hall.]

It was as if, in the beginning, man roared by nature in the open, but taught himself to whisper in the cave, and as if the essentials of language were first based on whispered sounds. Then, perhaps, came the discovery that if the whisperer roared at the same time, the roar acted as what would now be called a "carrier wave" for the whispered sounds.

This ingenious device has not yet been developed to its logical conclusion, and therefore almost all languages still consist of a jumble of voiced and unvoiced sounds. These differ enormously in carrying power.

Experiments which I have carried out with Miss Sylvia Paget show that in general the effect of voicing a vowel sound is to increase its carrying power from 10 to 20 times, as compared with the range of the corresponding whispered or unvoiced sound.

There is, I believe, only one language in which the roar and the whisper are perfectly combined—in other words, in which all the sounds are voiced—and that is the dialect of my native county of "Zummerzet." In that dialect all the sounds have a carrying power of the same order, besides all having the added beauty of musical inflection and melody. The "Zummerzet" dialect ought without doubt to become the standard form of English for all telephonic and broadcasting purposes!

In investigating the nature of human speech it is obviously simplest to start (as other investigators have done) with whispered speech.

It appears that in the case of every vowel sound the vocal cavity is producing two audible resonances. Some of these double resonances can be made audible by clapping the hands in front of the mouth, so as to drive air into it in sharp puffs and create resonance; and the upper and lower resonances can be varied independently so as to produce two scales in contrary motion.

The resonances heard in my own voice are shown in Fig. 1. It will be noticed that the two resonances of the vowel sounds e (men) and ɐ (earth) have similar intervals (measured in semitones), also æ (hat) and U (put), and that ʌ (up), ɑ (calm), ɒ (not), ɔ (all), o (know) and u (who) all have approximately the same interval between their upper and lower resonances.

This suggests that the vowels of the three series might be phonographically transformed or translated by varying the speed of the record, as has been done by Preece and Stroh (*Proceedings of the Royal Society*, A, 1879, vol. 28, p. 358) and D. C. Miller ("Science of Musical Sounds," p. 232).

I will illustrate the translation of e (men) to ɐ (earth), or æ (hat) to U (put), and of ʌ (up) to ɑ (calm), ɒ (not), ɔ (all), o (no) and u (who), by means of records of the three original vowels made on the dictaphone, the transformation being produced by appropriately reducing the speed of the revolving cylinder.

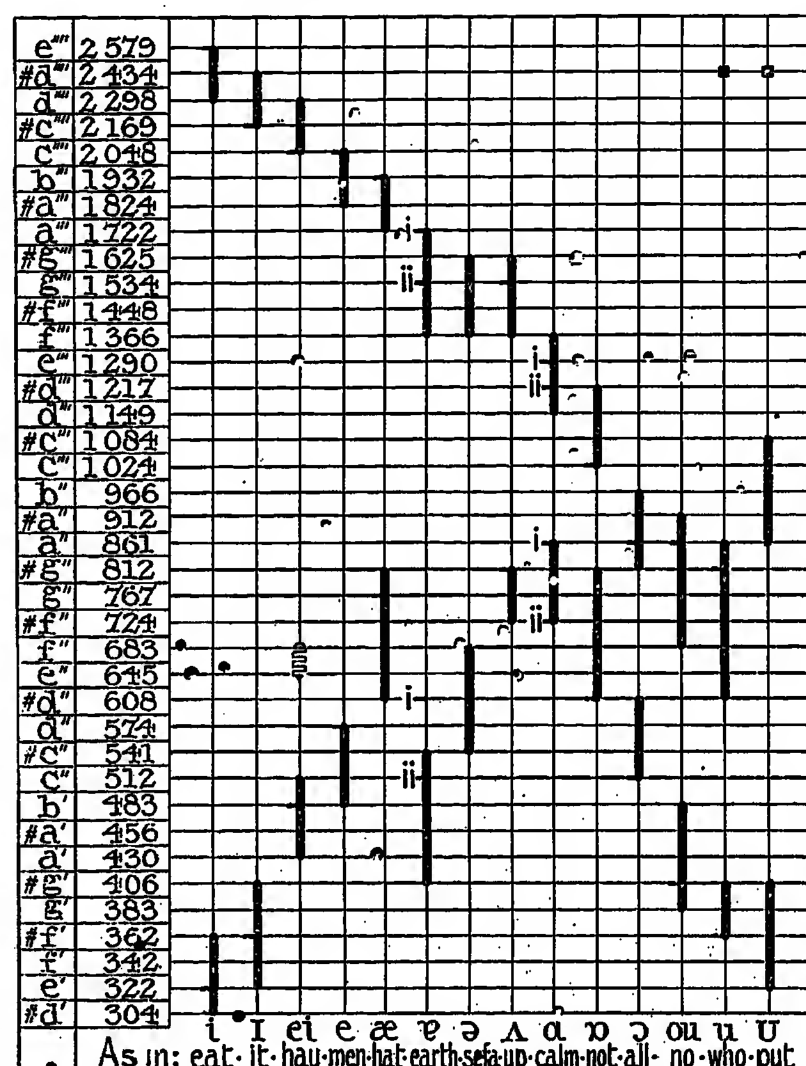

FIG. 1.—Resonances in Sir Richard Paget's voice.

Experiments with an artificial plasticine mouth show that the double resonances are produced by what are in effect two Helmholtz resonators in series, one behind the tongue and the other in front of it, the tongue operating as a movable stop of variable aperture. The two resonators are found to react on one another (as had been already indicated by Lord Rayleigh), but in the human mouth the necessary corrections are performed automatically.

I propose to blow, on Lord Rayleigh's demonstration organ (lent by the Royal Institution), plasticine resonators fitted with organ reeds and tuned to the resonances of the vowel sounds a (calm), e (men), I (it), ɔ (all) and U (who); also to blow other vowel models by mouth.

The conclusions arrived at are: (1) Whispered vowels are due to air passing through two Helmholtz resonators in series or in parallel; (2) voiced vowels

are produced by substituting vibrating air for a simple air-stream; and (3) Willis's fixed-pitch theory is confirmed.

The double-resonant character of all the English vowel sounds was published in *Nature* in March 1922. In April 1922 the idea suggested itself that these double-resonant vowel sounds might be produced electrically, by substituting electrical resonating circuits for Helmholtz resonators. Dr. Eccles promised to try the experiment. Before the opportunity occurred, however, the idea was independently evolved, and the experiment tried—with success—by Mr. John Q. Stewart in the Research Laboratory of the Western Electric Company of America.

Stewart's letter to *Nature* of July 1922 gave a diagram of his circuits (see Fig. 2) and stated:—

"Appropriate adjustments of the resonant circuits 1 and 2 were observed to result in the production of all

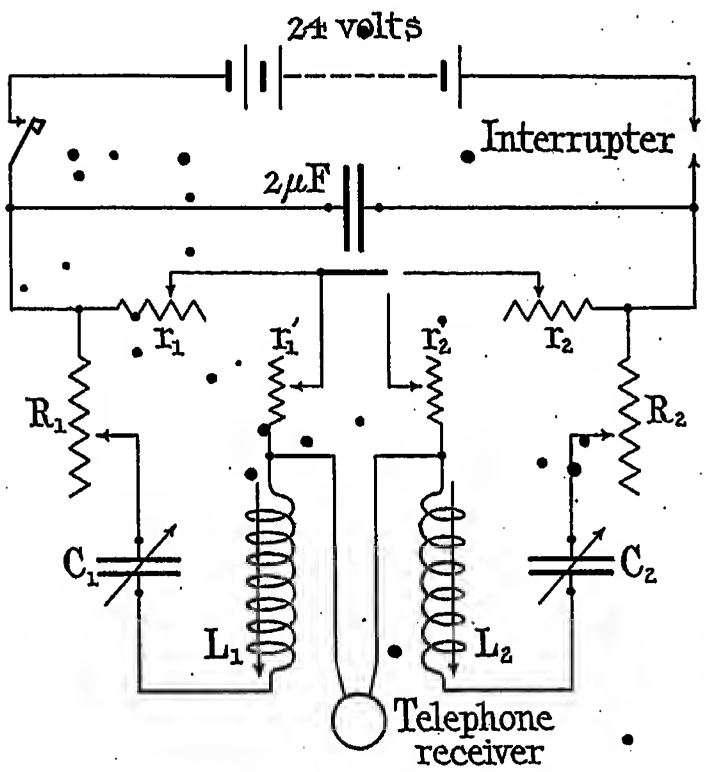

FIG. 2.—Circuit used by Mr. J. Q. Stewart.

the various vowels and semi-vowels in turn. Alteration of the frequency or damping of either resonant circuit was observed to result in alteration of the vowel produced. The frequency of interruption, which was the group frequency of the recurrent damped oscillations, was observed to determine the pitch of the vowel; but it did not determine what vowel was produced. It was found possible to produce the whispered vowels with interruptions that were non-periodic.

"The first three vowels given in this table are each characterized by a single train of recurrent damped oscillations; the remaining three are characterized by two trains of recurrent damped oscillations."

Dr. Eccles's experiment, which was first shown at the Royal Institution in 1923, differed in several interesting respects from Stewart's. In Dr. Eccles's arrangement (see Fig. 3) there were two sending circuits each of which could give six frequencies of different amounts over one million per second. The receiving circuit oscillated at one million per second and therefore sent to the loud-speaker heterodyne beats at audible frequency corresponding to the difference between one million and the two sending-station frequencies respectively. In the apparatus here shown, the interrupter which represents the "larynx" is connected to the sending circuits so that these are brought into action alternately; and persistence of audition in the human ear combines the two alternate frequencies into a single vowel-like sound. [The vowel sounds *i* (eat), ɔ (all), e (men), u (who), ɑ (calm) and ɐ (earth) were then reproduced.]

The experiments of Stewart and Eccles respectively give good confirmation of the theory of double resonance, though Stewart's apparent production of a (calm), ɔ (all), u (who) by single resonance needs explanation.

There is another respect in which a close analogy exists between the phenomena of acoustic and electrical transmission of vibratory energy—which has been pointed out by Mr. Rollo Appleyard, who wrote:—

"We are learning to think electrically. The reason for this is that the various factors that enter into calculations in electrical circuits can be more easily

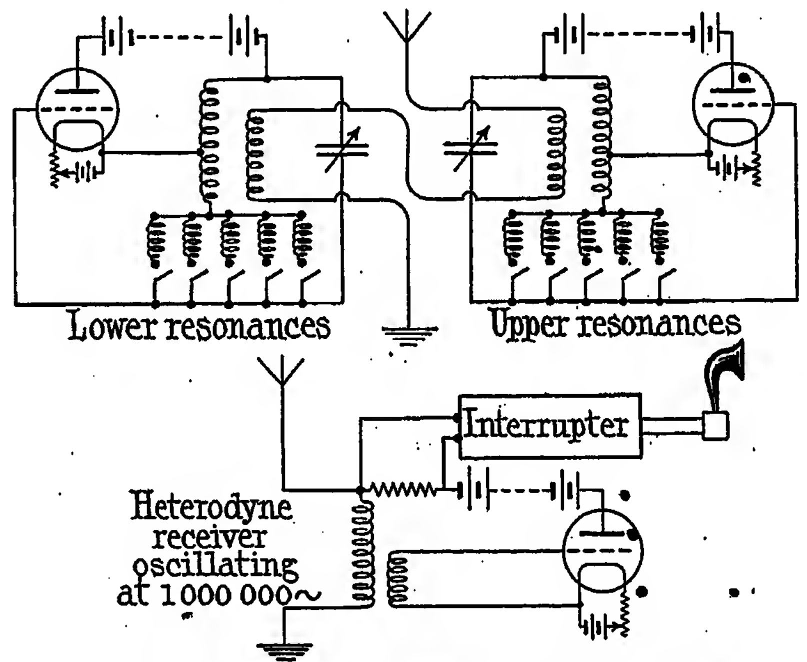

FIG. 3.—Arrangement used by Dr. W. H. Eccles.

measured, and isolated from one another, than is possible with their mechanical or acoustic analogies—when free, forced, coupled and compound vibrations are taken into account.

"Your vowel-resonators are a case in point. Their determining characteristics are, in general parlance, their shape, volume, and material. If we think electrically, however, we realize that they, their contents, and their surroundings, must be defined ultimately in terms analogous to the four cardinal attributes: resistance, inductance, capacity, and leakance. Hence, we examine them, and their associated acoustic system, for their equivalents: friction, inertia, elasticity, and slip or leakage. Further we are led to realize that these may, in some circumstances, be variables, depending upon 'frequency' and that we are consequently concerned, in our energy equations, with 'effective' values of the four cardinal attributes.

"Thanks to the work of Newton, who associated the transmission of sound with the motion of the pendulum

and gave us the earliest conception of an elastic medium through which pulsations are transmitted by successive condensations and rarefactions ("Principia," Second Part, Section VIII), thanks to the work of Lagrange ("Œuvres," vol. 1, p. 79) who solved the problem of a vibrating loaded catenary, and to the labours of Fourier, who, in 1822, taught physicists how to calculate the flow of heat along a metal bar, the way was prepared for Kelvin, Blakesley, Rayleigh, Heaviside, Pupin, Breisig, Fleming, and others to interpret the riddle of transmission, and of the attenuation of oscillatory electric currents of 'frequencies' within speech limits, through extended conductors. For any given 'frequency' the result is now clearly expressed in terms of those same four cardinals: resistance, inductance, capacity, and leakance.

"In recent years, yet another step has been taken. It is now realized that, in order that a current impulse may pass from one section of an electrical network to another, with minimum loss of energy, and with minimum distortion, the characteristics of the one section, expressed in terms of what I have here (for distinctiveness) called the four cardinals, must as nearly as possible resemble the characteristics of the other, in like terms. At a surface of transition there is energy-loss, unless the characteristics on each side of that surface are identical. At an intermediate surface of transition, there is, in general, reflection and attenuation; and at the end surface, there is, in general, reflection, to account for the energy-loss.

"May we not, by means of these energy relationships, develop a broad generalization which shall link acoustics and electrical transmission with mechanics, and thus complete the picture?

"For the telephone diaphragm the translation of energy has already been analysed by A. E. Kennelly and G. W. Pierce (see *Proceedings of the American Academy of Arts and Sciences*, 1912, vol. 48, p. 113).

"An illuminating study of the energy problem, including a summary of this work of Kennelly and Pierce, will be found in the Kelvin Lecture delivered by Professor J. A. Fleming to the Institution of Electrical Engineers on May 10, 1923."

The task of measuring the four cardinals in the case of acoustic systems, so that their performance can be predicted with the same certainty as that of their electrical analogies, offers much opportunity of useful acoustic research to the physicist.

Returning now to human speech, it is safe to affirm that the consonants are as essentially musical as the vowels—that they are also Helmholtz resonator effects—but that they differ from the vowels in being more complex and particularly in having (in many instances) components of much higher pitch than the vowels.

The consonants, or some of them, also differ from the vowels in another respect, namely, that they depend for their effects on our ears upon the rate of change of the frequency of their component resonances.

The vibration of the air in a system of resonators may be set up by a vibrating diaphragm. Thus an electrically-driven diaphragm (that of a "clear-hooter" horn) in which the horn has been replaced by a double resonator can be progressively changed so as to sound the word "away"—by varying the area of the front orifice by hand.

A variable double resonator may even be made by the operator's two hands working in conjunction with an artificial air-blown larynx of variable pitch, as in my device, the "Cheirophone."

I will blow this first by bellows to demonstrate the production of the various vowel sounds and subsequently by mouth to produce artificial speech—the latter requiring a more exact timing of the air supply.

[The names "Oliver Lodge" and "Vernon Boys" were pronounced, and the lecturer concluded with three cheers, on the Cheirophone, for "the Physical Society on the occasion of its Jubilee, not forgetting the great Institution in whose building the celebrations are being held."]

NORTHOLT RADIO STATION.

By A. C. WARREN, B.Sc., Student.

(ABSTRACT *of paper read before the* LONDON STUDENTS' SECTION, *9th May*, 1924.)

SUMMARY.

The paper gives a brief description of the equipment at the Post Office Radio Station at Northolt, near Harrow, and a survey of some of the experimental investigations which have been carried out at the station, namely :—

(*a*) The installation of a 30–40 kW valve transmitter.
(*b*) The design of a coupled circuit for the arc sets.
(*c*) Trials on a Lorenz alternator.
(*d*) Investigation into the losses occurring in transmitting inductances.
(*e*) Tests on insulating materials.

DESCRIPTION OF THE STATION.

Introductory.—The Northolt Radio Station is a medium-power telegraphic relay station capable of working a continuous service over a range of 1 000–2 000 miles at speeds up to 60 words per minute. The transmitting equipment consists of two arc sets and one valve set capable of delivering 16 and 30–40 kW respectively into the aerial. The transmission is controlled from the Central Radio Office, G.P.O. West, at which all reception is carried out.

Aerial system.—The main aerial is supported from three wooden lattice masts each 446 ft. high arranged in the form of an equilateral triangle of 650 ft. side. The lead down is taken from the centre of one side of the triangle and is led into the building through an insulator fitted in a glass window 6 ft. square. The earth system consists of copper plates and strip buried under the full area enclosed by the masts. The aerial constants are : Capacity, 7 000 $\mu\mu$F ; natural wave-length 2 000 m ; resistance 2 ohms at 6 950 m.

Power supply.—Power is obtained from the Uxbridge Power Supply Co. at 6 600 volts, three-phase, 50 periods, and is transformed down to 415 volts. Motor-generator sets giving 650 volts and 110 volts (d.c.) are provided for the main and auxiliary supplies to the arc sets. The valve set is run from the a.c. supply which is transformed up and rectified to give 8 000–18 000 volts (d.c.).

Transmitting plant.—The arc sets are of the Elwell-Poulsen type and are designed for a maximum input of 40 kW. Under working conditions the arcs are run through a coupled circuit, an input of 20–30 kW giving an aerial current of 45–55 amperes. The overall efficiency of the arcs is 25–30 per cent.

The valve set is equipped with a rectifying unit consisting of six silica valves which are fed from a three-phase transformer, three-phase full-wave rectification being employed. The oscillator unit comprises six silica valves or three water-cooled metal valves, and with the latter an output of 30 kW gives 110 aerial amperes. The overall efficiency is 50–55 per cent and the efficiency of the transmitting valves 75–80 per cent.

The normal wave-lengths of transmission are 6 950 m for the arc sets and 5 780 m for the valve set. Transmission is effected by means of marking and spacing waves, the difference between the two wave-lengths being of the order of 50 m.

OUTLINE OF THE DEVELOPMENT WORK.

Design and installation of the valve transmitter.—This work was commenced as soon as the arc sets had been installed. The design was necessarily largely experi-

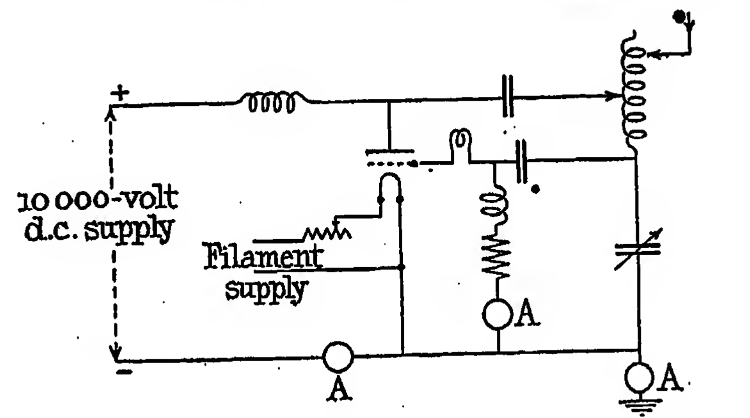

FIG. 1.

mental, as no set of this power had previously been attempted by the Post Office. Having in view the design of future high-power stations, the equipment was retained for experimental investigations.

The circuit is a modification of Colpitt's arrangement and is shown in skeleton in Fig. 1. Since the filaments of both rectifying and transmitting valves are fed from the three-phase supply, the only running machines necessary are the air compressor for the Creed key and the air blower for cooling the valve seals.

Two types of transmitting valve have been tried, namely, the Mullard silica valve and the Western Electric Co.'s water-cooled metal valve. The relative capacities of these are tabulated below.

Valve	Dissipation	Full-load output	Maximum anode voltage	Filament consumption
	kW	kW	volts	watts
Silica ..	2·5	7	10 000	720
Water-cooled	10	10	10 000	900

Installation of a coupled circuit for the arc sets.—A coupled circuit was designed and installed within a few

weeks of the station being put into commission. This had the effect of practically eliminating harmonic radiation, but under certain conditions the circuit became unstable.

The frequency of the oscillations generated is determined by the resonant frequency of the circuit shunted across the arc. If a secondary circuit is coupled to the

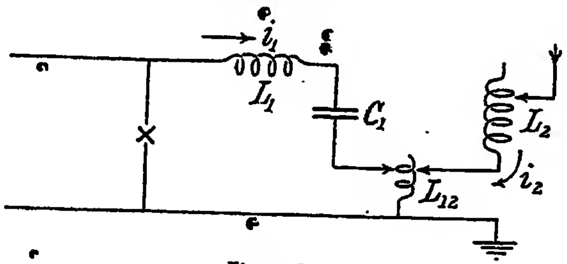

FIG. 2.

primary circuit (Fig. 2) it will be equivalent to an impedance Z_1' in the primary circuit, where

$$Z_1' = (i_2^2/i_1^2)(R_2 - jX_2) = (R_2 - jX_2)\ (\omega^2 L_{12}^2/Z_2^2),$$

X_2 being the reactance of the secondary circuit and L_{12} the mutual inductance between the two circuits. Thus the frequency generated will be a function of the coupling, the secondary resistance and the mistuning of the two

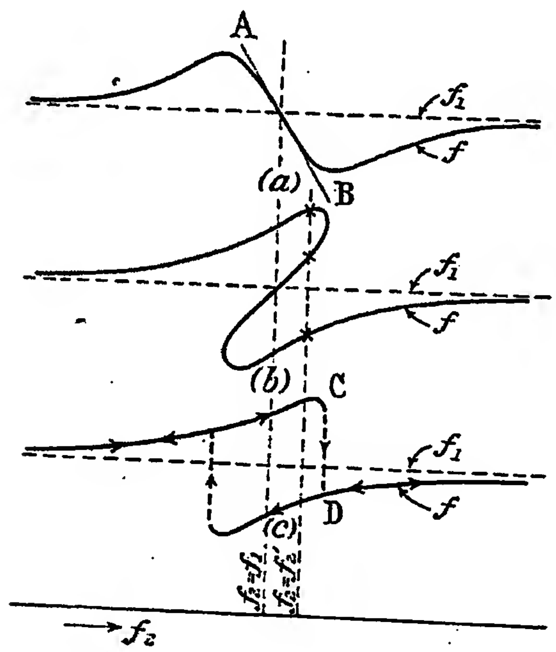

FIG. 3.

f = generated frequency.
f_1 = resonant frequency of primary circuit.
f_2 = resonant frequency of secondary circuit.

circuits. The actual equation for the frequency is a cubic and is given by

$$X_1 - \frac{\omega^2 L_{12}^2}{Z_2^2} X_2 = 0$$

where X_1 = the reactance of the primary circuit at the generated frequency.

The above equation may have either one or three real roots, depending upon the value of the mutual inductance between the two circuits. A typical frequency curve is indicated in Fig. 3 (*a*) in which the frequency generated (f) is plotted against the natural frequency of the secondary circuit (f_2). As the coupling is increased the slope of the line AB increases up to, and then beyond, 90°. In the latter case there may be three frequencies corresponding to any one tune f_2' of the secondary circuit [see Fig. 3 (*b*)]. If such a curve is plotted from practical measurements it becomes discontinuous as in Fig. 3 (*c*), i.e. it is possible that for one condition of tuning between primary and secondary circuits either one of two frequencies may be generated, depending upon the previous tuning conditions. Associated with the sudden frequency change at CD is a current and current-ratio change as indicated in Fig. 4, in which the ratio between secondary and primary currents (i_2/i_1) is plotted against the natural frequency f_2 of the secondary circuit.

Möller * in his paper on "The Theory of Ziehen," discusses the theory of the coupled circuit and gives formulæ and graphical methods for determining the frequency generated, the ratio between primary and secondary current, etc. The coupling which corresponds to a slope of AB equal to 90° [Fig. 3 (*a*)] is defined by Möller as the critical coupling. Beyond this coupling the change in frequency takes place not at resonance, but is drawn out beyond resonance between primary

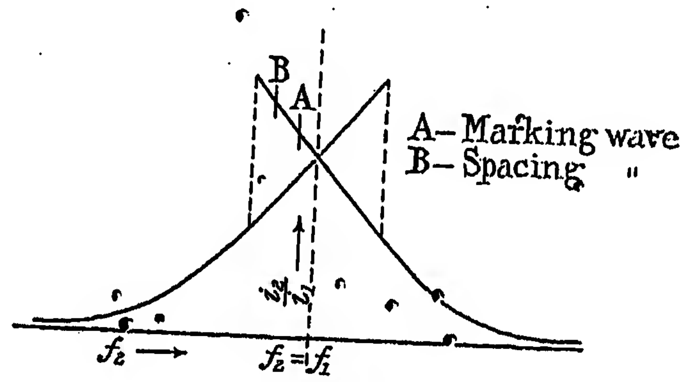

FIG. 4.

and secondary circuits as in Fig. 3 (*c*). This drawing out of the curve has been given the name of "ziehen" by Möller.

Obviously the above conditions either below or above the critical coupling may become unstable. In practice, however, it is found desirable to work with a fairly tight coupling corresponding to several times the critical coupling. Further, the limiting position of "ziehen" is definite and the set may be operated safely with the secondary circuit tuned beyond resonance, i.e. in the region of "ziehen" as indicated in Fig. 4, which shows the approximate working conditions for marking and spacing waves. The advantages derived from working within this region are improved efficiency and steadiness of working.

Tests on insulating materials.—Insulating materials for radio-frequency work must have low dielectric hysteresis losses, and these, rather than leakage losses, often determine the choice of insulating material. The usual form of test consists in placing samples of different materials of the same dimensions between two electrodes across which a pressure up to 30 000–40 000 volts at a frequency of 40 000–60 000 periods per second is applied. Observations are then taken of the breakdown voltage or temperature-rise.

Samples of wood 1 in. square × 4 in. long were tested,

* *Jahrbuch der drahtlosen Telegraphie und Telephonie*, 1920, vol. 16, p. 402.

the voltage being applied between the ends. Many kinds of wood break down and burn at voltages below 20 000, but American whitewood has been repeatedly tested and, after a short run during which the residual moisture is driven from the wood, has remained cool even when a voltage of 30 000–40 000 is applied for an indefinite period, and one sample tested to 55 000 volts showed no signs of serious heating or breakdown. The usual form of breakdown consists in a charring of the wood at points, not necessarily in contact with the electrodes. This gradually spreads along the grain, linking up and finally causing a flash-over. Comparative tests between whitewood, paxolin, bakelite and ebonite showed that whitewood was superior to paxolin and bakelite and compared favourably with ebonite.

In addition, numerous tests have been made on various kinds of granite, porcelain, etc., in connection with the Rugby Radio Station.

PROCEEDINGS OF THE INSTITUTION.

717TH ORDINARY MEETING, 24 APRIL, 1924.

(Held in the Institution Lecture Theatre.)

Dr. A. Russell, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting of the 10th April, 1924, were taken as read and were confirmed and signed.

The President: Before presenting the Faraday Medal to Dr. S. Z. de Ferranti, I shall call upon Colonel Crompton and Mr. Partridge to say a few words.

Colonel R. E. B. Crompton: In the very early days we electrical beginners found that the best way of advertising the dynamos and arc lights that we were then making, was by travelling the country with portable sets of arc lighting apparatus, so that we were looked upon rather as scientific showmen than as engineers. We were paid for lighting the grounds of the Alexandra Palace, and Sydney Baynes, who is now the Borough Electrical Engineer at St. Pancras, was in charge of the apparatus. He told me that a young man had become very interested in the working of our plant: that young man was Ferranti. A year or two later I met Ferranti again at the time when we were both hard at work trying to persuade the English public that the electric light was far superior to gas as it had no objectionable smell. We both found at that time that the hardest part of our work was to induce a few leading men who had brains, and at the same time sufficient money, to invest a little of the latter in our respective first attempts at supplying electric light from central stations. In carrying out this work Ferranti and I started on distinct and separate lines. He faced all the troubles, and invented all the distributing gear to enable the alternating current to be transmitted over a distance and converted at the users' premises, so as to allow the use of the 100-volt Swan lamps that were then available. I, on my part, put down smaller stations and supplied direct current at lower pressures, using accumulators. We both had our problems, but we both found that the biggest problem of all was finance. I had one advantage over Ferranti. He had to deal with the whole question of designing the power plant that he employed, whereas I shared the problem of the steam plant with that great genius P. W. Willans, so that in my case half the difficult problems were worked out for me by Willans. Ferranti was the first man to conceive the idea of a capital station placed in the most advantageous position to obtain cheap fuel supply and ample condensing water, and from thence to transmit at high pressure to interurban converting stations. He, therefore, is the real inventor of the capital power station. I think that Ferranti now sees that both of us played our part, at any rate that the early stage at which I with my smaller stations was able to generate and distribute at such a cost that we could pay dividends, eventually greatly helped his ideas. I need hardly say more; Ferranti as a steam engineer, as a designer of generating machinery, of high-pressure cables and of the distributing devices necessary with alternating current, was the man who did more than anyone else to start the electrical engineering profession, and no one knows it better than I.

Mr. G. W. Partridge: There is an old saying, "Honour to whom honour is due," and I have always thought that Ferranti never had the proper recognition which he should have had for the stupendous work he carried out 30 to 35 years ago. No one knows better than I the difficulties with which he had to contend and the marvellous way in which he overcame them. It was said by many in those days that Ferranti was 20 years in advance of his time, and that no good would come of his invention; but if we compare Ferranti's work 30 years ago with the most modern and up-to-date practice to-day we must all be proud that he belongs to this country. I think it may be of interest if I touch on one or two things which Ferranti did in those very early days. In 1886 he first conceived the idea, and saw the advantage, of running transformers in parallel, thereby making the alternating-current system

self-regulating. In those days when the system of generation and transmission was at 100 volts, or at the most 200 volts, and when small stations were supplying small areas in different parts of the cities and towns of this country, Ferranti conceived the idea of the capital station—the large station outside the inhabited area, on the river with ample water for condensing purposes, and room for extensions and with no risk of receiving an injunction for nuisance. In doing this it became necessary for him to increase the pressure, and he increased it to 10 000 volts, or 50 to 100 times as high as any other pressure then in use. In order to carry this into effect it became necessary for him to design every detail practically from the engine up to the meters controlling the lamps. In those days there were no alternating-current meters and we sold the current at so much a lamp per annum. Ferranti designed his generators—generators 10 times as large as any others then in use in this country, and generating direct at 10 000 volts, which to-day is about the maximum pressure for generators. Ferranti had to design every single detail himself, and in nearly every case he had actually to make it himself. Having got his generating station to work, he found that the cables which had been supplied by an outside contractor were quite inadequate to run at such a high pressure and broke down continuously. Most engineers would have been in despair, but Ferranti immediately set to work to design his own paper-insulated cables, 14 miles of which are still in use running at a pressure of 11 000 volts. What do we find to-day? In the most up-to-date practice all cables, whether used for high or low pressure, are paper-insulated—exactly the same insulation as Ferranti used in those early days. A well-known engineer recently remarked to me, "Well, Ferranti must be a very old man now." Does he look an old man? I told this engineer Ferranti's age and he was dumbfounded that any one man at the age of 20 or thereabouts should have conceived and carried out such stupendous work. It is a great pity that the British electrical industry did not take advantage of Ferranti's genius and so get a start of all other countries, but this was entirely due to Government legislation. If there had been a medal for valour in those days similar to the much-coveted Victoria Cross, Ferranti would surely have been given it for his courage and perseverance in the face of enormous difficulties. There is, however, a medal given by the Institution which confers the highest possible honour it can give, and everyone will agree that in presenting the Faraday Medal to Dr. Ferranti it is being given to one who is in every way worthy of it.

The President: In his Presidential Address* to the Institution in 1910, Dr. Ferranti advocated electricity everywhere and for all purposes. During the 36 years since I first met him, I know of no one who has striven harder or more successfully to advance the applications of electrical science. This is exactly the object for which this Institution was founded. It is natural, therefore, that we should all delight to honour Dr. Ferranti.

The President then presented, in the name of the Institution, the Faraday Medal to Dr. Ferranti.

* *Journal I.E.E.*, 1911, vol. 46, p. 6.

Dr. S. Z. de Ferranti: I cannot express how deeply I feel the honour which has been conferred upon me by the Institution. Going back to those very early days about which Colonel Crompton has spoken, I have always appreciated, and have never forgotten, the very great effect which the obtaining of knowledge from those who were actually engaged in the production of electric light had upon me. Colonel Crompton and his assistants freely showed me all that they were doing and gave me all the information they could, so that I had the first chance of acquiring that knowledge which was so necessary to me afterwards. Later on I derived the greatest possible help from being allowed as a boy to work with Mr. Sydney Baynes, Colonel Crompton's chief assistant in the installation of the electric light at King's Cross terminus. As the President has mentioned, I have for a very long time striven to increase the applications of electricity. I take this Medal as a compensation for my failures and as an encouragement for further work in this same good cause. I wish to remind you all, as I endeavoured to do in my Presidential Address to the Institution in 1910, that we cannot have too much electricity. In that Address I attempted to show what should be done and the course that should be followed. I feel that although electricity has gone very far and its application is enormous, the progress since 1910 is somewhat disappointing. I think that this is largely due to the fact that there has been no fundamental reduction in the cost of generating electricity. Electricity supply has become a very complicated business, and I feel that in the future the process must be greatly simplified. I wish to remind members of this Institution, and electrical engineers generally, that the electrical engineer's work along this one line alone will only be approaching completion when there is no more combustion carried on for either power or heat within populous areas. I am more than ever persuaded that eventually we shall use electricity for all the services which are now served through the burning of some kind of fuel within such areas. Electricity, even to-day, is the great labour-saver. Electricity under those conditions would be an immensely greater labour-saver and I feel that discoveries will be made which will enable us to generate electricity much more cheaply and so bring in its train the other simplifications connected with electrical supply and make such a system that electricity can be furnished for all our wants, as I have just explained. Even though I feel that I, myself, can only accomplish very little, I shall hope so to encourage others and excite their interest that they will work on this subject and eventually bring it to success. In conclusion, I should again like to say how much I appreciate the honour which has been conferred upon me by the presentation of this Medal. I appreciate it now, and for the rest of my life I shall continue to appreciate it just as much.

Mr. G. Semenza then delivered the Fifteenth Kelvin Lecture entitled "Kelvin and the Economics of the Generation and Distribution of Electrical Energy" (see page 882). A vote of thanks to the lecturer, proposed by Mr. W. M. Mordey and seconded by Mr. R. T. Smith, was carried with acclamation, and the meeting terminated at 7.53 p.m.

39th MEETING OF THE WIRELESS SECTION, 7 MAY, 1924.

(Held in the Institution Lecture Theatre.)

Mr. E. H. Shaughnessy, O.B.E., Chairman of the Section, took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section held on the 2nd April, 1924, were taken as read and were confirmed and signed.

A paper by Mr. L. C. Pocock, B.Sc., Associate Member, entitled "Faithful Reproduction in Radio-Telephony" (see page 791), was read and discussed.

On the motion of the Chairman a vote of thanks to the author was carried with acclamation, and the meeting terminated at 8 p.m.

52nd ANNUAL GENERAL MEETING, 8 MAY, 1924.

(Held in The Institution Lecture Theatre.)

Sir James Devonshire, K.B.E., Vice-President, took the chair at 6 p.m.

The Chairman: The President is representing the Institution to-night at the Annual Dinner of the Iron and Steel Institute and he has asked me to preside at this meeting in his absence.

The notice convening the meeting was taken as read. The minutes of the Ordinary Meeting held on the 24th April, 1924, were also taken as read and were confirmed and signed.

A list of candidates for election and transfer, approved by the Council for ballot, was taken as read and was ordered to be suspended in the Hall.

Messrs. A. W. Marshall and R. W. Hughman were appointed scrutineers of the ballot for the election and transfer of members and, at the end of the meeting, the result of the ballot was declared as follows:—

Elections.

Members.

McNicol, Archibald John.
Turner, Edgar Perceval.

Associate Members.

Armstrong, Reginald Basil.
Ash, Arthur Stanley.
Baxter, James MacGowan.
Canning, Sidney, B.Sc. (Eng.).
Chiba, Shigetaro.
Clerk, George Brownlow.
Connor, Robert.
Drape, Stanley.
Dymond, John Drayson.
Green, Alexander Henderson.
Hargreaves, Tom.
Jones, Reginald Cleveland.
Kitchen, Percy Inman.
Leslie, George Herbert, Captain, A.E.C.
Lloyd, Thomas.
Mazoomdar, Tarak Charan.
Pantvaidya, Mahadev Vaman.
Rann, John Selwyn.
Raworth, Alfred.
Webber, Ernest Clifford.
Wigner, Sydney Howard.

Graduates.

Banks, Albert.
Boddington, Frank Stanfield.
Bradley, Robert Walter.
Chase, Stephen Hayter.
Downie, Christopher Edmund.
Galbraith, Reginald Arthur H., Lieut., R.C.C.S.
Gardner, Geoffrey Harold.
Gupta, Krishna Chandra.
Halle, Charles Richard.
Hobbs, Percy George.
Holt, Walter Raymond K.
Hudson, William James.
Leake, William Richard.
L'Estrange, Wilton Oldham.

Graduates—continued.

Narasimham, R. D., B.E., M.E.
Nunn, Darrell.
O'Sullivan, Stephen.
Philip, Archibald, B.Sc.
Pocock, Hugh Shellshear.
Stobbs, John George.
Taylor, Harold Charles.
Todd, William Montgomery.
Tuffill, George William.
Williams, Thomas Vaughan.

Students.

Aschman, Geoffrey Donald.
Atkinson, Sidney.
Baldwin, Alfred William T.
Barker, Frederick Albert.
Barratt, Noel Marshall.
Bennett, James Miller.
Blizard, Charles Hillyer.
Boardman, Tom.
Boullen, Harold Godfrey.
Campbell, Michael C.
Carruthers, John Edward.
Dowe, Henry George P.
Durand, Philippe Henri R.
Edwards, Sydney Lawrence.
Elven, Robert Slade.
Farnes, Thomas Louis.
Farnworth, Benjamin.
Field, Arthur Henry M.
Fryer, Harold Herbert.
Gardiner, Robert Charles.
Gibson, Thomas.
Green, George Norman.
Higson, Donald Hesketh.
Holt, Philip John.
Hubbard, Edward John E., B.A.
Jones, Arnold Edward.
Landsbert, Reginald Ernest.
Lucette, Philip Arthur C.
MacColl, Hugh Geoffrey.
Mainar, Oswald Edwin.
McWhirter, Eric Malcolm S.
Middleton, Samuel Charles.
Mitchell, Denys Lindley.
Moffatt, Joseph Walton.
Newton, John Alfred.
Odling-Smee, Charles William.
Orchard, Frederick Charles.
Parry, Herbert Watkin T.
Perris, Frank Robert, B.Sc.
Pheasant, John William A.
Pollock, Jack Campbell.
Porter, Frank.
Potter, Jack.
Prangnell, James Ernest.
Rice, Edmund Stewart, Jun.
Roberts, David Harold.
Roberts, Frederick Walter.
Roberts, Leonard Craig.
Robertson, Philip White.
Sakr, Hussein Tewfik.
Shaw, Thomas Frederick.
Shields, Ernest Gerald.
Showler, Thomas Henry.
Smith, Cyril Blake.
Tagg, George Frank.
Turnbull, Frederick Laughlin.
Vaughan, Alfred Bentley.
Walter, Charles Lockhart.
Warrington, Eric.
Webb, Frederick George.
Wharfe, Lawrence Edward.
Whitcher, Athol Eric J.
Willard, Leslie Albert.
Williams, Harold.
Williams, James Rex.

TRANSFERS.

Associate Member to Member.

Cave-Brown-Cave, Nigel Frederick, Capt., B.Sc.
Clayton, Albert Edmund, D.Sc.
Dawson, Boyd.
Hilder, Walter Trevethan.
McKinnon, Ernest Cyril.
Myers, Ernest Robertson.
Regnauld, Alfred, B.Sc.
Sharp, Harry Gilkes.
Sims, John Walter.
Wilkinson, Arthur Rowland.

Graduate to Associate Member.

Anderson, John.
Dennis, William Edwin.
Dunbar, Leslie.
MacEwan, Lewis Barclay, B.Sc.
Nixon, Thomas Edgar B.

Student to Associate Member.

Esmond, Leslie Purcell.
Ferguson, Alexander Dalgety.
Heritage, Hubert James E.
Jolly, Edward Ernest.
Lyon, Edwin.
Steel, Harry Gordon.
Topley, Harry.

Associate to Associate Member.

Sloan, George Andrew.

Student to Graduate.

Burgum, William Thomas.
Deedes, John Gordon, M.B.E., Capt., R.C.S.
Gerry, Lionel Frederick.
Latham, Ashton.
McLennan, Roderick Arthur.
Millington, Stanley.
Ogilvie, Harold Erskine.
Verity, Conrad Edward H.
Wellsteed, Albert Edward.
Wright, George Thomas.

Messrs. R. Grierson, F. Pooley and Captain R. J. Wallis-Jones were appointed scrutineers of the ballot for the election of new Members of Council.

The following lists of donations were taken as read and the thanks of the meeting were accorded to the donors.

Library.—Messrs. George Allen and Unwin, Ltd.; R. M. Archer; the Astronomer Royal; Messrs. E. Benn, Ltd.; C. Boileau; the British Cast Iron Research Association; the British Engineering Standards Association; J. Bruce; Department of the Interior, Canada; Messrs. Chapman & Hall, Ltd.; the Chief Experimental Officer, Signals Experimental Establishment, Woolwich; the Chief Inspector of Factories; Dr. A. E. Clayton; C. G. Conradi; Messrs. Constable and Co., Ltd.; W. R. Cooper; the Director-General of Posts and Telegraphs, India; Dr. C. V. Drysdale, O.B.E.; C. F. Elwell; Dr. J. A. Fleming, F.R.S.; B. Hague; K. Hedges; F. L. Henley; the Imperial Mineral Resources Bureau; the Institution of Heating and Ventilating Engineers (Incorp.); the Institution of Royal Engineers, Chatham; the International Electrotechnical Commission; A. C. Jolley; Dr. A. E. Kennelly; E. T. Larner; Prof. M. Maclean; Prof. E. W. Marchant; Messrs. Marconi International Code Co., Ltd.; J. W. Meares, C.I.E.; the Meteorological Office; Prof. S. Narayan; the National Electric Lamp Association, Ohio; R. E. Neale; E. W. L. Nicol; Messrs. Sir Isaac Pitman and Sons, Ltd.; Purdue University; J. H. Reyner; Dr. A. Russell, F.R.S.; Dr. E. Sacchetto; M. G. Say; H. G. Solomon; Dr. S. P. Smith; Messrs. E. and F. N. Spon, Ltd.; S. G. Starling; C. F. Wade; Prof. Miles Walker; and Messrs. Williams and Norgate.

Benevolent Fund (see list of Donations on page 480).

The Chairman, after reviewing the work of the session, moved "That the Annual Report of the Council * for the year 1923-24, as presented, be received and adopted."

The resolution was seconded by **Prof. E. W. Marchant, D.Sc.,** and comments and suggestions were made by **Mr. W. R. Cooper, Mr. J. J. Stewart** and **Mr. F. W. Purse,** to which the Chairman replied as follows:—

The Chairman: Mr. Cooper may be assured that the improvement of the lighting of the Lecture Theatre is very much in hand. I can assure Mr. Stewart, who spoke in regard to the Electrical Appointments Board, that the sense of his remarks will be transmitted to the proper Committee. We are much obliged to Mr. Purse for taking notice of the work of the Council in obtaining the privilege for the members to use the title "Chartered Electrical Engineer."

The Report was then unanimously adopted.

Mr. P. D. Tuckett (Hon. Treasurer): It is your misfortune that the Bye-Laws have deprived you of so exceptionally capable an Honorary Treasurer as you possessed in Sir James Devonshire, but I am glad to say that the inherent vitality of the Institution enables me to submit a Statement of Accounts with which I think the members have every reason to feel satisfied. The year's Income shows an increase of £596, and the Expenditure a reduction of £5 020, omitting the various Reserve provisions at the foot of the Accounts. The increased Income is mainly due to an increase of £1 000 in subscriptions, offset to the extent of £394 by reduced Entrance Fees and to the extent of £141 by reduced Dividends and Interest. The reduced Expenditure is spread over a number of items. First, there is the elimination of the following special items which appeared in last year's Accounts, viz. H.M. Office of Works, £222; Commemoration Meetings, £226; War Memorial, £85; Faraday Medal, £113; Thompson Memorial Library, £32; and there is also a reduction of £285 in the expenses incidental to the Royal Charter. Next, there are gratifying reductions of £525 in Management Expenses, of £387 in the various items under the heading "Institution Building," of £335 in Mortgage Interest, of £433 in the net cost of the *Journal*, of £28 in the cost of the Institution Meetings, and of £325 in the cost of the Local Centres; and, lastly, there is the large reduction of £1 057 in the net cost of *Science Abstracts*, and a further reduction of £900 odd in the net annual cost of this building, resulting from an increase of that amount in the rents paid by our tenants and deducted from the gross cost. Last year these rents amounted to £3 474, as compared with £2 491 in the previous year. For the current year, now that the building is fully let, they will exceed £5 500, so that the portion of the building reserved for Institution purposes is enjoyed by us at a very moderate cost. The reduction in the net cost of the *Journal* is due to an increase of £1 413 from Sales

* See page 526.

and Advertisements, and a similar increase of £1 360 accounts for the reduced cost of *Science Abstracts*. In 1921 *Science Abstracts* cost us £978, and in 1922 £1 084, whereas this last year we were called upon to find only £27. I think that the Committee controlling the publication are to be congratulated on this very marked improvement, which I hope we shall see maintained in the current year. Referring to what I have called the Reserve provisions at the foot of the Revenue Account, it will be seen that £4 500 has been applied to redeeming the balance of the mortgage on the Tothill-street property, as compared with £3 000 applied to its reduction in the previous year, while £1 701 has been spent on Furniture, Fittings and Apparatus, as compared with £718. There is no very material difference in the other items, but it will be noted with satisfaction that the Balance carried to the General Fund in the Balance Sheet is £3 957, as compared with £862 a year ago. For the current year there will be a decrease of some £3 500 in the income from subscriptions, consequent on the reductions which were sanctioned a year ago and which came into force at the beginning of this year, but I hope that this decrease may be largely made good by additional membership, by the increased rents now being paid by our tenants, by increased sales of the *Journal* and advertising receipts, and by the return on the accumulated surplus of last year. Turning to the Balance Sheet, it will be seen, as mentioned in the Report, that taking the Tothill-street property and the Investments at cost, and the Institution Building, the Library and the Furniture at their written-down values, the Assets amount to £145 239; and deducting from this figure the outstanding mortgage of £14 801 on this building, and the other liabilities aggregating £5 038, there is a net surplus of £125 399, showing an increase of £11 000 over the corresponding figure a year ago. This gratifying result affords striking evidence of our strong financial position and, if the progress of the industry is what I believe we have every reason to anticipate it will be, should ensure our ability to take advantage of the enlarged scope for our many activities. The various items in the Accounts have been dealt with on the same lines as before and appear to me to call for no special comment, and I do not propose therefore to take up time by reviewing the detailed figures, but I shall of course be glad to furnish any explanation of them which any member may desire. As indicated in the Note at the foot of the Accounts, the Investments are taken at cost and show some depreciation, but I am glad to say that it now amounts to less than £1 000, so that those members who are optimistically inclined may justifiably hope before very long to see the Investments worth the figure at which they stand. That is all which I have to say on the Accounts, but I should like to take this opportunity of expressing my grateful appreciation of the extremely careful and businesslike way in which they are kept by the Secretary and his staff. I now formally move: "That the Statement of Accounts and Balance Sheet for the year ended 31st December, 1923,* as presented, be received and adopted."

The resolution was seconded by **Mr. F. Pooley** and, after **the Chairman** had replied to comments by **Mr. F. W. Purse,** was unanimously adopted.

The following resolution, moved by **Mr. W. R. Rawlings** and seconded by **Mr. A. H. Allen,** was carried with acclamation: "That the best thanks of the Institution be accorded to the following officers for their valuable services during the past year: (*a*) The Hon. Secretaries of the Local Centres and the Local Hon. Secretaries and Treasurers abroad: (*b*) The Hon. Treasurer (Mr. P. D. Tuckett)."

Captain R. J. Wallis-Jones then moved "That Messrs. Allen, Attfield & Co. be appointed Auditors for the year 1924–25."

The resolution was seconded by **Mr. W. E. Rogers** and carried unanimously.

The meeting terminated at 6.40 p.m.

* See page 536.

INSTITUTION NOTES.

Scholarships.

The following Scholarships have been awarded by the Council for 1924–25 :—

David Hughes Scholarship (*value* £50).

H. E. W. Tumath (Belfast Municipal College of Technology).

Salomons Scholarship (*value* £50).

E. Youel (Liverpool University).

Associate Membership.

Candidates for Associate Membership are reminded that they may present a thesis in lieu of taking the A.M.I.E.E. Examination. Members are asked to bring this fact to the notice of anyone intending to apply for admission to that class.

Third International Conference on E.H.T. Supply Systems.

The Council have decided that the Institution shall be represented at the above Conference, to be held at Paris next June (see page 816), and the following British National Committee has been set up to co-operate with the French Committee, to co-ordinate the work of the British representatives, to watch British interests, and to arrange for the submission of reports to the Conference. The British Dominions are to be invited, through the Institution's Local Honorary Secretaries, to nominate representatives to attend the Conference.

BRITISH COMMITTEE.

W. B. Woodhouse (*Chairman*).

J. R. Beard
T. Bolton
N. E. P. Harris
A. Jacob
R. Borlase Matthews
E. Parry
G. V. Twiss

The Chairman of the Papers Committee, and representatives of the following :—

The Electricity Commissioners.
The British Electrical and Allied Manufacturers' Association.
The Cable Makers' Association.
The British Engineering Standards Association.
The British Electrical and Allied Industries Research Association.
The General Post Office.
The Incorporated Municipal Electrical Association.
The International Electrotechnical Commission.
The Incorporated Association of Electric Power Companies.

The Benevolent Fund.

The following is a list of the Donations and Annual Subscriptions received during the period 26 September–25 October, 1924 :—

	£	s.	d.
Bloome, J. (Manchester)		2	6
Farrer, M. (Twickenham)		5	0
French, A. J. (London)		10	6*
Gibbins, J. (Newcastle-on-Tyne)		2	6
Gilbert Club (per Mr. C. E. Benham)	40	5	11
Lisle, G. S. (Gateshead-on-Tyne)		5	0
Smith, A. Eric (Tipton)	1	1	0
Smith, J. L. (Leyton)		5	0
Verity, G. (Birmingham)	1	1	0
Walter, C. L. (Christchurch, N.Z.)		5	0

* Annual Subscription.

The following have subscribed £5 or more in one amount to the Benevolent Fund since its inception in 1890 :—

	Total Subscribed to 25th Oct., 1924. £	s.	d.
Abel, Sir Frederick, Bart., F.R.S.	5	5	0
Anderson, Sir James	26	5	0
Andrews, W.	52	10	0
Aron, Professor H.	5	5	0
Aron Electricity Meter, Ltd.	10	10	0

OBITUARY NOTICES.

JOHN RICHARD BAINTON received his early training in London and went to Australia about 1889, where for several years he was associated with the representation of Messrs. Woodhouse and Rawson, of London. Later he joined Messrs. Edge and Edge, electrical engineers, of Sydney, and whilst with them constructed and equipped a pioneer electric railway at Brighton-le-Sands, New South Wales. He also introduced the electric lift into Australia, later becoming connected with the Standard Electric Elevator Co., of Sydney. When Messrs. Dick, Kerr and Co. secured the first contract for electric lighting plant for the city of Sydney he became the company's Australian representative, and subsequently was associated with many large contracts. In 1920, arrangements were made by Messrs. Standard-Waygood-Hercules, Ltd. (which the Standard Electric Elevator Co. had become by amalgamation with other concerns) to manufacture heavy electrical and steam machinery in Australia to the designs of the English Electric Co., the Australian company taking the name of the English Electric Co. of Australia, Ltd. Of this company he was a managing director up to the time of his death. As a director of Automatic Telephones (Australasia), Ltd., he introduced the automatic telephone to Australia; and he was also one of the pioneers in the use of motor bicycles and motor cars. He was elected an Associate of the Institution in 1889 and a Member in 1899, and was also a foundation member of The Electrical Association of New South Wales (since incorporated in The Institution of Engineers, Australia), serving as President in 1901 and 1902. He took a keen interest in the local volunteers and at one time commanded the company of engineers responsible for military searchlight work in connection with the defence of Sydney. G. B. C.

FRANCISCO BHERING was born in the State of Minas Geraes, Brazil, on the 1st January, 1867, and adopted as his profession that of a civil engineer. In 1895 he joined the staff of the Brazilian Government Telegraph Department. His promotion was rapid and he became chief of the Sao Paulo District in 1901. In the same year he was appointed Brazilian delegate to the International Telegraph Conference held in London. He served in a similar capacity at the International Wireless Conference of 1912, and, in fact, he may be described as the pioneer of wireless telegraphy in Brazil. In 1916 he was appointed sub-director and in 1920 director of the technical department of the Brazilian Telegraphs, and in 1922 he became director general of the Telegraphs, a position which he held at the time of his death, which took place at Paris on the 13th April, 1924, when he was on a visit to Europe on account of his health. The early land line telegraph system of Brazil followed the coast line, and the wires suffered considerably from corrosion. Dr. Bhering's most important work was the diversion of these lines into the interior through virgin forests. In addition to his other duties, he was requested by the Institute of Brazilian Engineers (of which he was a Fellow) to organize and complete a geographical map of Brazil to commemorate that country's centenary. He was one of the founders of the Engineering College at Sao Paulo, and was Professor of the Engineering College of the Rio de Janeiro University. He was elected a Member of the Institution of Electrical Engineers in 1913. The Municipality of Rio de Janeiro, to honour and commemorate his services, has given his name to the street leading to the Arpoador Wireless Station. R. B. D.

LAWRENCE BIRKS, B.Sc., was educated at Prince Alfred College and at the University of Adelaide, where he obtained his B.Sc. degree with triple honours in 1895. In the following year he was awarded the Angas Engineering Scholarship, which entitled him to three years' training in Great Britain. This period was spent at University College, London, and in the workshops and test departments of Messrs. Easton, Anderson and Goolden, of Erith, and of Messrs. Callender's Cable Co. He served for a time as lecturer in electrical engineering under Prof. Silvanus Thompson at Finsbury Technical College, and also as assistant professor of engineering at Heriot-Watt College, Edinburgh. In 1900 he returned to Adelaide, and, after one session as lecturer in electrical engineering at Adelaide University, was appointed assistant engineer to the Sydney electric tramways in connection with the reconstruction of Ultimo power house and the installation of high-tension underground feeders and substations. In 1903 he was appointed city electrical engineer at Christchurch, N.Z., in connection with the first installation of electric power in that city, the power being derived from the destruction of refuse. In the following year he was appointed lecturer in electrical engineering at the Canterbury College, but after one session he took up the duties of engineer to the New Zealand Electrical Construction Co., a local company formed for the purpose of constructing the Christchurch electric tramways. On the completion of this work he was appointed engineer of Rotorua. In 1910, at the passing of the Aid to Water Power Act, he became assistant to Mr. Evan Parry, chief electrical engineer for the Dominion and, after assisting in the design of, and specifications for, the Lake Coleridge works, was transferred to Christchurch in 1913 to supervise the construction of those works and to manage the commercial side of the undertaking. On Mr. Parry's resignation in March 1919, Mr. Birks was appointed chief electrical engineer to the Public Works Department, when active steps were taken by the New Zealand Government to materialize a comprehensive scheme of power supply planned for the North Island. The

following works were carried out during his period of office, viz. the development of the Mangahai source with transmission lines to Palmerston, Wellington, Wairapa and Hawkes Bay. Preliminary works were carried out at Waikaremoana and Arapuni, and a contract placed for headworks and plant for the latter source. During this period also the power-house plant at the Horahora Falls belonging to the Waihi Gold Mining Co. was taken over by the Government, extended and utilized for the supply and distribution in the Waikato district. In April 1924, he left New Zealand to represent the Dominion at the World Power Conference in London, but on his arrival in Adelaide he was obliged to seek medical advice, as a result of which he immediately returned to New Zealand, where he died on the 25th July at Wellington. His knowledge and experience of all matters pertaining to hydro-electric power development and of distribution systems as applied to the general supply of electricity were very extensive. His engineering achievements also were considerable and varied, and one of them deserves particular recognition: the result of his work in Canterbury was to demonstrate to the world at large the commercial possibility and the economic advantage to a State of a generous supply of electricity to every home, not only for light but for every purpose, including water-heating. In character he was energetic and resourceful, open-minded and generous. All his actions bore the impress of high ideals and his life was an inspiration to all who were associated with him. He joined the Institution as an Associate in 1896, was elected an Associate Member in 1899, and a Member in 1912. He was also a Member of the Institution of Civil Engineers, a member of the Institution of Mechanical Engineers and a Member of Council of the New Zealand Society of Civil Engineers. He took an active part in the affairs of the New Zealand Institute, and was one of the sub-editors of the *New Zealand Journal of Science and Technology*.

E. P.

CHARLES EUGENE L. BROWN died at his home in Montagnola, near Lugano, on the 2nd May, 1924, at the age of sixty-one, from heart failure following a short illness. He was born in Winterthur on the 17th June, 1863, being the son of the late Mr. Charles Brown, who was mainly responsible for the Sulzer drop valve-gear. After a year as improver with Burgin in Basle, he entered the Oerlikon Machine Works and two years later, when barely 24 years old, became manager of the electrical department. His early years at Oerlikon were occupied in developing a direct-current system and in designing commercially workable direct-current machinery. His first machines were of the two-pole Manchester type with ring armatures, and for the first power transmission in Switzerland (Kriegstetten-Solothurn, 37 kW over five miles) machines of this type were employed. By successive stages in development, four-pole designs with slotted drum armatures were arrived at, which (contrary to the usual practice at that time) were distinguished by relatively large magnetic fluxes and a small number of armature conductors, so that even machines for 600 volts had but one turn per segment and sparkless commutation was ensured. Among the early power plants which he constructed may be mentioned the Neuhausen plant, the 6 000- and 12 000-ampere machines for which remained for long the largest direct-current dynamos in Europe; those for 12 000 amperes had vertical shafts, and multiple series-parallel winding was used for the first time. He employed for his first alternating-current transmissions single-phase generators and synchronous motors, which were of the Kapp ring-armature type, and these were the first machines provided with direct-coupled exciters. The practical development of the polyphase motor was realized during the year 1890. Simultaneously with Dobrowolski he originated the polyphase winding with rectangular coils in slots (in practically its present-day form), whereby magnetic leakage is so far reduced that a sufficiently high starting torque can be reached. Later on, he used for the first time the distributed winding in slots for the stators and rotors of the larger polyphase motors. The year 1891 brought the opening of the Frankfort Exhibition and the celebrated power transmission from Lauffen to Frankfort (110 miles) with three-phase current at 25 000 volts, this effectively demonstrating the technical possibility and commercial feasibility of the transmission of power over great distances by electricity. He designed for this power transmission (the failure of which was confidently predicted in electrical circles at that time) the 40-pole generators with claw pole-wheel and single exciter coil and oil-cooled 86/25 000-volt transformers. The latter —the first oil-immersed transformers—were made with three cores situated at 120° to one another, connected above and below by a round yoke, and for them was used for the first time the double concentric winding. In 1891, in association with Mr. W. Boveri, he founded the works of Brown, Boveri and Co., Baden, Switzerland, many of whose present-day designs bear the impress of the original ideas of the technical founder of the firm. The high position in the construction of single-phase and polyphase machinery to which he brought his firm by means of his inventions and designs became apparent in 1894 when eight alternators (four of 525 kW and four of 1 050 kW running at 85 r.p.m.) were built for the city of Frankfort in face of great competition from German firms. From the year 1895 onwards the development of many Swiss water powers was actively carried out, and for the vertical units called for by the low falls the umbrella type of generator was designed (1897). Two years earlier he had constructed the first flywheel generators with pole-wheels rotating outside the stationary armatures. In 1896 were built the 8 000-volt generators for Schwyz, while in 1898 the noteworthy 14 500-volt generators for Paderno were constructed. In the electric railway field the Lugano tramway, installed in 1894, was the first traction system for which three-phase motors were used, and this was followed by many mountain and other polyphase railways, which are all in successful operation at the present day. The acquisition by his firm in 1900 of manufacturing licences under the Parsons steam-turbine patents turned his thoughts to some of the special problems due to the introduction of high-speed machinery, and he soon recognized that for turbo-alternators

of large outputs and high peripheral speeds the construction with projecting field-poles could not be satisfactory. This led to the creation of the generator rotor in the form of a cylinder with radial or parallel slots for carrying the excitation winding, which has proved to be the only possible constructive solution and has been universally adopted. In the direction of switch and control gear many original designs were developed, amongst which may be mentioned the multiple-break oil circuit-breaker and the so-called "horn" arrester. After the conversion of the firm of Brown, Boveri and Co. into a limited company in 1900, he became chairman of the board of directors and held that position until 1911, when he retired altogether from his business and technical activities. In 1912 he was awarded the honorary degree of Doctor by the Technical College of Karlsruhe. He was elected a Foreign Member of the Institution in 1892 and became a Member in 1911. A. C. E.

SIR ALBERT J. LEPPOC CAPPEL, K.C.I.E., died on the 20th April, 1924, in his eighty-eighth year. He was one of the dwindling band of men who saw service in the Crimea, having served with the Turkish Contingent in 1855–6. In 1857 he entered the Indian Telegraph Service, then in its infancy, becoming Director of Traffic in 1869, Deputy Director-General in 1879, and Director-General four years later. He held the position for six years before retiring, and saw the department expand almost beyond recognition of the earlier days. In February 1887 the knighthood of the Order of the Indian Empire was conferred on him, and at the time of his death he was the senior holder of that rank. Sir Albert's interest in telegraphy did not cease with his retirement from India. For much more than a quarter of a century after his retirement from the Indian Telegraph Department he was actively interested in the work of the Eastern and Associated Telegraph Companies. He joined the Board of the Eastern Telegraph Company in 1888, and in the following years became a director of the other companies of this group. He was also a director of the Globe Telegraph and Trust Company, and a trustee of the Submarine Cable Trust. He gave his whole heart to this work, and was almost daily in attendance at the offices of the cable companies up to within a few days of his death. He was elected a Member of the Institution in 1878, and served on the Council in the years 1900–1902. H. J. L. C.

COLONEL GEORGE ANDERSON CARR, late R.E., who died on the 20th March, 1924, was one of the pioneers of electrical science in the British Army. Born in 1857 at Nymans, near Crawley, Sussex, he was educated at Uppingham and at the Royal Military Academy, Woolwich. He received his first commission as a lieutenant in the Royal Engineers in August 1876 and, after the usual two years' course of instruction at the School of Military Engineering, was posted to the Submarine Mining Service. Here he came into contact with a little group of Royal Engineer officers who were studying and developing the application of electricity to military purposes. Of these, the best-known to the general public were Major R. Y. Armstrong, R.E., Lieut. P. Cardew, R.E., and Lieut. (now Major-General Sir R. M.) Ruck. Working under and with these officers, he soon found his life work. Not only did he show a great mastery of detail, but he early proved his capacity as a lecturer. Possessed of a remarkable gift for clear and accurate thinking, he was able to explain his thoughts in simple language. With these qualifications it was inevitable that much of his life should be spent in instructional appointments in the electrical branch of the School of Military Engineering and in the School of Submarine Mining at Gillingham, and he held in turn every grade of such appointments at both these establishments. He was for many years the Examiner in Electricity at the R.M. Academy, Woolwich. Among other subjects with which he dealt were the training of army telegraphists and the design of telegraph stores, also the shutter board and test room and all stores used in the submarine mining service and for defence electric lights. In his various capacities as instructor or assistant instructor he was an *ex officio* member or associate member of the Royal Engineers Committee which deals with all patterns of military stores, and he served on all the electrical sub-committees and many special sub-committees of that body. He represented the War Office at the original trials of the Marconi system and formed a personal friendship with Signor Marconi. He became an Associate of the Institution in 1882, served on the Council in 1895-6, and was elected a Member in 1896. W. B. B.

WILLIAM CHEW was born in Manchester in 1855, moving in 1863 to Blackpool, where he joined his father at the gas-works a few years later. In his early days, although attached to the gas industry, he took a keen interest in the development of electricity. He was responsible for the introduction of electric lighting into Blackpool and held the dual appointment of electrical engineer and assistant gas engineer until 1893, when, owing to the growth of the undertakings, it became necessary to separate the two departments. He succeeded his father in 1913 as manager of the gas-works. He was always proud of the fact that he was the first to light a seaside esplanade in this country with electric arc lamps. These were on 9 steel masts each 50 ft. high, and each lamp was run from a separate dynamo. Although continuing in the gas industry he took a broad-minded view and quickly introduced electric power where it could be advantageously used in the gas-works. He died on the 9th April, 1924. He was elected a Member of the Institution in 1893. J. H. C.

DAVID COOK was born in 1856 near Lochranza, in the Isle of Arran, Scotland, and died at Richmond on the 23rd July, 1924. From an early age he was keenly interested in electricity, and from the beginning of 1881 was engaged exclusively in electrical work. Up to the end of 1883 he was connected with the Edison Electric Light Co., Ltd., and on the amalgamation of this firm with the Swan United Electric Light Co., Ltd., he was responsible for their work in Scotland until February 1885. From March 1885 to February 1886 he was associated with

the firm of Muir and Mavor, Glasgow, and for several years subsequently he practised as a consulting engineer. In 1889 he was appointed consulting engineer to the Associated Fire Insurance Companies, and was later chosen, chiefly on the recommendation of Lord Kelvin, to become superintending electrical engineer for the Glasgow Corporation. Subsequently, again on the recommendation of Lord Kelvin, he acted for some time—with conspicuous success—as chief engineer and general manager of the City of London Electric Lighting Company. He was later associated with Cecil Rhodes in a vast scheme for growing in the Sudan the entire supply of cotton for the needs of Great Britain. This scheme was to be carried out by regulating the flow of the Nile as it issues from the Great Lakes, but was, for various reasons, not proceeded with at the time. The Government have since, however, advanced a sum of £3 500 000 to enable it to be commenced. His later activities were connected with engineering and development schemes both at home and abroad. He was elected a Member of the Institution in 1890. A. D.

ROWLAND EDWARD DIXON was born on the 20th October, 1872. He received his early education at private schools and from 1887 to 1890 attended Stanley Hall, Wakefield. From there he went to Yorkshire College, Leeds, and to the Polytechnic, London. From 1892 to 1895 he was apprenticed to the firm of B. Verity and Sons, Covent Garden (now Veritys, Ltd.), and at the end of this period he became a director and chairman of Messrs. S. Dixon and Sons, Leeds, electric lighting and power contractors and manufacturers of overhead line materials for tramways and also of patent point controllers for tramways, etc. He remained with this firm until his death, which occurred after a short illness, on the 28th November, 1923. He was elected an Associate of the Institution in 1895 and a Member in 1913.

ARTHUR EDGAR GOTT was born in Sunderland, where he received his early education, his technical education being obtained at the Rutherford College of Science, Armstrong College, and Manchester Technical School. He served his apprenticeship with Messrs. Weedon and Irish, of Sunderland. He then went to the works of Messrs. J. H. Holmes and Co., and carried out the electrical installations on a number of ships and in various mills and factories. He was with this firm 16 years, the last 7 years as senior assistant engineer. He then joined Messrs. Veritys as manager of the controller and switchboard department, a position which he held for five years. After a short engagement with the J. L. Manufacturing Co., of Southall, he went as engineer-representative to the British Petroleum Co. in connection with the application of liquid fuel in manufacturing processes. He later spent two years with the Waddle Patent Fan and Engineering Co. At the outbreak of war he joined the Sperry Gyroscope Co., acting chiefly as patent expert. He was the author of the Sperry gyro-compass instruction book used by the British and Allied Navies, and drew up the lecture charts and syllabus for the various Compass Schools of these Navies. He was also instructor to naval officers in the use and maintenance of the gyro-compass. He died on the 18th December, 1923, at a nursing home near Bedford at the age of 57, after being for nearly three years in failing health brought on by overwork during the war. He was elected an Associate Member of the Institution in 1901 and a Member in 1919. H. A. G.

ARCHIBALD ERNEST GRANT was born at Swansea on the 1st May, 1870, and was educated at St. Andrew's College, Swansea, where he gained distinction in mathematics and also excelled at football and swimming. On leaving school he served his apprenticeship as a mechanical engineer with the Globe Dry Dock and Engineering Co., and after going to sea obtained his "Extra Chief" Certificate as a marine engineer. He then studied electricity and, in August 1901, obtained an appointment in the contract department of Messrs. British Insulated and Helsby Cables. After four years' experience in the laying and jointing of high-tension and low-tension cables and in the construction of electric tramways, including the laying of the track and the erection of the overhead equipment, he was appointed in 1905 to take charge of the company's sales agency in South Wales. In July 1913 he was promoted to represent the company in Canada and subsequently, in February 1916, became their principal representative in India. He returned to this country in June 1923 and died suddenly on the 29th November, 1923. He was elected an Associate of the Institution in 1901, became an Associate Member in 1903, and a Member in 1916. B. W.

ROBERT FRANCIS HAYWARD, who died in London on the 10th April, 1924, was born in 1865 and was educated at Harrow School, passing thence to University College, London, where he held the Gilchrist Engineering Scholarship. After serving his apprenticeship with Messrs. Crompton and Co. at Chelmsford, he became their works manager in 1890, and left in 1894 for the United States to take up the position of general manager of the Salt Lake and Ogden Gas and Electric Light Co. In this capacity, and subsequently as chief engineer of the Utah Light and Railway Co., he was responsible for a considerable amount of pioneer work in connection with high-tension transmission. In 1905 he left the United States to join the Mexican Light and Power Co. in Mexico City as their general manager, and the four years for which he remained with this company was a period of great development of their hydro-electric system, which is now one of the largest in Latin America. From 1909 until 1920 he was chief engineer and general manager of the Western Canada Power Co., furnishing bulk power to the British Columbia Electric Railway Co. and the Vancouver district generally from a 40 000-h.p. hydro-electric plant at Stave Falls. When the control of the Chilian Electric Tramway and Light Co. and the Cia. Nacional de Fuerza Electrica passed to the S. Pearson and Son interests, and the Cia. Chilena de Electricidad was formed, he was appointed general manager and occupied that position until a few months before his death. This covered three years of intense

construction activity, including the transformation of the whole distribution system of the city of Santiago, the erection of 110 000-volt transmission lines from the Andes to Santiago and Valparaiso, the addition to the system of a 35 000-h.p. hydro-electric plant, and considerable extensions to the steam station. He was of the best type of travelled Englishman, possessing a charming personality, wide knowledge, and a sterling character, and will be greatly missed by a host of friends in all the countries to which his work took him. He was elected a Member of the Institution in 1912.

S. G.

WILLIAM DODS HUNTER served his apprenticeship with Messrs. Clarke, Chapman and Co., and later was employed by Sir Charles Parsons. In 1889 he became engineer to the Newcastle and District Electric Lighting Co., Ltd., and was later appointed managing director and engineer. He did a great deal of strenuous work during the war and never quite recovered from the effects, being compelled in 1918 to retire from active management. He remained on the directorate, however, and gave the benefit of his knowledge to the company. He died on the 17th May, 1924. He was elected a Member of the Institution in 1892, and for many years served on the Committee of the North-Eastern Centre, of which he was chairman from 1900 to 1905.

GORDON LAYTON received his early education at private schools at Birchington and Luton. On leaving school in 1897 he was apprenticed to the Electrical Power Storage Co. At the end of his apprenticeship he joined the London Electric Cab Co., where he was in charge of the generating station and the high-tension substation. In 1899 he became associated with the Westinghouse Co. and was sent to the Westinghouse works at Pittsburg to study American methods. On his return he worked in the correspondence department, of which he later became the head. He was subsequently transferred to the sales department and became manager of the Manchester district office. He afterwards returned to the works and was appointed manager of the district offices. On account of failing health he found it necessary to go abroad and he took up a position with the company in South Africa. He afterwards returned and became manager, and later managing director, of the Cosmos Lamp Works, which position he held until his death on the 31st January, 1924. He was connected with the promotion of the Engineers' Clubs at London and Manchester. He was elected a Student of the Institution in 1897, an Associate in 1900, and a Member in 1912. From 1907 to 1910, and from 1911 to 1914, he served on the Committee of the North-Western Centre, of which he was vice-chairman in 1914–15.

MAURICE LEBLANC was born in 1857 and received his technical education at the École Polytechnique in Paris. At the conclusion of his studies in 1878 he joined the Compagnie des Chemins de Fer de l'Est and in 1886 was associated for a short period with an industrial company. In 1888 he commenced a series of researches on electrical apparatus, which included compound alternators, transformers, rotary converters, frequency changers and phase advancers, the last-named of which he claimed to be the first to produce. In conjunction with Hutin he introduced the damping device known as the amortisseur. In 1897 the General Electric Company of America offered him the post of Engineer-in-Chief, but he did not accept it. In 1901 a number of his electrical patents were purchased by Mr. George Westinghouse for the Westinghouse Electric and Manufacturing Co. and the General Electric Co. of America. From this time, at Mr. Westinghouse's suggestion, he directed his attention to mechanical engineering problems, particularly in connection with steam condensers, rotary compressors, etc. While engaged in this work he evolved his well-known rotary air pump by which very high vacua are produced. On the outbreak of the European War he took part in the invention of a trench mortar and was instrumental in developing a new aeroplane engine. In later years he put forward a proposal to utilize high-frequency currents for the propulsion of electric railway trains. He was a director of the Hewittic Electric Co. and consulting engineer to the Société Anonyme Westinghouse. During the years 1912–14 he was President of the International Electrotechnical Commission, and in 1918 was elected the first member of the Industrial Section of the Académie des Sciences. He died on the 27th October, 1923, at the age of 66. He was elected an Honorary Member of the Institution in 1915.

JOHN ST. VINCENT PLETTS was born on the 22nd January, 1880, and died at his home at Surbiton on the 26th April, 1924, after a short illness. He received his general education at the Isle of Wight College and in 1896 went to the Central Technical College, in the department of electrical engineering, where he stayed for three years. He then joined the Marconi Wireless Telegraph Co. and was engaged in erecting wireless stations for the company in Hawaii, Labrador, the Congo, Russia and the Far East. From 1910 until 1919 he was head of the company's patent department. In the capacity of consulting engineer he was their expert in all legal cases on patents relating to wireless telegraphy, including the well-known "7777" case and the "Mullard valve" case. He was a member of various technical societies and a writer of technical articles, in addition to being the inventor of a slide rule and a cryptograph machine. During the war he acted as expert in cryptography at the War Office. He was a very reserved man and, though holding a prominent position, was very unostentatious and considerate towards those who worked for him. He was elected an Associate of the Institution in 1902 and a Member in 1919.

WILLIAM STEWART ROBERTSON died on the 1st September, 1924, in his seventieth year. His connection with telegraphy commenced in 1873 when he entered the service of the Post Office at Edinburgh. Five years later he was selected for service under the Japanese Imperial Telegraphs. On the termination,

in 1884, of his contract with the Japanese Government he obtained employment in the Pouyer Quartier Cable Co. and in 1886 with the Western and Brazilian Telegraph Co. (now the Western Telegraph Co.). He served first at Bahia as an operator, becoming later Assistant Superintendent at Rio. In 1896 he was loaned to the Amazon Telegraph Co. in Para, where he was later appointed Superintendent of the Western Telegraph Co.'s station. He held that appointment until 1904, with a short interval during which he served as electrician on the cable ship "Buccaneer." In March 1904, he was appointed General Superintendent of the Western Telegraph Co. in South America, with headquarters at Rio de Janeiro, and held that position until his retirement in June 1920, after nearly 48 years of telegraph service, during which he saw submarine telegraphy emerge from its preliminary stages and grow into the efficient high-speed service of the present day. Although he had no share in the invention of systems and apparatus which have resulted in the existing improved working of submarine cables, he kept pace with the times and took a prominent and practical part in their application to the sections and stations under his control. He was elected a Member of the Institution in 1898.

DAVID CURLE SMITH was born in Aberdeen and was for five years an apprentice in the Great North of Scotland Railway Co., Aberdeen, also attending the Edinburgh University engineering classes. He then went for two years as assistant to Prof. Jamieson of Glasgow. At the end of this period he joined the Griffen Gas Engine Co., of Bath, as draughtsman, leaving there in 1887 to go to Melbourne, Australia, where he was employed by a leading engineering firm. He was later appointed electrical engineer to the New Australian Electric Co., Melbourne, and subsequently became chief engineer to the municipality of Kalgoorlie. He died on the 28th December, 1922. He was elected a Member of the Institution in 1896.

CHARLES PROTEUS STEINMETZ, who was elected a Member of the Institution in 1912, was born in Breslau, Silesia, on April 9th, 1865. At the time of his death on October 26th, 1923, at the age of fifty-eight, 34 years had elapsed since Carl Steinmetz landed in New York in June 1889 from the steerage of a French liner and adopted America as his country and Charles Proteus Steinmetz as his name. In the preface to "America and the New Epoch" he states that he then "had ten dollars and no job, and could speak no English." Dr. E. W. Rice thus describes his first impressions of Steinmetz :—

"I shall never forget our first meeting at Eickemeyer's workshop in Yonkers. I was startled, and somewhat disappointed, by the strange sight of a small, frail body surmounted by a large head, with long hair hanging to the shoulders clothed in an old cardigan jacket, cigar in mouth, sitting cross-legged on a laboratory worktable. My disappointment was but momentary, and completely disappeared when he began to talk. I instantly felt the strange power of his piercing but kindly eyes, and, as he continued, his enthusiasm, his earnestness, his clear conceptions and marvellous grasp of engineering problems convinced me that we had indeed made a great find. It needed no prophetic insight to realize that here was a great man, one who spoke with the authority of accurate and profound knowledge, and one who, if given the opportunity, was destined to render great service to our industry. I was delighted when, without a moment's hesitation, he accepted my suggestion that he come with us."

Steinmetz's 34 years in America was a period of prodigious performance on his part. In any attempt to obtain a measure of his activities as an inventor, the 195 American patents taken out in his name should be multiplied many times to take into account the inspiration which he communicated to his assistants and colleagues of all ranks and ages. The wide variety of his inventions may be indicated by mentioning the following amongst the subjects of the Steinmetz patents : phase transformation, methods of regulating the power factor of a distribution system, compensated alternating-current motors, magnetite arc lamps, flaming arc electrodes containing titanium carbide, seals for fused quartz lamps, and many patents relating in general to generators, motors, synchronous converters, induction regulators, frequency changers, transformers and measuring instruments. He presented 44 technical papers before the American Institute of Electrical Engineers and was its President in 1901. He also made many contributions to the *Proceedings* of the Illuminating Engineering Society, of which he was President in 1915. He also often contributed notable papers and made important addresses at Conventions and meetings of the National Electric Light Association, at meetings of sections of the American Institute of Electrical Engineers, and of university technical societies. Some of his most fascinating addresses were of a popular character. On one well-remembered occasion when he addressed a large audience in Schenectady at Edison Hall, the subject was "Soap Bubbles." Steinmetz, with one knee on the seat of a chair, blowing bubbles under all sorts of conditions, directed the attention of a fascinated audience to the various phenomena involved. In addition to many engineering papers in the *Transactions* of technical societies, he contributed almost innumerable articles to other publications and on all manner of subjects. We find such titles as : "Physiology of Light," "The Second Law of Thermodynamics and the Thermodynamics of the Atmosphere," "Commission Control," "Competition and Co-operation," "Industrial Efficiency and Political Waste," "The World Belongs to the Dissatisfied," "Socialism and Invention," "Electricity and Civilization," "The Tungsten Gun," "The Ether," "Our Civilization," "Shorthand," "Democracy," "Science and Religion," "Twisting Magnetism," "Biography of Rudolf Eickemeyer," "Electrical Consonance," "Soviet Plan to Electrify Russia," and "Mobilizing Niagara to Aid Civilization." Eleven treatises of a very authoritative character on electrical subjects were published by Steinmetz and the majority of them were revised and greatly extended in several successive editions. Already in 1888 he had published a book on "Astronomy, Meteorology and Cosmogony." The Steinmetz law of hysteresis is well known, as are

also his contributions to the development and use of the complex-quantity method of treating alternating-current problems.

Steinmetz's activities were by no means confined to engineering. He took a very deep interest in human questions and in economics, and gave his cordial support to all movements whose success he considered would be of advantage to mankind. In this category he included the adoption of the metric system. At the University of Breslau he studied mathematics, astronomy, physics, chemistry, medicine and economics. Subsequently at Zurich he studied mechanical engineering at the Polytechnic. In later life, at Union College in Schenectady, he was professor of electrical engineering and afterwards of electro-physics. As the candidate of the Socialist Party in 1915 Steinmetz was elected President of the Common Council of Schenectady. He served two terms as President of the Schenectady Board of Education. In 1902 Harvard University conferred on him the degree of Master of Arts, and in 1903 Union College awarded him the degree of Doctor of Philosophy.

It was the writer's privilege to be much with Steinmetz as one of his assistants in 1892 and the immediately following years, and again to have associations with him in the years preceding his death. In the writer's opinion the best pen-picture of Steinmetz in these later years is that drawn by Mr. M. P. Rice as follows :—

"The unassuming figure without hat or overcoat, that was so well known about the streets of Schenectady, was literally a world power. To him every country looked for authoritative dicta on all matters of electricity. The man who welcomed friends to his summer camp with an almost boyish glee, whose kindly soul went forth in the fondling of a favourite dog, whose life and likings were the most simple—this man was an international figure, a giant in his profession, a conservator of the world's natural resources, and a friend to every user of electricity. We mourn his passing, we are deeply grateful for the wealth of knowledge that he has contributed to the world's progress, and we treasure as a choice possession the memory of an earnest, simple man who devoted his transcendent mind and talents to the service of his fellow men."

For many years Steinmetz had made his home in Schenectady, New York, with the family of Mr. J. L. R. Hayden, his adopted son. Mr. Hayden was his constant companion and also his collaborator in many of his investigations and papers. Their home included a fine library and a well-equipped chemical and physical laboratory, and Steinmetz divided his attention between the home laboratory and various laboratories at the Schenectady works of the General Electric Company of America.

H. M. H.

W. HOWARD TASKER, who was born in 1857 and who died on the 17th September, 1924, was educated at Eastbourne and Guildford and trained as an architect—his father's profession. Dr. Graham Bell's lecture in London on the telephone in 1878 turned Mr. Tasker's thoughts to electrical engineering. He made in his own workshop many models of telephonic and electrical apparatus, and later these models were used when giving evidence in the Law Courts. He worked as an improver in the shops of Messrs. Warner and Lee, mechanical engineers, London, and studied at the School of Submarine Telegraphy and Electrical Engineering, representing it at the first British Exhibition of Electrical Engineering held at the Crystal Palace in 1882. He was assistant electrician to the Yorkshire Brush Electrical Engineering Co. He erected for them, and subsequently managed, the first central electric lighting station at Middlesbrough, supplying electricity to the North-Eastern Steel Works and neighbouring blast furnaces, and while with the Brush Company he advised several local engineering works on their electrical plant. During his career he worked as an engineer for the Primary Battery Co., Ltd., the Fitzgerald Electric Light and Power Co., Ltd., and the Union Electric Light and Power Co., Ltd., and was for many years with the Chelsea Electricity Supply Co., Ltd., which was the first supply company in London to get to work under the Electric Lighting Act of 1886. As resident engineer he carried out for the Brush Company the contract for the supply of electricity at Dover, and he was subsequently connected with the British Westinghouse Electrical and Manufacturing Co., Ltd., and with the Hart Accumulator Co., Ltd. He had a charming personality and was an enthusiast in both work and play. He organized the first bicycle road-racing teams in Surrey in 1875 and 1876 and was a keen lacrosse player, representing the South more than once in the annual North v. South match. He was elected an Associate of the Institution in 1882 and a Member in 1891.

R. T. S.

PAUL SOMMERVILLE THOMPSON was born on the 31st January, 1876, and died after a short illness at Saltburn on the 4th July, 1924. His early education was received at the Rutherford and Armstrong Colleges, Newcastle-upon-Tyne, and he served an apprenticeship with Messrs. E. Scott and Mountain, Ltd., afterwards holding appointments with the Wallasey and Malvern Urban District Councils and acting as assistant mains engineer at Manchester. From 1904 to 1922 he was with the Cleveland and Durham Electric Power and the Newcastle-upon-Tyne Electric Supply Companies, being general station superintendent to the former for a period of about 11 years. During his residence on Tees-side he endeared himself to numbers of young engineers in the electrical supply industry and devoted much of his spare time to the furtherance of their interests. He was an active member of the Tees-side Sub-Centre, serving as its first Hon. Secretary and later as its chairman. He also assisted with the formation of the Electrical Power Engineers' Association, and will be remembered for the part he played in helping to consolidate the Whitley Council policy of that Association. He became an Associate Member of the Institution in 1902 and a Member in 1918.

A. H. M.

HAROLD LYON THOMSON, who died after a short illness on the 13th March, 1924, was one of the earliest electrical engineers. He was the son of the late R. W. Thomson of Edinburgh, to whom the automobile owes so much for his invention of rubber

and pneumatic tyres, and he inherited much of his father's genius for mechanics. In 1880 he went to Crompton's works at Chelmsford at a time when the invention of the electric lamp by Swan and by Edison had made indoor electric lighting a possibility. His first work was in A. P. Lundberg's shop. At that time he showed remarkable facility in designing domestic fittings of all kinds, and a large proportion of the ordinary fittings now used in connection with indoor lighting were then designed by him, in many cases the original form being still in use with very little modification. He was with Cromptons when they carried out at the Law Courts the first large installation of electric light, this installation being completed in 1882. Many of his fittings are still in use and serve to show how little his first designs have been departed from. He was Cromptons' representative in Paris at the first Electrical Exhibition in 1881. In the early days when so much propaganda work in connection with electric light was carried out by means of portable apparatus he was generally to the fore in showing the advantages of the new illuminant. When representing Cromptons at the Vienna International Exhibition he was invited by the then Khedive of Egypt to go to Egypt, originally to develop electrical work in that country, but eventually to become secretary to the Khedive. Gradually he went over to the political side, that being the stormy period when the expedition was arranged for the relief of General Gordon at Khartoum. When at Cairo he became a student of Arabic and Oriental literature, and on his return to this country he became a distinguished Orientalist. Later he was elected to the Westminster City Council, subsequently becoming Alderman, and Mayor in 1912. He was responsible for Westminster being the first city to take up mechanical transport, and he developed it to such an extent that when the war broke out in 1914 he went over to Flanders in charge of a fleet of the Westminster City vehicles. His skill as a mechanic was exceptional and was much remarked on by his friends. Just before his death he was engaged on finishing the miniature set of gold saucepans for the Queen's doll house which has been shown at the Wembley Exhibition. Westminster owes to him many improvements, not the least of which is the daily collection of house refuse. As a man he was universally loved and his place will be found a difficult one to fill. He was elected a Member of the Institution in 1898. R. E. C.

EDGAR LESLIE THORP was born on the 3rd June, 1874, and was the son of the late Rev. T. Moorhouse Thorp, Wesleyan Minister. He was educated at Kingswood School, Bath, and later at the City and Guilds Institute (London). For many years he was associated with Messrs. Shepherd and Watney, consulting engineers, of Leeds, leaving that firm in 1899 to undertake private consulting work at Nottingham and later at Edenfield in Lancashire. During this period he carried out research work in electrolytic bleaching and wrote a textbook on the subject. In 1912 he returned to Messrs. Shepherd and Watney and on their retiring from the business in 1918 came into possession of it. From that time he was principally engaged in the preparation and carrying out of schemes for all classes of electrical installations, mechanical and hydraulic work, heating plants, etc. His health became affected by incessant toil, but he still struggled on, especially anxious to complete the electrical installation at Marlborough College. He took a special interest in the artistic side of his work and derived much satisfaction from the ingenious treatment of the illumination of the College chapel. The work was almost completed when he had at last to give in. He died on the 21st September, 1923, at the age of 49. He was elected an Associate Member of the Institution in 1899 and a Member in 1920. N. D. T.

ROBERT MULLINEUX WALMSLEY, D.Sc., F.R.S.E., who was elected an Associate of the Institution in 1884 and a Member in 1890, died on the 15th June, 1924, as the result of a street accident which occurred two days previously and for which no one was to blame. He was a pioneer in the vast fields of electrical enterprise which were opened up during the eighties of last century, but was chiefly a distinguished educationist who sought to weld the industries with the higher training institutions and university technical colleges. This desire for unification of the whole structure of technical industry was perhaps reflected in the "sandwich system" of training at the Northampton Engineering College in Clerkenwell and in the affiliation of the College to the University of London. Certainly he did much to eliminate the false distinction between "theory" and "practice" and to dignify the term "Academic"—too often used with indulgent contempt. His ruling passions were the Northampton Institute, of which he was principal for nearly 30 years, and the University of London, but his interest was extended to widely differing stages and types of education.

Dr. Walmsley was born near Liverpool, where he received his early education. He took his London B.Sc. degree in 1882 and, after a short period of teaching experience, became the first senior demonstrator in the electrical department of the Finsbury Technical College under Prof. Ayrton. Continuing under Prof. Silvanus Thompson he took his doctorate in 1886 and in the following year became principal of the Sindh Arts College of Bombay University, where he advised the Government on various educational matters. In 1888 he became senior mathematical lecturer under Prof. Henrici at the City and Guilds Engineering College, and from 1890 to 1895 was the first professor of electrical engineering at the Heriot-Watt College, Edinburgh. In 1895 he was appointed the first principal of the Northampton Polytechnic Institute and with characteristic energy and enthusiasm began the immense task of building up from small beginnings one of London's greatest technical institutes. He was deeply interested in the progress of technical optics and was chairman of important optical bodies. Space does not permit a detailed account of his manifold educational activities. In connection with his work in the University of London, he was chairman of numerous senatorial committees of the University Extension Board, of the Board of Studies in Electrical Engineering,

and of the Board of Examiners, the culmination being his appointment as Chairman of Convocation.

His distinctively electrical work began in his Edinburgh days when he was consulting engineer for the electric lighting of several important Scottish buildings. His writings include "The Electric Current" (1894) and "Electricity in the Service of Man," which began as a revision of Dr. Urbanitzky's book and was transformed, expanded and reissued in numerous editions until in 1904 it was completely rewritten and became his own work. In the same year he read before the Institution a paper on "Transatlantic Engineering Schools," the fruit of study during three months spent in Canada and the United States at the instance of the Governing Body of the Northampton Institute. An earlier paper which appeared in the *Journal* dealt with the electrical features of the Edinburgh International Exhibition, 1890. He also collaborated with Mr. C. E. Larard in a paper on "Engineering Colleges and the War" for the Institution of Mechanical Engineers.

As a man Dr. Walmsley's outstanding characteristics were an extraordinary capacity for work; a geniality and humour which kept him a boy at heart, even to the end of his 70 years; a gift of astute diplomacy, most valuable in controversial or administrative affairs, and a kindliness which glowed with unexpected warmth when his imagination was wakened to anxieties or sorrows among those with whom he came into contact. He loved music, of which he had a wide knowledge, and was ever ready to hear or to tell a good joke. Many may see his character in a new light when they realize that his father's premature death left him with eight younger brothers and sisters to bring up. The distinction won by many of them shows his success, but to such strenuous beginnings may be traced the extreme austerity and self-sacrifice of his devotion to the great technical institute which he served so long. Students and others who hold him in affectionate remembrance must feel, as they stand within the walls of the "Northampton," the applicability of Wren's epitaph in St. Paul's Cathedral:—

"Si monumentum requiris circumspice."

INDEX TO VOL. 62.

1924.

EXPLANATION OF ABBREVIATIONS.

(P) indicates a reference to the general title or subject of a paper or address.

(p) indicates a reference to a subject dealt with in a paper or address of which the title is not quoted.

(D) indicates a reference to a discussion upon a paper or address of which the general title or subject is quoted.

(d) indicates a reference to a subject dealt with in a discussion on a paper or address of which the general title is not quoted.
